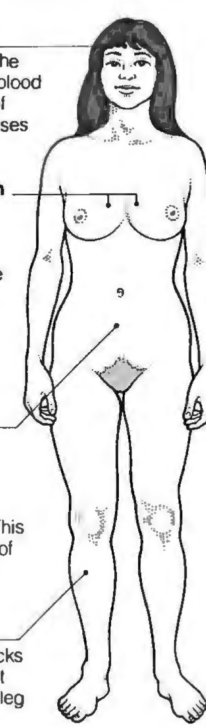
Blood clots are the most common type of embolus; they have usually broken off from a larger clot that has formed elsewhere in the blood circulation. Pulmonary embolism is usually the result of a fragment from a deep vein *thrombosis* (a blood clot formed deep in a vein, usually in a leg) breaking off and being carried via the heart to block an artery supplying the lungs; this is a common cause of sudden, unexpected death. Similar blood clots may form in the lining of the heart after a *myocardial infarction* (heart attack); they may travel as emboli toward the vital arteries of the brain and cause a cerebral embolism, leading to a *stroke*.

Fat embolism is a blockage of blood vessels caused by fat globules, particularly after fractures of the arm or leg. Amniotic fluid embolism is when some of the fluid that surrounds the baby in the uterus is forced into the mother's circulation toward the end of a normal pregnancy.

SYMPTOMS



Factors that determine symptoms include the extent of blockage, the size and type of embolus, and the size, nature, and location of the affected blood vessel. In pulmonary embolism the sufferer feels faint and breathless, and has chest pains. If the embolus causes a stroke, the symptoms depend on which part of the brain is affected; it may, for example, cause inability to speak, inability to move a part of the body, loss of consciousness, or a disturbance of vision. In the small number of serious cases of fat embolism, 48 hours after the major fracture occurs the patient's heart rate and rate of breathing rise dramatically; this is accompanied by restlessness, confusion, drowsiness, and *cyanosis*.

TYPES OF EMBOLISM

Embolisms are named after the part of the circulation affected or the embolus involved (e.g., a fat embolism is caused by fat globules released from a bone fracture). When an embolus is released, it is carried through branches of an artery until it becomes lodged. Blood is prevented from reaching parts of the body beyond the blockage.

Arm embolism
This X ray of the upper arm was taken after the injection of a radiopaque dye into the blood vessel. It shows, near the top, an embolus obstructing the normal flow of blood through one of the main arteries.

Cerebral embolism
A blockage of one of the arteries that supplies blood to the brain; it is one of the most common causes of a stroke.

Pulmonary embolism
A blockage of one of the arteries that supplies blood to the lungs. This may cause chest pain, breathlessness, and sudden death.

Amniotic fluid embolism
The escape of some of the fluid that surrounds the baby in the uterus into the mother's circulation. This may cause blockage of an artery in one of her lungs

Leg embolism
An embolism that blocks one of the arteries that supplies blood to the leg. Gangrene may occur below the blockage.

TREATMENT

If a pulmonary or other severe type of embolism causes the person to collapse, emergency lifesaving procedures are carried out to keep breathing and circulation going. If the person survives, *embolectomy* (surgery to remove the blockage) may be possible. Under general anesthesia, an incision is made in the artery and the embolus is aspirated (sucked out). The incision is closed with stitches. If surgery is not possible, *thrombolytic drugs* (to dissolve blood clots) and *anticoagulant drugs* (to prevent clot formation) may be given.

OUTLOOK

In all severe types of embolism, survival depends on the success of resuscitation attempts, the importance of the vessel obstructed, and the speed with which blood flow is reestablished. If the source of the embolus is treated, the long-term prospects for the patient are good.

Embolism, therapeutic

Also called embolization, the deliberate obstruction of a blood vessel to stop internal bleeding or cut off blood flow to a tumor.

WHY IT IS DONE

Therapeutic embolism is increasingly being performed to stop otherwise uncontrollable bleeding, particularly when the patient is too sick to undergo surgery. Among its uses are the control of bleeding from small vessels in the lining of the intestines, often due to a malformation of blood vessels (similar to a birthmark in the skin).

Using the technique to deprive a tumor of its blood supply has several effects. It can relieve the pain caused by the growth; it can cause the tumor to shrivel, making it easier to remove surgically; or it may stop the tumor from spreading. Therapeutic embolism may be used to treat tumors that would be difficult to remove surgically, such as tumors in the liver. It is also used to treat certain vascular tumors on the face, such as *hemangiomas*, in preference to surgery that might leave unsightly scars.

HOW IT IS DONE

The procedure is usually carried out by a radiologist with the patient under a general anesthetic. The first step is to obtain an image of the blood vessel to be blocked and those leading to it. This image is obtained by means of *angiography*, an X-ray procedure in which an opaque dye is introduced into the blood vessels through a *catheter* (a flexible tube).

The catheter is then guided, by means of television monitoring, as close as possible to the vessel to be blocked, and the embolus that will block the blood vessel is released. Emboli are made of many materials, such as blood-clotting agents (such as fibrin), metal coils, silicone balloons, wool, and medicinal glue.

RISKS

There is always a risk that an embolus may lodge in the wrong place; an embolus that blocks a vessel in the brain may cause a *stroke*. The procedure is still being refined.

Embolus

A clump of material that is present (usually as a result of an accident or a disease of the heart and blood vessels) in the blood circulation, where it travels eventually to cause an arterial obstruction. (See *Embolism*.)

Embryo

The unborn child during the first eight weeks of its development following conception; for the rest of the pregnancy it is known as a *fetus*.

Development of the embryo is governed internally by genes inherited from the parents, and externally by factors such as the woman's diet and any medication taken during pregnancy. (See box, overleaf.)

THE FIRST TWO WEEKS

The embryo develops from an egg, fertilized by a sperm (see *Fertilization*). It starts as a single cell—just large enough to be seen by the naked eye. As the fertilized egg travels along the tube to the uterus, the cell divides in two. These cells divide further, eventually forming a spherical mass of cells; a hollow depression develops in the center of the sphere. The cells form into two groups: one makes up the wall lining the sphere; the other expands to form the embryo itself.

On about the sixth day the sphere of cells becomes attached to and then embedded in the lining of the uterus. At the site of attachment the outer layer of cells obtains nourishment from the woman's blood; the outer layer later will become the placenta.

Two bubbles form side by side within the cell mass. Between the bubbles a flat disk forms, consisting of layers of cells from which all the baby's tissues and organs will form. The amniotic sac develops around the growing embryo.

THE THIRD WEEK

Early in the third week the disk of cells becomes pear-shaped. The head of the embryo forms at the rounded end and the lower spine at the pointed end. A group of cells develops along the back of the embryo to form the notochord, a rod of cells that constitutes the basis for the spine. From this time on, the embryo has two recognizable halves that develop more or less symmetrically. The notochord then furrows and the edges grow toward each other. They fuse to form the neural tube, which later will develop into the brain and spinal cord.

THE FOURTH WEEK

During the fourth week the embryo becomes recognizable as a mammal. The back grows more rapidly than the front, giving the embryo a C-shape, and a tail becomes visible. Within the embryo, buds of tissue form that will later develop into the lungs, pancreas, liver, and gallbladder.

The neural tube extends toward the head of the embryo, where a broad fold becomes visible that eventually will grow into the brain. The developing ears first appear as pits. Rudimentary eyes develop in the form of stalks. The outer layers begin to form the limb buds and the branchial arches (folds of tissue) that will become the jaws and other structures in the neck.

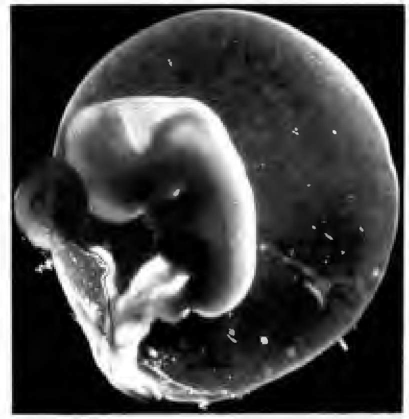
Paired bulges appear on the sides of the neural tube that will become the cartilage, bone, and muscle of the back. On the front of the embryo, just beneath the head, a rudimentary heart develops in the form of a straight tube. As the branchial arches develop, the heart is pushed down into the chest. It is during this period that the embryo is at the greatest risk of birth defects caused by abnormal genetic or external factors (see *Birth defects*).

THE FIFTH WEEK

The external ears become visible, pits mark the position of the developing nose, the upper and lower jaws form, and the limb buds extend, becoming flattened at the end where the hands and feet will develop.

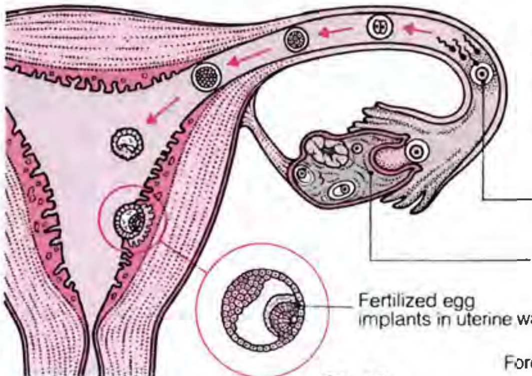
The two folds of tissue meet at the front of the embryo and fuse to form the front wall of the chest and abdomen. The umbilical cord develops.

THE SIXTH TO EIGHTH WEEKS



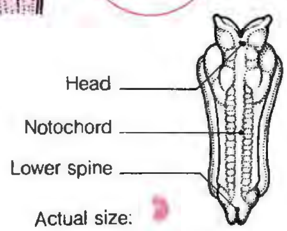
The face becomes recognizably human, the neck forms, the trunk becomes less curved and the head more erect, the tail between the buttocks disappears, the limbs become jointed, and fingers and toes appear.

After eight weeks the embryo is 1 inch (2.5 cm) long. Most of the internal organs have formed and all the external features are present.

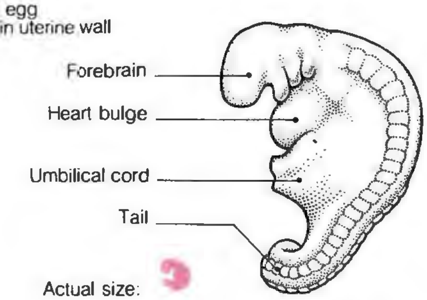


E

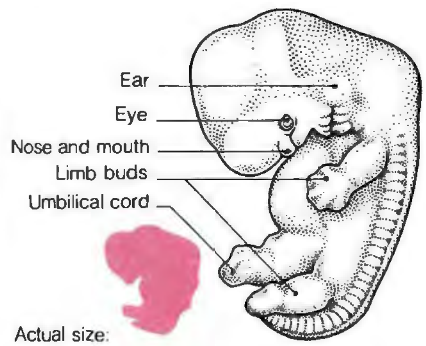
THE DEVELOPING EMBRYO



From the time of conception until the eighth week, the developing baby is known as an embryo. At conception, the fertilized egg consists of a single cell, the zygote, which contains genetic material from the sperm and the egg. The zygote divides several times to form a ball of cells, which then implants into the lining of the uterus. At the point of attachment, the outer layer of cells forms the placenta, while a group of cells within one area of the cell ball develops into the embryo. A sac filled with amniotic fluid forms around the embryo to protect it. As the embryo grows, it begins to form features and, by the fifth week, it has developed a recognizable head and limb buds.

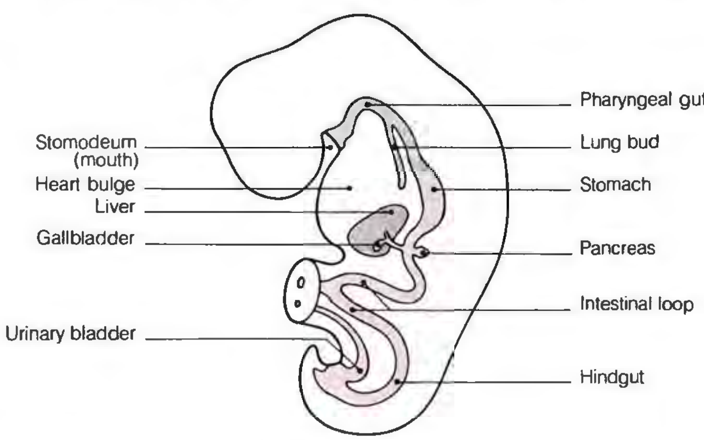


Embryo at about six weeks
The embryo is floating in the amniotic sac. The smaller sac at left (the yolk sac) provides nourishment for the early embryo.



Passage to the uterus
The egg is fertilized in one of the fallopian tubes and is carried into the uterus, where it embeds in the uterine lining.

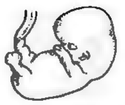
Three weeks
The embryo becomes pear-shaped, with a rounded head, pointed lower spine, and notochord running along its back.



Four weeks
The embryo becomes C-shaped and a tail is visible. The umbilical cord forms and the forebrain enlarges.

Six weeks
Eyes are visible and the mouth, nose, and ears are forming. The limbs grow rapidly from initial tiny buds.

INTERNAL ORGANS AT FIVE WEEKS



All the internal organs (such as the liver, pancreas, stomach, heart, lungs, kidneys, and sex organs) have begun to form by the fifth week. During this critical stage of development, the embryo is highly vulnerable to harmful substances consumed by the mother (such as alcohol and medication), which may cause birth defects.

Eight weeks
The face is more "human," the head is more upright, and the tail has gone. Limbs become jointed and digits appear

Embryology

The study of the development and growth of the *embryo* and then the *fetus* from conception until birth.

Embryology is an essential part of the medical student's training, since it leads to a greater understanding of adult anatomy and of the ways structural defects in the body arise. For example, the occurrence of congenital heart defects (such as "holes in the heart" and transposition of the main blood vessels) is easier to understand when the stages of fetal heart development have been explained.

Until recently, embryology was based on the study of animal embryos and dead human embryos at different stages of development. More details about the nature of physical and chemical processes involved in embryo development have been established by examination of live embryos grown in the laboratory (see *Embryo, research on*).

Embryo, research on

Human embryos are regularly grown in laboratories as part of the treatment of infertility (see *In vitro fertilization*). Physicians usually fertilize more eggs than they need, since they do not know how many will "take" (begin the process of cell division and growth); the unwanted embryos may then be frozen for use in later attempts at achieving a pregnancy. Surplus embryos are being used for research aimed at improving the results of in vitro fertilization, at finding better methods of contraception, and at detecting genetic disorders at an early stage in pregnancy.

In several countries, such research has been prohibited or the physicians concerned have agreed not to perform it for ethical reasons. As yet there is no consensus on the circumstances under which research on embryos is ethically acceptable.

Emergency

Any condition that requires urgent medical treatment, such as cardiac arrest, or any procedure that must be performed immediately, such as *cardiopulmonary resuscitation*.

Emergency physician

A physician who has been specially trained to deal with a broad range of life-threatening conditions, ranging from acute asthma attacks to bullet wounds. The first concern of the emergency-care physician is to save the life of the patient and then to stabilize the condition as much as possible before transferring the patient to an appropriate hospital unit for further care.

Emesis

The medical term for *vomiting*.

Emetic

A substance that causes vomiting, used to treat some types of poisoning and drug overdose. Emetics work by stimulating the part of the brain that controls vomiting and/or by irritating the lining of the stomach.

The most widely used emetic is *ipecac*. Emetics should not be given to a person who is drowsy because he or she may inhale the vomit.

EMG

The abbreviation for electromyogram, a test in which the electrical activity in muscle is analyzed after being amplified, displayed, and recorded.

WHY IT IS DONE

An EMG can reveal the presence of muscle disorders, such as *muscular dystrophy*, or disorders in which the nerve supply to muscle is impaired, such as *neuropathy* or *radiculopathy*. In cases of nerve injury, the actual site of nerve damage can often be located.

HOW IT IS DONE

The technique for obtaining an EMG (called electromyography) is harmless and takes 30 to 60 minutes to perform, depending on the number of muscles to be tested. There are no side effects. Impulses are recorded by attaching small disk electrodes to the skin surface over the muscle or by inserting needle electrodes into the muscle. The electrical activity is evaluated during muscle contraction and at rest. Impulses are seen on an oscilloscope screen or heard over a loudspeaker. Changes in the electrical wave forms and sounds associated with them allow the electromyographer to determine whether nerve or muscle disorders are present.

Emollient

A substance such as olive oil, lanolin, or petroleum jelly that has a soothing, softening effect when applied to the skin, eyes, or mucous membranes (for example, the lining of the nose and mouth). By forming an oily film, emollients prevent the loss of water from these surfaces and therefore have a moisturizing effect. Emollients are used in creams, ointments, nasal sprays, and suppositories.

Emotional deprivation

Lack of sufficient loving attention and warm, trusting relationships during a child's early years, leading to difficulty in normal emotional development. Emotional deprivation may result if *bonding* does not occur in the early months of life, if a child is frequently separated from his or her parents for long periods during the first five years, or if parents cannot meet the child's emotional needs.

Emotionally deprived children are often impulsive, crave attention, cannot cope with frustration, and may even be mildly mentally retarded.

Emotional problems

A common term for a wide range of psychological difficulties. The problems may be due to upbringing, relationships, or psychiatric illness, but external feelings of *anxiety* and *depression* generally predominate. Age, sex, and social and cultural factors influence the most suitable methods of coping with emotional problems.

Empathy

The ability to partake in and understand the thoughts and feelings of others. It is possible to share an emotion with another person by comparing it with our own experiences.

In *psychoanalysis* the therapist relies on empathy to establish a relationship with a patient. Empathy can also help in making a diagnosis.

Emphysema

A disease in which the alveoli (tiny air sacs) in the lungs become damaged. The disorder causes shortness of breath and in severe cases can lead to respiratory and/or heart failure.

CAUSES

In almost all cases, emphysema is caused by cigarette smoking. Atmospheric pollution is sometimes a predisposing factor. Rarely, a predisposition to emphysema is inherited due to a deficiency of a chemical called alpha$_1$-antitrypsin in the lungs; the disease appears early in life, but its development is hastened and intensified by smoking.

The alveoli, of which there are many millions in each lung, are groups of air sacs at the end of bronchioles (tiny air passages). Through their thin walls, inhaled oxygen is passed into the bloodstream and carbon dioxide is removed from the capillaries to be breathed out. Tobacco smoke and other air pollutants are believed to cause emphysema by provoking the

release of chemicals within the alveoli that damage the alveolar walls. Alpha$_1$- antitrypsin is thought to protect against this chemical damage; hence, people with a deficiency of this substance are particularly badly affected. The damage is slight at first, but in heavy smokers it becomes progressively worse, with the alveoli bursting and blending to form fewer, larger sacs with less surface area, and with consequent impairment of oxygen and carbon dioxide exchange. Over the years the lungs become less and less elastic, which further reduces their efficiency.

Eventually—sometimes after many years—the level of oxygen in the blood starts to fall, with one of two effects. In some cases *pulmonary hypertension* (raised blood pressure in the pulmonary artery) develops, leading to *cor pulmonale* (enlargement and strain on the right side of the heart) and, subsequently, *edema* (accumulation of fluid in the tissues), particularly in the lower legs. Other sufferers are able to compensate for oxygen deficiency to some extent by breathing faster. Why individuals react in these different ways is not known.

Emphysema is often accompanied by chronic *bronchitis*, also brought on by air pollutants and smoking. Emphysema and chronic bronchitis together are sometimes called chronic obstructive lung (or airways) disease.

INCIDENCE

Several hundred people per 100,000 in the US suffer from some degree of emphysema. About 30 people per 100,000 in the US each year die from chronic obstructive lung disease; of these, about six deaths are ascribed to emphysema alone.

SYMPTOMS AND SIGNS

Initially, and for a considerable time in mild cases, there may be no symptoms, but as the disease progresses it results in increasing shortness of breath. At first this may be noticed only when climbing stairs or steep inclines, but gradually it becomes more severe until eventually it occurs after only mild exercise or is present even at rest.

A sign of emphysema is a barrel-shaped chest associated with air being trapped in the outer part of the lungs. There may also be a chronic cough (caused by accompanying bronchitis) and a slight wheeze.

As the disease progresses, sufferers in whom cor pulmonale develops start to turn purple-blue due to oxygen deficiency in the blood and their legs swell because of edema; these people are known as blue bloaters. Those who breathe rapidly and retain normal coloring are called pink puffers. Many people, however, show signs somewhere in between these two extremes. As respiratory and/or heart failure develops, sufferers find it increasingly difficult to breathe.

DIAGNOSIS

The diagnosis is made from the patient's symptoms and signs, from a chest examination, and from various tests. Tests include taking a blood sample from an artery to measure the concentration of the blood gases (e.g., oxygen and carbon dioxide) and sometimes a sample from a vein (to determine whether the disease is due to alpha$_1$-antitrypsin deficiency). Chest X rays are taken to exclude the possibility of another lung disease being responsible for the symptoms and to determine how great an area of the lungs has been affected. *Pulmonary function tests* are carried out to assess breathing capacity and the efficiency of the alveoli in exchanging gases.

TREATMENT

Because emphysema is incurable—lung tissue that has been damaged cannot be replaced—treatment can only control the disease. This means preventing more damage to the lungs by a total and lifelong ban on smoking, and improving the efficiency of remaining lung tissue, which is done in various ways. *Bronchodilator drugs* are given to widen the bronchi (the airways linking the windpipe to the lungs) and the bronchioles. These drugs can be taken by means of a hand-held aerosol inhaler or an electrically operated *nebulizer* that produces a fine spray. Occasionally, *corticosteroid drugs*, taken by inhaler to reduce inflammation in the lungs, are also beneficial.

To treat edema, a sodium-restricted diet and *diuretic drugs* may be given to reduce the volume of fluid within the body by promoting output through increased urine production.

If the oxygen level of the blood falls considerably, oxygen may need to be given by mask or *cannula*. The patient may be given oxygen equipment to use at home.

OUTLOOK

The course of the disease depends on how far it has progressed before the patient gives up smoking. If extensive areas of lung have been damaged or if cor pulmonale has developed, death occurs sooner or later from respiratory and/or heart failure.

Emphysema, surgical

The abnormal presence of air in tissues underlying the skin. It most often occurs as a complication of *pneumothorax* (the abnormal presence of air in the pleural cavity between the lung and chest wall). This can itself result from injury, chest surgery, or as a result of a diving accident.

Empirical treatment

Treatment undertaken when a precise diagnosis cannot be made. In the case of a fever of undetermined origin, for example, a physician might prescribe antibiotics on the basis of experience with similar cases.

Empyema

An accumulation of pus in a body cavity or in certain organs.

Pleural empyema occurs as a rare complication of a lung infection such as pneumonia or pleurisy; it may also develop after a severe injury to the chest that penetrates the pleural space. The main symptoms are chest pain, breathlessness, and fever.

The diagnosis is confirmed by taking X rays of the chest and aspirating some of the pus for smear and culture. Treatment is an operation to open the infected cavity and drain the pus; antibiotic therapy is also used.

Empyema of the gallbladder may occur as a complication of *cholecystitis*, when it usually causes abdominal pain, fever, and sometimes jaundice. It is treated by *cholecystectomy* (surgical removal of the gallbladder).

Enalapril

An *ACE inhibitor drug* used in the treatment of *hypertension* (high blood pressure) and *heart failure* (reduced pumping efficiency). It may be given in conjunction with a *diuretic drug*. Enalapril was introduced in 1986.

Enamel, dental

The hard outer layer of a tooth that covers and protects the inner structures (see *Teeth*).

Encephalitis

Inflammation of the brain, usually caused by a viral infection. In many cases the *meninges* (the membranes that cover and enclose the brain) are also affected. An attack may be so mild that it is barely noticeable, but in most cases it is a serious condition.

CAUSES AND INCIDENCE

The virus most commonly responsible for encephalitis is the *herpes simplex* virus type 1, which also causes cold

sores. In the US, another cause is a virus transmitted to humans by mosquito bites, which causes an illness known as St. Louis encephalitis. In addition, an increasing number of cases are caused by infection with HIV (human immunodeficiency virus), the organism responsible for *AIDS*. Rarely, the condition may be a complication of certain other viral infections, including measles and mumps.

SYMPTOMS AND SIGNS

Encephalitis has variable effects but often starts with headache, fever, and prostration, and progresses to hallucinations, confusion, paralysis of one side of the body, and disturbed behavior, speech, memory, and eye movement. There is a gradual loss of consciousness and sometimes coma. Epileptic seizures may also occur.

If the meninges as well as the brain are inflamed, the neck usually becomes stiff and the eyes become abnormally sensitive to light.

DIAGNOSIS

Diagnosis is based on symptoms, signs, and the results of *CT scanning* of the brain, an *EEG* (which records the electrical activity of the brain), and a *lumbar puncture* (taking a sample of cerebrospinal fluid from the spinal canal for analysis). Blood tests and, rarely, a brain *biopsy* (removal of a small sample of tissue for analysis) may also be required to confirm the diagnosis, which permits lifesaving treatment of some patients.

TREATMENT AND OUTLOOK

The antiviral drug acyclovir, administered by an intravenous drip, has proved an effective treatment for encephalitis caused by the herpes simplex virus. When the disease results from other viral infections, there is no known effective treatment. Depending on the infecting agent, some patients die and some of those who recover are left with brain damage, resulting in mental impairment, behavioral disturbances, and persistent epilepsy.

Encephalitis lethargica

An epidemic form of encephalitis (inflammation of the brain). There have been no major outbreaks since the 1920s, although rare sporadic cases still occur.

The symptoms are as for encephalitis, with additional lethargy and drowsiness—hence the illness's popular name of "sleeping sickness."

About 40 percent of sufferers died during the major epidemics; of those who survived, many later developed postencephalitic *parkinsonism*, a movement disorder marked by symptoms such as tremor, rigidity, immobility, and disturbed eye movements.

A small number of survivors from the post-World War I epidemics were still alive in the 1970s, when administration of a new antiparkinsonian drug, levodopa, brought a remarkable improvement in their conditions. However, after half a century of almost complete immobility, most sufferers were seemingly unable to cope with this "awakening," and lapsed back into their torpid state.

Encephalomyelitis

Inflammation of the brain and spinal cord, resulting in damage to the nervous system. The condition occurs as a complication of about one in 1,000 cases of measles, developing a few days after the rash appears. Rarely, it may occur after other viral infections, such as chickenpox, rubella (German measles), or infectious mononucleosis (glandular fever), or it may follow vaccination against rabies.

SYMPTOMS

Symptoms include fever, headache, drowsiness, confusion, epileptic seizures, partial paralysis or loss of sensation, and sometimes coma.

DIAGNOSIS AND TREATMENT

Diagnosis is as for *encephalitis*. Critically ill patients require careful nursing in a hospital. There is no cure for the disease, but *corticosteroid drugs* are given to reduce inflammation and *anticonvulsant drugs* are given to control epileptic seizures.

OUTLOOK

About 10 to 20 percent of patients die; those that recover may suffer permanent damage to the nervous system, causing mental retardation, epilepsy, paralysis, pituitary insufficiency, loss of sensation, or incontinence.

Encephalopathy

Any disease or disorder affecting the brain, especially chronic degenerative conditions (see *Brain* disorders box).

Wernicke's encephalopathy is a degenerative condition of the brain caused by a deficiency of thiamine (vitamin B_1) and is most common in alcoholics. Hepatic encephalopathy is caused by the effect on the brain of toxic substances having accumulated in the blood as a result of liver disease and liver failure, and is characterized by symptoms such as impaired consciousness, memory loss, personality change, tremors, seizures, stupor, and coma.

Encopresis

A type of *soiling* in which children pass normal feces in unacceptable places after the age at which bowel control is normally achieved (usually 2 to 3 years). These children have no specific physical problem, but often refuse to use a potty or toilet; they defecate in their clothes or in other, secretive, places, such as behind furniture, usually during the day. The problem almost invariably improves with time and is rare after the age of 10.

Endarterectomy

An operation to remove the lining of an artery narrowed by *atherosclerosis*, the buildup of fatty tissue. Removing the diseased lining restores normal blood flow to the part of the body supplied by the artery.

WHY IT IS DONE

Endarterectomy is performed to treat *cerebrovascular disease* (in which there is a serious reduction of blood supply to the brain) or to treat *peripheral vascular disease* (in which blood supply to the legs is impaired).

HOW IT IS DONE

Before surgery, the site of narrowing is located by means of an X-ray procedure called *angiography*, which requires a local anesthetic. For the operation itself the patient is given a general anesthetic.

Endarterectomy is a delicate procedure that may take several hours to perform. The artery is exposed, clamps are applied, an incision is made, and the diseased lining is removed along with any thrombus (blood clot) that has formed. The incision is closed with stitches.

RESULTS

New lining grows in the artery within a few weeks of surgery. The operation often brings about a considerable improvement in symptoms (for example, it can greatly reduce pain in the legs in peripheral vascular disease), but its long-term effect is more limited, since narrowing of an artery is rarely confined to one site. When narrowing is widespread, *arterial reconstructive surgery* may have to be carried out.

Endemic

A medical term applied to a disease or disorder that is constantly present in a particular region or specific group of people, in contrast to an *epidemic*, which is not generally present but occasionally affects a large number of people. *AIDS*, for example, has become endemic in central Africa and

has also spread to many other parts of the world. The lung disease *pneumoconiosis* was formerly endemic in coal miners before safety regulations enforced controls over coal dust, the causative agent.

Endocarditis

Inflammation of the endocardium (internal lining of the heart), particularly the heart valves, usually due to infection. It may occur alone or as a complication of another disease. The various types of endocarditis include acute bacterial, subacute bacterial, fungal, and nonbacterial.

CAUSES AND INCIDENCE

In both types of bacterial endocarditis, causative microorganisms enter the bloodstream and infect the lining of the heart and valves, eventually causing damage. This process is encouraged if the endocardium is already damaged (by congenital *heart disease* or *rheumatic fever*, for example) because clots form on the injured surface and then trap the microorganisms, which multiply rapidly at the site of damage.

Bacteria may be introduced into the bloodstream during cardiac surgery, particularly in places where foreign bodies such as stitches, monitoring tubes, or an artificial heart valve are inserted. Large numbers of microorganisms pass into the bloodstream when people undergo major dental treatment, especially tooth extraction. Surgical and investigative procedures of the gastrointestinal and genitourinary systems—for example, *cystoscopy* (passing a viewing tube through the urethra to inspect the bladder)—carry the same risks.

Drug addicts are susceptible to endocarditis (even if their hearts are healthy) because of the possibility of introducing bacteria and fungi from a dirty syringe and because of the risk of transmitting infection from unclean skin at the site of injection.

Fungal endocarditis may occur in people with previously damaged tissue and in people who have low resistance to infection, especially those on *immunosuppressant drugs*.

Endocarditis that is nonbacterial is a rare feature of some cancers as well as *autoimmune disorders* such as systemic *lupus erythematosus*.

SYMPTOMS

In the subacute form, the disease smolders undetected, sometimes for many months, during which time it causes serious damage to a heart valve. Symptoms are general and nonspecific; the sufferer may complain of fatigue and weakness, feverishness, night sweats, and vague aches and pains. On examination the only evident abnormality may be a heart murmur that changes from time to time.

Acute bacterial endocarditis, which occurs less frequently, comes on suddenly. The patient suffers from severe chills, high fever, shortness of breath, and rapid or irregular heart beat. The infection progresses quickly and may destroy the heart valves, leading to rapidly progressive heart failure (reduced pumping efficiency).

Apart from the inflammation and its effects on the heart, the clots attached to the valves tend to break up and fragments of infected tissue are carried in the blood. This may cause an *embolism* (blockage of an artery) and may carry the infection to other parts of the body.

DIAGNOSIS AND TREATMENT

Any patient suspected of having endocarditis is given a thorough physical examination. Blood samples are examined for bacteria or fungi and, if possible, the organisms are grown in culture so that their sensitivity to antibiotics can be determined. Tests on the heart may include the *ECG*, *echocardiography*, and *angiography*.

Once the diagnosis is confirmed by blood tests, patients are treated with high doses of *antibiotic drugs*. The drugs are usually given intravenously; treatment is started in the hospital, may be continued at home, and may last for as long as 6 weeks.

If a valve has been extensively damaged by erosion due to infection it may have to be replaced surgically with an artificial one. Artificial valves often become infected, in which case they must be replaced. Heart valve replacement may need to be done as an emergency procedure.

PREVENTION AND OUTLOOK

People who are known to have heart valve defects are prescribed antibiotics before undergoing any procedure that runs a significant risk of introducing bacteria into the bloodstream. People with heart valve defects should also be aware of the warning signs of endocarditis and call the physician should they appear.

Before the introduction of antibiotics, endocarditis was practically incurable and the bloodstream infection and valve damage resulted in death in 95 percent of patients; today, 65 to 80 percent recover. The disease is usually fatal if not treated.

Endocrine gland

A gland that secretes chemicals directly (that is, not through a duct) into the bloodstream. Examples include the thyroid gland, ovaries, and adrenals, which release thyroxine, estrogens, and hydrocortisone, respectively. The endocrine glands in the body make up the *endocrine system*. (See also *Exocrine gland*.)

Endocrine system

A collection of glands that produces hormones (chemical substances necessary for normal body functioning) that regulate the body's rate of metabolism, growth, and sexual development and functioning. Unlike *exocrine glands*, the secretions of which pass through ducts to local areas, endocrine glands are ductless and release their hormones directly into the bloodstream to be transported to organs and tissues throughout the body. (See also box, opposite.)

Endocrinologist

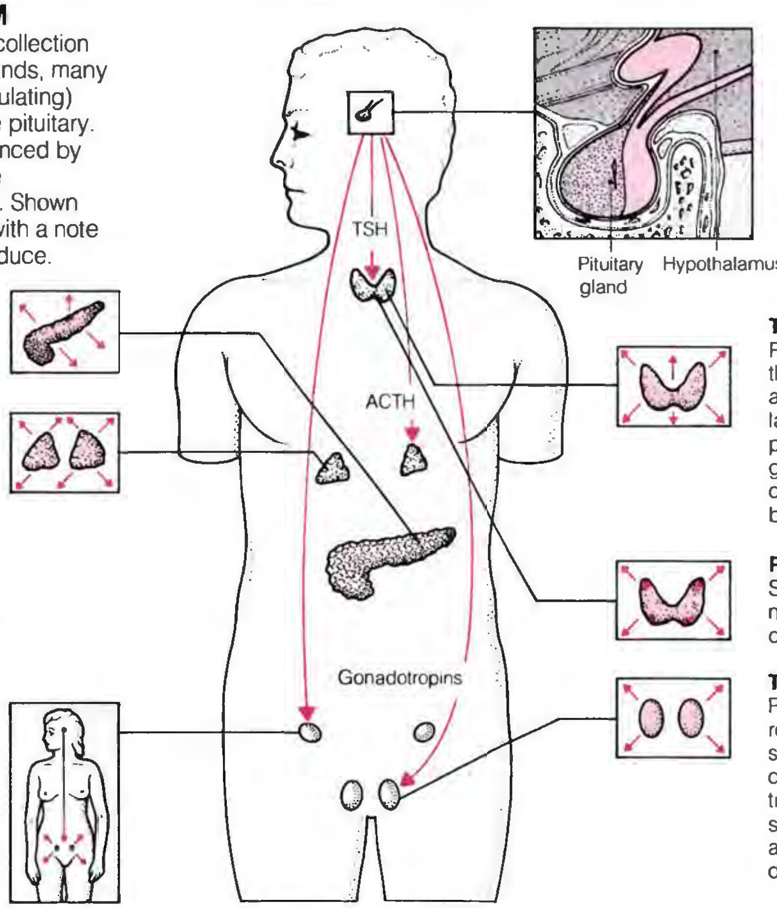
An internist who specializes in diseases and disorders of the *endocrine system*. Patients include people with *thyroid* disorders or *diabetes mellitus*.

Endocrinology

The study of the endocrine glands and the hormones they secrete, including the investigation and treatment of their disorders.

The hormones produced by the endocrine glands are responsible for numerous body processes, including growth, metabolism, sexual activity, temperature regulation, and response to stress. Any increase or decrease in the production of a specific hormone interferes with the process it controls.

One example of overproduction is *Graves' disease*, in which the thyroid gland produces too much thyroxine.



The symptoms and signs of an endocrine disorder may lead a family physician to suspect such a disease, but confirmation usually requires referral to an endocrinologist for specialized tests, including measurement of the amounts of various hormones in the blood and urine.

Endodontics

The specialized branch of dentistry concerned with the causes, prevention, diagnosis, and treatment of disease and injury affecting the nerves and pulp in teeth and the periapical (surrounding) tissues in the gum. Endodontics includes *pulpotomy* and *root-canal treatment*.

ENDOCRINE SYSTEM

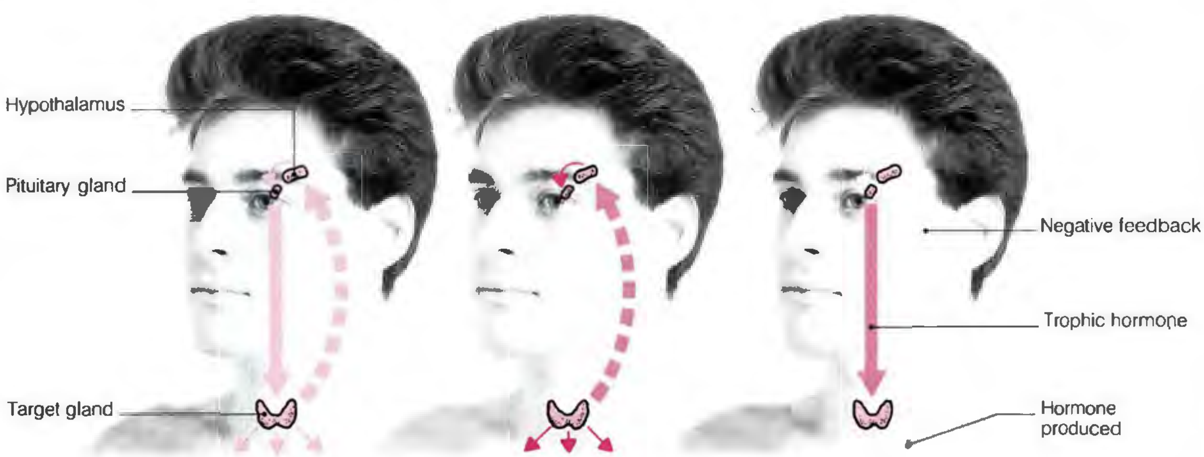
The system consists of a collection of hormone-producing glands, many regulated by trophic (stimulating) hormones secreted by the pituitary. The pituitary is itself influenced by hormones secreted by the hypothalamus in the brain. Shown are the principal glands, with a note on the hormones they produce.

Pancreas
Secretes insulin and glucagon, which control the body's utilization of glucose

Adrenal cortex
When stimulated by ACTH, produces hydrocortisone, which has widespread effects on metabolism; also produces androgen hormones and aldosterone, which maintains blood pressure and the body's salt balance.

Ovaries
Produce the hormones estrogen and progesterone, which influence multiple aspects of female physiology. These processes are controlled by gonadotropic hormones secreted by the pituitary.

Pituitary gland
Secretes hormones that stimulate the adrenals, thyroid, pigmentation-producing skin cells, and gonads; also secretes growth hormone, antidiuretic hormone, prolactin, and oxytocin.



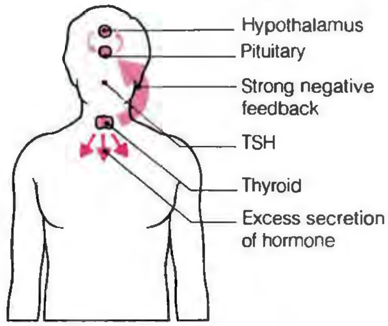
Thyroid gland
Produces the hormones thyroxine, triiodothyronine, and calcitonin, which stimulate metabolism, body heat production, and bone growth. Thyroid activity is controlled by TSH, secreted by the pituitary.

Parathyroid glands
Secrete parathyroid hormone, which maintains the calcium level in the blood.

Testes
Produce testosterone in response to gonadotropins secreted by the pituitary. A combination of gonadotropins and testosterone stimulates sperm production and the development of other male characteristics

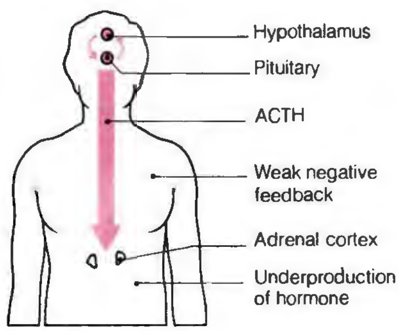
CONTROL OF HORMONE PRODUCTION

Production of too much or too little hormone by a gland is prevented by feedback mechanisms. Variations in the blood level of the hormone are detected by the part of the brain known as the hypothalamus, which prompts the pituitary to modify its production of trophic (gland-stimulating) hormone accordingly.



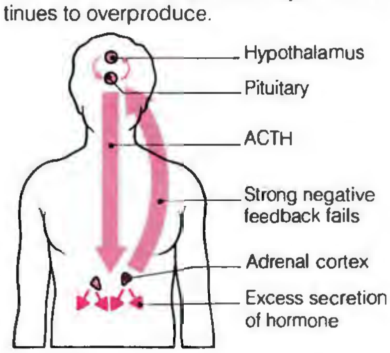
1 The production of hormone by the target gland (in this illustration, the thyroid gland) and of trophic hormone by the pituitary gland is normal.

2 If hormone production by the target gland rises too high, the feedback effect causes less trophic hormone to be produced, which tends to return the situation to normal.



3 If hormone production by the target gland drops too low, the feedback lessens and more trophic hormone is produced, which tends to return the situation to normal.

ENDOCRINE DISORDERS



In all endocrine disorders, there is either deficient or excess production of a hormone by a gland. Common causes of abnormal hormone production include a tumor or an autoimmune disease affecting a gland, or a disorder of the pituitary or the hypothalamus, which control many other glands. Abnormal hormone production often has a feedback effect on the secretion of trophic (stimulating) hormones by the pituitary and the hypothalamus – as in two of the examples shown. The blood levels of different hormones may need to be measured to pinpoint the cause of a disorder.

Thyrotoxicosis
This disorder is usually due to an autoimmune disease of the thyroid. Excess hormones cause the symptoms; the output of TSH and its hypothalamic releasing hormone is reduced, but the thyroid continues to overproduce.

Addison's disease
Symptoms are caused by reduced hormone production by the defective adrenal cortices. Feedback is weak, so the pituitary pours out adrenocorticotropic hormone (ACTH), but it fails to stimulate the adrenals.

Cushing's syndrome
This disorder is caused by excess ACTH secretion by a pituitary tumor. This stimulates the adrenal cortices to make excess hydrocortisone, leading to the symptoms of the syndrome. Feedback fails to suppress ACTH secretion.

Endodontist

A dentist who is specially trained to treat the nerves and pulp in teeth and the periapical (surrounding) tissues in the gum. *Root-canal treatment* is a common endodontic procedure.

Endogenous

Arising from causes within the body. For example, an endogenous infection may occur if bacteria from around the anus invade the urinary tract.

The term endogenous depression was formerly used to describe depression with no discoverable external cause that was thought to be due to a chemical imbalance in the brain.

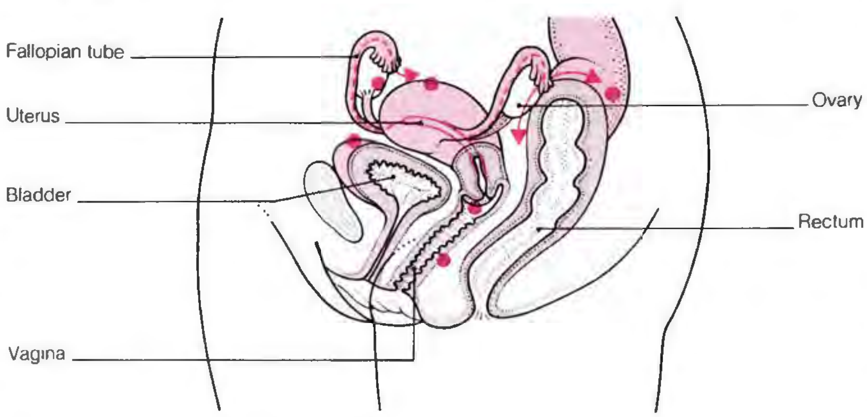
Most disorders, however, are exogenous (caused by external infections, poisoning, or injury).

Endometrial cancer

See *Uterus, cancer of.*

Endometriosis

A condition in which fragments of the *endometrium* (lining of the uterus) are found in other parts of (or on organs within) the pelvic cavity.



INCIDENCE AND CAUSE

Endometriosis is most prevalent between 25 and 40 and is a common cause of *infertility*. About 10 to 15 percent of infertility patients have endometriosis and about 30 to 40 percent of women suffering from endometriosis are infertile.

The exact cause of endometriosis is uncertain, but in some cases it is thought to occur because fragments of

SITES OF ENDOMETRIOSIS

Fragments of the *endometrium* may travel from the uterus into the pelvic cavity via the fallopian tubes. They then implant on parts of the pelvic organs (such as the uterus, ovaries, vagina, cervix, bladder, and rectum). The patches of endometrium continue to respond to the menstrual cycle and bleed every month, causing the formation of painful cysts, which can be very small or as large as a grapefruit.

Severe endometriosis
The uterus, fallopian tubes, and ovaries shown above had large cysts growing around them due to endometriosis. As the patient was nearing the menopause, the affected organs were surgically removed

the endometrium that are shed during *menstruation* do not leave the body with the menstrual flow. Instead, they travel up the fallopian tubes and into the pelvic cavity. There, they may adhere to and grow on any of the pelvic organs.

These displaced patches of endometrium continue to respond to the menstrual cycle as if they were still inside the uterus, so each month they bleed. This blood cannot escape, however, and causes the formation of slowly growing cysts from the size of a pinhead to the size of a grapefruit. The growth and swelling of the cysts are responsible for much of the pain associated with endometriosis.

SYMPTOMS AND SIGNS

The symptoms of endometriosis vary widely, with abnormal or heavy menstrual bleeding being most common. There may be severe abdominal and/or lower back pain during menstruation, which is often most severe toward the end of a period. Other possible symptoms include dyspareunia (see *Intercourse, painful*) and digestive tract symptoms such as diarrhea, constipation, or painful defecation. Rectal bleeding that happens only at the time of the menses may occur. In some cases, however, endometriosis causes no symptoms.

DIAGNOSIS AND TREATMENT

Laparoscopy (examination of the abdominal cavity with a viewing instrument) confirms the diagnosis.

Treatment depends on many factors, including the age and health of the patient, the severity of the condition, and the desire of the woman to have children. Some cases are mild and require no treatment. Drugs to prevent menstruation (including danazol, progesterone, or the combined birth-control pill) may be given. In some cases, pregnancy can suppress endometriosis.

In severe cases, surgical removal of the cysts may be necessary in addition to drug therapy. This may relieve symptoms and aid fertility. If the woman is planning to have no children or she is nearing the menopause, a *hysterectomy* may be considered.

Endometritis

Inflammation of the *endometrium* (uterine lining) due to infection.

Endometritis is a feature of *pelvic inflammatory disease* (PID). It may also occur as a complication of abortion or childbirth, after the insertion of an *IUD*, or as the result of a sexually transmitted infection.

Symptoms include fever, vaginal discharge, and lower abdominal pain. Treatment includes removing any foreign body (such as an IUD or retained placental tissue) and the administration of antibiotics.

Endometrium

The membrane that lines the inside of the *uterus*. It increases in thickness during the menstrual cycle until ovulation occurs. The surface layers are shed during *menstruation* if conception does not take place.

Endorphins

A group of substances formed within the body that relieves pain. Endorphins have a similar chemical structure to *morphine* (it is because of this similarity that morphine has an analgesic effect).

In 1973 morphine was found to act at specific sites (called opiate receptors) in the brain, spinal cord, and at other nerve endings. This discovery led to the identification of small protein molecules produced by cells in the body that also act at opiate receptors; these morphinelike proteins were named endorphins (short for endogenous morphines).

Two other small proteins produced within the brain were originally considered to be examples of endorphins, but they have now been reclassified as *enkephalins* because they are released from different nerve endings.

FUNCTIONS

Since their discovery, endorphins have been found at several sites in the body apart from the nervous system, including the pancreas and testes. Research is being performed to elucidate their full range of functions.

In addition to their analgesic effect, endorphins are thought to be involved in controlling the body's response to stress, regulating contractions of the intestinal wall, and determining mood. They may also regulate the release of hormones from the pituitary gland, notably growth hormone and the *gonadotropin hormones* (which act on the ovaries or testes).

Addiction and *tolerance* to narcotic analgesics, such as morphine, are thought to be due to suppression of the body's production of endorphins; the withdrawal symptoms that occur when the effects of morphine wear off may be due to a lack of these natural analgesics. Conversely, acupuncture is thought to produce analgesia partly by stimulating the release of endorphins and enkephalins.

Endoscope

A lighted viewing instrument that is inserted into a body cavity for the purpose of investigating and treating disorders. (See also box, overleaf.)

Endoscopy

Examination of a body cavity by means of an *endoscope*, a tubelike instrument with lenses and a light source attached. The procedure is safe and in only some cases is a general anesthetic required. Endoscopes may be used with a camera or video recorder, which enable permanent records of the appearance of the internal organs of the body to be obtained and used for reference.

HISTORY

Attempts to view the interior of the body through a rigid, lighted, telescopelike tube were made in the early 1900s, but endoscopy really began in the 1930s with the invention of a semiflexible gastroscope for viewing the stomach. In the late 1950s, a second revolution came with the introduction of *fiberoptics* (flexible bundles of glass or plastic fibers along which light is transmitted). This enabled more versatile instruments to be developed and led to the acceptance of endoscopy as a routine part of hospital medicine.

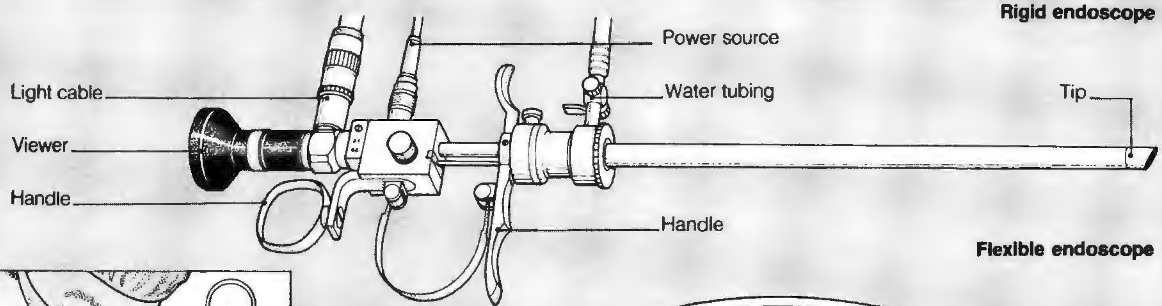
USES

There are two main uses of endoscopy—diagnostic and therapeutic. For patients suspected of having a tumor or other disorder in the stomach, bladder, lungs, or other organs, endoscopy enables the physician to study the relevant organ and to take a *biopsy* sample (small piece of suspicious tissue for testing), procedures that once required a major operation. Since endoscopy is safe and can be repeated at frequent intervals, it is also useful in assessing how well an ulcer of the stomach or duodenum is healing.

Endoscopy is valuable in the treatment of acute emergencies such as bleeding from the stomach. It allows the cause and site of the bleeding to be identified and, in some cases, to be treated with electrocautery or a *laser*.

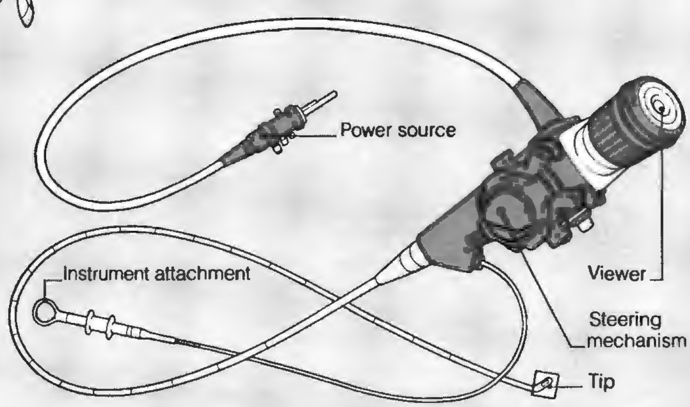
Many minor disorders of the knee joint that formerly required a major operation can now be treated quickly and easily. Other uses include removal of polyps (small growths) and swallowed foreign bodies, local application of drugs, and sterilization operations for women. (See also *Arthroscopy*; *Bronchoscopy*; *Colonoscopy*; *Cystoscopy*; *ERCP*; *Gastroscopy*; *Laparoscopy*; *Laryngoscopy*.)

ENDOSCOPES

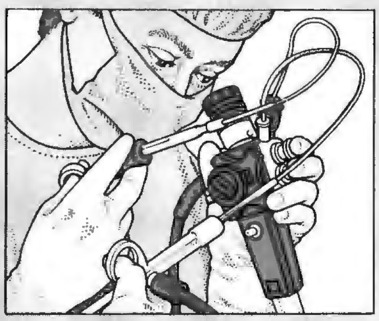


A typical flexible fiberoptic endoscope consists of a bundle of light-transmitting fibers (see *Fiberoptics*). At one end is the head (featuring a viewing lens and steering device) and a power source. The tip has a light, a lens, and an outlet for air or water. Side channels enable attachments to be passed through to the tip of the endoscope.

A rigid endoscope is a straight, narrow viewing tube that is not flexible. Attached to it is a light source, which is usually fiberoptic.



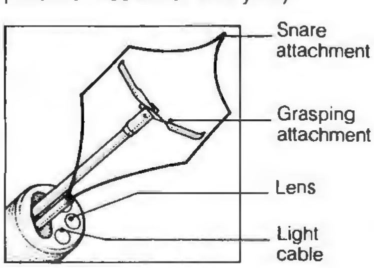
COMMON TYPES OF ENDOSCOPES

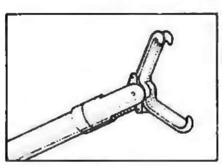


Instruments	Region	Nature
Cystoscope	Bladder	Rigid
Bronchoscope	Bronchi (main airways of the lungs)	Flexible or rigid
Gastroscope	Esophagus, stomach, and duodenum	Flexible
Colonoscope	Colon (large intestine)	Flexible
Laparoscope	Abdominal cavity	Rigid
Arthroscope	Knee joint	Rigid

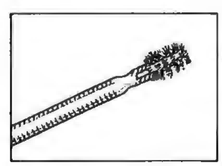
Rigid endoscope

Flexible endoscope



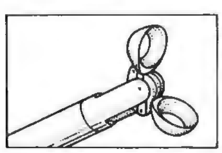


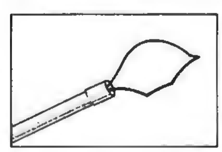
Endoscopic examination
The physician looks through the viewing lens and uses the handles to manipulate the attachments.



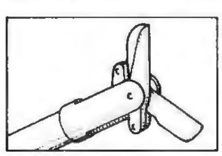
ATTACHMENTS

Various specialized attachments are available for use with the endoscope. They enable the physician to perform diagnostic and therapeutic procedures such as taking a biopsy specimen (a small piece of tissue for analysis).

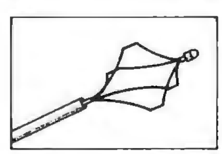




Grasping forceps
Sharp-toothed forceps that allow foreign bodies to be grasped firmly and removed.



Brushes
Small brush attachments are used to obtain cells for cytologic examination.



Biopsy forceps
Used for taking small samples of tissue for microscopic analysis.

Snare
A thin wire loop, used to remove polyps, through which an electric current is passed

Scissors
Tiny surgical scissors are used for cutting through tissue and removing small growths.

Basket
A wire basket is sometimes used to trap and remove stones from the bile duct.

Endothelium
The layer of cells that lines the heart, blood vessels, and lymphatic ducts. The cells are squamous (thin and flat), providing a smooth surface that aids the flow of blood and lymph and helps prevent the formation of thrombi (blood clots). See also *Epithelium*.

Endotoxin

A poison produced by certain bacteria but not released until after the death of the bacteria; until then the toxin remains in the cell wall of the bacteria. Released endotoxins produce two major effects. First, they cause a fever by acting on the temperature-regulating center in the brain. Second, they make the walls of blood capillaries more permeable. This causes fluid to leak into the surrounding tissue, sometimes resulting in a serious drop in blood pressure, a condition called endotoxic shock. (See also *Enterotoxin*; *Exotoxin*.)

Endotracheal tube
A narrow plastic tube passed through the mouth or nose into the trachea (windpipe) by an anesthesiologist. The tube is held in place by an inflatable cuff at its lower end, giving an airtight fit. Endotracheal intubation is performed to deliver oxygen to the lungs if a patient is not breathing adequately and needs mechanical *ventilation*. It may be necessary in a comatose or anesthetized patient, or in a person with respiratory disease.

Enema
A procedure in which fluid is passed into the rectum through a tube inserted into the anus, either as treatment or for diagnostic reasons.

WHY IT IS DONE
An enema is performed for one of three reasons. It can be used to clear the intestine of feces to relieve constipation or to make the tract suitably clean for surgery of the abdominal cavity. Traditionally, this enema was performed by passing soap and water into the rectum. The soap irritated the wall of the intestine, causing contractions and thus stimulating defecation. Soap and water has now largely been replaced by prepacked, small volume enemas containing medication that has the same effect.

Another use of the enema is to administer medicine, such as corticosteroids dissolved in small volumes of fluids to relieve bleeding and inflammation in ulcerative colitis, or, less commonly, electrolyte solutions to treat severe dehydration.

A third use is in *barium X-ray examinations* to investigate the large intestine for the presence of disease. Barium sulfate, a metallic chemical impervious to X rays, is introduced by enema and outlines the intestine on X-ray pictures.

HOW IT IS DONE
No anesthetic is needed, although the procedure may cause slight discomfort as the fluid distends the intestine. The patient lies on his or her side with hips raised on a pillow. A catheter (flexible tube) with a soft, well-lubricated tip, is gently inserted into the rectum and the fluid for the enema, warmed to prevent sudden contraction of the intestine, is slowly introduced through it.

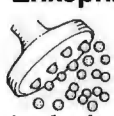
Energy
The capacity to do work or effect a physical change; nutritionists now also refer to the fuel content of a food as its energy content.

There are many different forms of energy—including light, sound, heat, chemical, electrical, and kinetic (the energy possessed by an object by virtue of its motion)—and most of them play a role in the body. For instance, the retina converts light energy to electrical nerve impulses, thereby making vision possible. Muscles use chemical energy—obtained from food—to produce kinetic energy (movement) and heat.

Energy is measured in units called calories (symbol c), which are becoming obsolete, or joules (symbol J). One calorie is defined as the amount of energy needed to raise the temperature of 1 gram (about 0.033 ounce) of water by 1°C (about 0.6°F); 1 calorie is equivalent to about 4.2 joules (therefore, 1 joule equals approximately 0.24 calories). However, these units are too small for many practical purposes. In medicine, especially in nutrition, the most commonly used units of energy are the kilocalorie (1,000 calories, often called simply a Calorie and represented by a capital C) and the kilojoule (1,000 joules, or 1 kJ).

METABOLIC ENERGY
The most important forms of energy in the body are chemical and heat. The body's *metabolism* comprises thousands of different chemical reactions, some of which liberate energy and some of which use it. Overall, there is a balance between the amount liberated and the amount consumed (see *Energy requirements*).

In general, the energy liberated from the breakdown of nutrients such as glucose and fats (protein is broken down for energy only in extreme situations) is stored as chemical energy in the form of ATP (adenosine triphosphate) molecules. The energy in the molecules is then available to power processes that consume energy, such as muscle contraction or the building up of complex substances needed for repair and maintenance of body structures. Some body processes (muscle contraction, for instance) produce energy in the form of heat. A certain amount of this energy is needed to maintain body temperature, but any excess cannot be used and must leave the body by mechanisms such as radiation of heat from the skin or sweating.



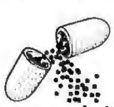
Energy requirements
The amount of *energy* needed by a person for cell metabolism, muscular activity, and growth. This energy is provided by nutrients in the diet, primarily carbohydrate, fat, and protein, and from stored nutrients in the liver and muscles.

ENERGY EXPENDITURE
Energy is needed to keep the heart beating and the lungs functioning and to maintain body temperature. The rate at which these processes use energy is known as the basal metabolic rate (BMR). The BMR accounts for three quarters of the total daily expenditure of energy of the average sedentary person. Any form of movement increases energy expenditure above the BMR. The greater the muscular effort required, the more energy is expended.

Additional energy is needed during growth to provide for extra body tissue. During pregnancy and lactation the mother's energy requirement increases because she must meet the needs of the baby as well as her own. (See also *Nutrition*; *Obesity*.)

Engagement
The arrival of the head of the fetus into the mother's pelvis. In a woman's first pregnancy, engagement usually occurs by the 37th week but, in subsequent pregnancies, it may not occur until labor begins. Rarely, engagement may fail to occur—if, for example, the baby's position in the uterus is abnormal, the baby's head is too big for the mother's pelvis, or if there is *placenta previa* (abnormal position of the placenta across the opening of the uterus).

Enkephalins



A group of small protein molecules that are produced in the brain and by nerve endings elsewhere in the body (in the digestive system and adrenal glands, for example) that have an analgesic effect. In addition, they are thought to produce sedation, to affect mood, and to stimulate motivation.

Enkephalins were initially considered to be *endorphins* (endogenous morphines), but it has since been discovered that they are released by different nerve endings and that they differ slightly chemically.

Enophthalmos

A sinking inward of the eyeball. The most common cause is fracture of the floor of the orbit (bony cavity making up the eye socket).

Enteric-coated tablet

A form of drug preparation whose surface is covered with a substance that is resistant to the action of stomach juices. Enteric-coated tablets pass undissolved through the stomach into the small intestine, where the covering dissolves and the contents are absorbed.

Such tablets are used either when the drug might harm the stomach lining (as may occur with certain corticosteroids, such as prednisone) or when the stomach juices may destroy the efficacy of the drug, as can happen with sulfasalazine.

The drawback of some enteric-coated tablets is that they may pass through the gastrointestinal tract without dissolving.

Enteric fever

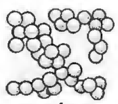
An alternative name for either *typhoid fever* or *paratyphoid fever*.

Enteritis

Inflammation of the small intestine. Enteritis may result from infection, particularly *giardiasis* and *tuberculosis*, or from *Crohn's disease*, which is sometimes called regional enteritis. Enteritis usually causes diarrhea. (See also *Gastroenteritis*; *Colitis*.)

Enteritis, regional

Another name for *Crohn's disease*.



Enterobiasis

An infestation of the intestines by a small roundworm, ENTEROBIUS VERMICULARIS. (See *Pinworm infestation*.)

Enterostomy

An operation in which a portion of small or large intestine is joined to another part of the gastrointestinal tract or to the abdominal wall. When part of the colon (large intestine) is brought through an incision in the abdominal wall to allow the discharge of feces into a bag attached to the skin, the operation is called a *colostomy*. When the ileum (last section of the small intestine) is used for the opening, it is called an *ileostomy*.

Enterotoxin

A type of *toxin* (poison released by certain bacteria) that inflames the lining of the intestine, causing vomiting and diarrhea. Staphylococcal *food poisoning* is due to eating food contaminated with an enterotoxin that is produced by staphylococci bacteria; the toxin is resistant to heat and thus is not destroyed by cooking. The severe intestinal purging that occurs in *cholera* is also caused by an enterotoxin, but by one that is actually produced in the intestine by the cholera bacteria. (See also *Endotoxin*.)

Entropion

A turning in of the margins of the eyelids so that the lashes rub against the cornea and the conjunctiva.

CAUSES

Entropion is sometimes congenital, especially in fat babies. It is common in the elderly, when weakness of the muscles surrounding the lower part of the eye allows the lower lid plate to turn inward. Entropion of the upper or lower lid may be caused by scarring on the inner surface of the lid—for example, due to *trachoma* (a bacterial eye infection).

SYMPTOMS AND SIGNS

Entropion is easily recognized by the sufferer or his or her family. The lid margin is rolled inward so that the lashes are concealed, which sometimes irritates the conjunctiva. When gentle pressure is applied with the fingertip over the lid, the margin pops out, revealing the lashes again.

COMPLICATIONS

In babies, entropion rarely causes any complications because the lashes are very soft and unlikely to damage the cornea. In later life, entropion can cause irritation, conjunctivitis, or corneal ulceration. Persistent entropion may permanently damage the cornea and cause problems with vision and, in some people, blindness.

TREATMENT

Entropion that affects babies usually disappears spontaneously within a few months and seldom requires treatment. In the elderly or in sufferers from trachoma, surgery to correct the entropion prevents damage to the cornea.

ENT surgeon

See *Otolaryngologist, head and neck surgeon*.

Enuresis

The medical term for bed-wetting. Enuresis is a common phenomenon; about 10 percent of children still wet the bed at the age of 5 years, and many of these continue to do so until the age of 8 or 9. A slightly higher number of boys than girls are bed-wetters, and the problem tends to run in families.

CAUSES

In most cases, bed-wetting is due to slow maturation of nervous system functions concerned with control of the bladder. Occasionally it results from psychological stress. In a small number of bed-wetters, there is a specific physical cause—for example, a structural abnormality of the urinary tract present from birth, *diabetes mellitus*, infection of the urinary tract, or a nervous system defect, such as *spina bifida* or spinal cord damage. In each of these cases, the child also has difficulty with daytime bladder control (see *Incontinence, urinary*).

INVESTIGATION

The physician tries to discover, by a full physical examination, urine testing, and other procedures, whether the problem is due to psychological stress or to a nervous system or other physical disorder. If these diagnoses are excluded, tests may be needed to assess bladder function (see *Cystometry*). However, these tests are usually performed only on older children. They involve inserting a catheter into the bladder, which is difficult for a young child to tolerate.

TREATMENT

In the absence of an ascertainable cause, or until the problem can be more fully investigated, treatment starts with training the child to pass urine regularly during the day. This helps the child recognize when the bladder is full, even during sleep. Systems such as rewarding the child with a star on a chart for each dry night are often successful.

If such simple measures fail to work, a nighttime alarm system may be recommended by the physi-

cian. The system consists of a pad, placed in the child's bed between the lower sheet and the mattress, that is sensitive to moisture and that triggers a loud alarm when urine is passed. This awakens the child, who can then use the toilet. Eventually, the child wakes whenever urine is about to be passed. Alarms are said to help over two thirds of bed-wetting children over 7 years old.

Other measures that can help include encouraging the child not to drink for two or three hours before sleep, getting him or her to go to the toilet each night immediately before bed, and waking the child to use the toilet two or three hours after going to bed. Antidepressant drugs have also been used successfully in the treatment of bed-wetting.

Parents should not punish a child for bed-wetting or focus undue attention on it, as this may only make the child more anxious and make the problem worse. The vast majority of bed-wetting children eventually become dry at night.

Environmental medicine

The study of the effects on health inherent in different naturally occurring phenomena, such as climate, altitude, sunlight, and the presence of various minerals. The effects of working environments, such as in coal mining, is a separate study (see *Occupational medicine*).

CLIMATE

Certain regions, such as the south of France and the Canary Islands, have long been considered generally beneficial to health; more recently, these sites have been joined by Florida and California.

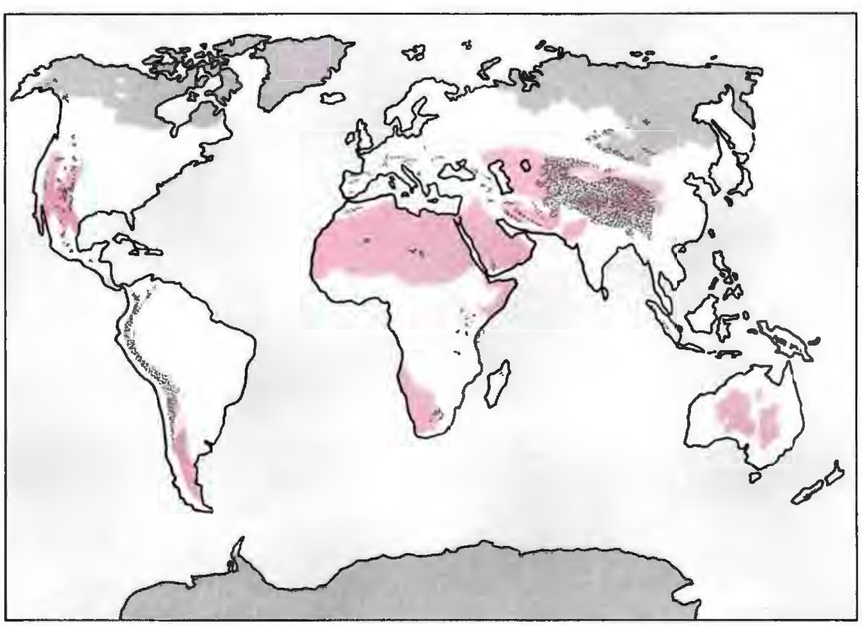
There is also convincing evidence that particular types of illness respond well to certain climates. For example, sufferers from chest disorders, such as chronic bronchitis and asthma, usually obtain some relief from their symptoms in warm, dry climates. In the US and Europe, where most respiratory complaints are more common in winter, sufferers benefit from spending their winters in a warm environment. Until the introduction of chemotherapy in the 1940s, the prime treatment for pulmonary tuberculosis was to move the patient to a mountain sanatorium to enjoy cool, clean, dry air.

ALTITUDE

Although mountainous regions have much less atmospheric pollution, they are not necessarily beneficial to health because air becomes thinner as altitude increases. Anyone with a chest disease who ascends quickly from sea level to 5,000 feet (about 1,500 meters)—the altitude of Denver, Colorado—may find that his or her breathing difficulty becomes worse. Above 10,000 feet (about 3,000 meters), breathing becomes difficult even for healthy people. Rapid ascent from sea level to 12,000 feet (3,600 meters) or higher carries the risk of altitude sickness, which can produce symptoms ranging from nausea and sleeplessness to coma or death. Only a few communities in the high Andes of South America live permanently above that level.

Sustained living seems to be impossible above 20,000 feet (about 6,000 meters) since at that level the blood cells increase to compensate for lack of oxygen. This strains the heart and causes a predisposition to thrombosis (blood clotting).

SUNLIGHT



White people who live in sunny climates may more easily suffer ill effects from repeated exposure to sunlight, including wrinkling of the skin and an increased risk of skin cancers, such as *basal cell carcinoma* and malignant *melanoma*, and the precancerous condition actinic *keratosis*.

MINERALS

Variations in the distribution of certain *minerals* in the environment are known to have an effect on health. For example, it has recently been discovered that, in areas where the radioactive gas radon is emitted (from rocks of the granite type), there is a higher-than-average incidence of cancers. In contrast, communities that are located in regions where the water has a high fluoride content have a lower-than-average incidence of dental caries.

THE GROWING IMPORTANCE OF ENVIRONMENTAL MEDICINE

Large areas of the world are naturally hostile to humans and were, in the past, avoided. Today, exploitation of natural resources has lured people into these regions and has highlighted the importance of environmental medicine.

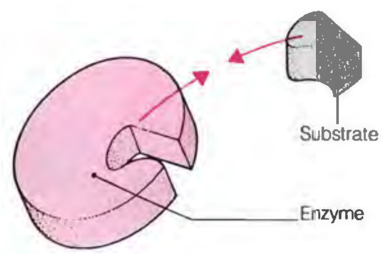
Key

- Desert regions
- Cold regions with average winter temperature below −10°F (−23°C)
- Mountain regions above 10,000 feet (3,000 m)

Enzyme
A protein that regulates the rate of a chemical reaction in the body. There are thousands of enzymes, each with a different chemical structure. It is this structure that determines the specific reaction regulated by an enzyme. To function properly, many enzymes need an additional component called a coenzyme, which is often derived from a vitamin or mineral.

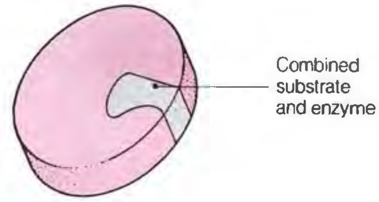
Every cell in the body produces various enzymes; different sets of enzymes occur in different tissues, reflecting their specialized functions. For example, the pancreas produces the digestive enzymes lipase, protease, and amylase; among the numerous enzymes produced by the liver are some that metabolize drugs.

INDUCTION AND INHIBITION
Enzyme activity is influenced by many factors. Liver enzyme activity is increased by certain drugs, such as barbiturates, which affect the rate at which other drugs are metabolized by the liver. This effect, known as enzyme induction, is responsible for many important *drug* interactions.



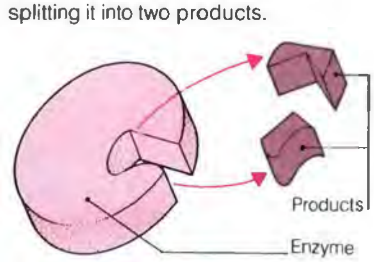
Conversely, many drugs inhibit or block enzyme action. Some antibiotics destroy bacteria by blocking bacterial enzymes while leaving human ones unaffected. Similarly, some anticancer drugs work by blocking enzymes in tumor cells, affecting normal body cells to a lesser degree.

ENZYMES AND DISEASE
Measuring enzyme levels in the blood can be useful for diagnosing disorders of certain organs or tissues. For example, the level of heart enzymes is raised after a *myocardial infarction* (heart attack) because the damaged heart muscle cells release enzymes into the bloodstream; muscle enzyme levels are raised in *muscular dystrophy*; and liver enzymes—measured in *liver function tests*—may be raised as a result of certain liver disorders.



Many inherited metabolic disorders, such as *phenylketonuria*, *galactosemia*, and *G6PD deficiency*, are caused by defects in, or deficiencies of, specific enzymes.

ENZYMES AND TREATMENT
Enzymes can play a valuable role in treating certain diseases and disorders. Pancreatic enzymes may be given as digestive aids to patients with *malabsorption* related to pancreatic disease; enzymes that loosen phlegm in the airways may be given to people with chronic lung disease who find it difficult to cough up the phlegm; enzymes such as streptokinase from bacteria and activated tissue plasminogen are used to treat acute *thrombosis* (especially in the coronary arteries) and arterial *embolism* (especially pulmonary embolism). Papain from the papaw fruit can be used in the dressing of wounds and ulcers because it dissolves dead tissue and coagulated blood and may also reduce bruising and swelling.



HOW ENZYMES WORK
An enzyme is a type of protein that acts as a catalyst for a chemical change in the body – that is, it greatly speeds up the rate at which the change occurs. The change may be a small modification to the structure of a substrate (chemical) in a body tissue, the splitting of a substrate, or the joining of two substrates.

1 The shape of an enzyme determines its activity. It will combine only with a specific substrate that has molecules of a complementary shape.

2 When enzyme and substrate combine, their interaction causes a chemical change within the substrate – in this case, splitting it into two products.

3 After the reaction, the enzyme molecule is unchanged and can move on to combine with another substrate molecule and repeat the process.

Ependymoma
A type of *brain tumor* that occurs commonly in children. It is a *glioma*, a tumor arising from the glial (supporting) cells within the nervous system.

Although ependymomas are one of the more common types of tumor in childhood, in overall terms they are rare. In the US, there are about two to three cases annually per million people. The cause is unknown.

Symptoms, diagnosis, and treatment of ependymomas are as for other types of brain tumor.

Ephedrine
A drug that stimulates the release of *norepinephrine* (a chemical *neurotransmitter* released from nerve endings).

Ephedrine is used in eye drops to narrow dilated blood vessels and to relieve redness of the eyes caused by minor irritation, such as smoke.

Other uses occasionally include the relief of motion sickness, bed-wetting in children, and delayed ejaculation. Ephedrine is prescribed as a *decongestant drug* and as a *bronchodilator drug*.

Epicanthic fold
A vertical fold of skin extending from the upper eyelid to the side of the nose. It is a normal feature in Orientals. In other races, it is rare except in babies; the folds usually disappear as the nose develops.

Epicondylitis
A painful inflammation of an epicondyle, one of the bony prominences of the elbow at the lower end of the humerus (upper arm bone). Various forearm muscles that bend or straighten the wrist or fingers are attached by tendons to the epicondyles. Overuse of these muscles can lead to epicondylitis due to repeated tugging of the tendons at their point of attachment to the bone.

Epicondylitis affecting the prominence on the outer side of the elbow, caused by overuse of the muscles that straighten the fingers and wrist, is called *tennis elbow*. When the prominence on the inner side of the elbow is affected, caused by overuse of muscles that bend the fingers and wrist, it is called *golfers' elbow*.

Epidemic
A medical term applied to a disease that for most of the time is rare in a community, but which suddenly spreads rapidly to affect a large number of people. Epidemics of new strains of influenza are probably the

most common, occurring periodically when the influenza virus changes to a form to which the population has no resistance. (See also *Endemic.*)

Epidemiology

The study of disease as it affects groups of people, as opposed to individuals. Originally, as its name suggests, epidemiology dealt mainly with epidemics of infectious diseases (such as cholera, plague, and influenza) and outbreaks of infections (such as gastroenteritis) associated with food poisoning. More recently, it has been applied to widespread noninfectious diseases, such as cancer and heart disease.

Members of a population (or, in comparative studies, populations) under study are carefully counted and defined in terms of each person's race, sex, age, occupation, social class, marital status, and the like. Then the incidence of the disorder (the number of new cases per week, month, or year) and its prevalence (the number of people with the disorder at any given time) are determined. These observations may be repeated at regular intervals to detect changes occurring over time. The result is an exact statistical record that often yields many valuable findings.

Groups that spend all their lives in one defined area often provide more useful information than highly mobile populations whose environments change considerably over the course of their lives. For example, a high incidence of cancer of the esophagus has been studied among the inhabitants of one region of China and among other inhabitants of Iran. This incidence has been compared to similar groups in other regions of the countries; certain foods have been implicated.

COMPARATIVE EPIDEMIOLOGY

In the attempt to conquer cancer, heart disease, and other widespread diseases that afflict people in the West today, comparative epidemiology is proving to be one of the most potent weapons. Two or more groups are chosen—one having, the other not having, a characteristic that may affect the frequency of a disease. For example, in a study of the link between smoking and lung cancer, one group may consist of smokers and the other of nonsmokers; the proportion with cancer in each group is then calculated. In such cases, the epidemiologist is careful to make the two groups as nearly identical as possible in other respects, carefully matching such factors as age, sex, weight, and socioeconomic status.

Another approach is to compare a group of people that has a certain disease, such as hypertension, with a control group (people without the condition but similar in other respects); the aim is to isolate identifying factors, such as obesity, that differ between the two groups.

The links discovered by comparative epidemiology—such as the correlation of a high level of fish oils in the diet and low prevalence of heart disease—do not demonstrate cause and effect. For example, epidemiologists have discovered that the prevalence of heart disease is high in countries in which most people have an automobile. This association obviously does not mean that owning an automobile causes heart disease, but, since such ownership suggests a more sedentary life-style, the link does reinforce the belief that lack of exercise increases the risk of heart disease. The study thus justifies more research on the subject.

Epidermolysis bullosa

A rare, inherited condition in which blisters appear on the skin after minor damage. The disorder mainly affects young children and has a wide range of severity, from the type in which blisters form on the feet in hot weather, to a form with widespread blistering and scarring.

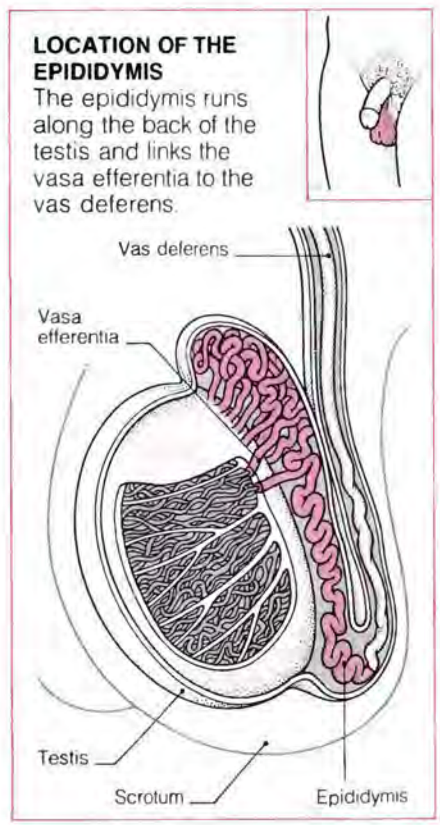
CAUSES AND OUTLOOK

The condition is caused by a genetic defect that may show either an autosomal dominant or autosomal recessive pattern of inheritance (see *Genetic disorders*). It is diagnosed by skin *biopsy* (removal of a small amount of skin for microscopic analysis).

No special treatment for the condition is available, although injury to the skin should be avoided and simple protective measures should be taken to prevent rubbing of affected areas when blisters appear.

The outlook varies from a gradual improvement in mild cases of epidermolysis bullosa to progressive serious disease in the most severe cases.

Parents of affected children should obtain *genetic counseling* so that the risks of any future children being affected can be calculated.



Epididymal cyst

A harmless swelling, usually painless, that may develop in the upper rear part of a testicle. Small cysts are very common in men over the age of 40 and need no treatment. Rarely, they may become tender or may enlarge and become uncomfortable, in which case it may be necessary to remove the cysts surgically.

Epididymis

A long, coiled tube connecting the vasa efferentia (small tubes leading from the testicle) to the vas deferens (the sperm duct leading to the urethra). Sperm cells produced in the testicle pass slowly along the epididymis, maturing there until they are capable of fertilizing an egg. They are then stored in the seminal vesicles until *ejaculation*.

Disorders affecting the epididymis include *epididymo-orchitis* (inflammation of the epididymis and testicle) and *epididymal cysts* (fluid-filled swellings). Infection or injury can block the epididymis; if this occurs in both testicles, it can cause infertility.

LOCATION OF THE EPIDIDYMIS
The epididymis runs along the back of the testis and links the vasa efferentia to the vas deferens.

Epididymitis

See *Epididymo-orchitis.*

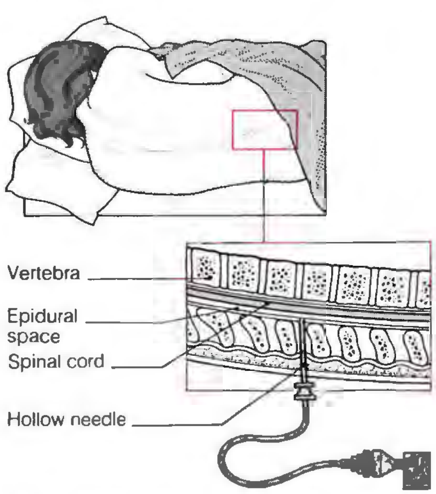
Epididymo-orchitis

Acute inflammation of a testicle and its associated epididymis (the coiled tube that carries sperm away from it) characterized by severe pain and

swelling at the back of the testicle and accompanied by swelling and redness of the scrotum in severe cases.

The inflammation is caused by infection. Often there is no obvious source of infection, but sometimes the cause is a bacterial infection spread from the urinary tract via the vas deferens (sperm duct). Rarely, epididymo-orchitis occurs through spread of a tuberculosis infection.

DIAGNOSIS AND TREATMENT



The symptoms of severe pain and swelling are similar to those of torsion of the testicle, in which the testicle cord becomes twisted and blocks its own blood supply (see *Testis, torsion of*). An exploratory operation may be necessary to make a firm diagnosis and save the testicle. In some cases testicular scans may be helpful.

Treatment is with antibiotics and rest. If there is an underlying urinary tract infection, its cause is investigated. The tuberculous form of the disease usually responds to treatment given for tuberculosis elsewhere in the body. In all cases it may take several months for the testicle to return to its normal size. Sometimes normal size is never attained. (See also *Orchitis*.)

Epidural anesthesia

A method of pain relief for surgery in which local anesthetic is injected into the epidural space in the middle and lower back to numb the nerves leading to the chest and the lower half of the body. Epidural anesthesia may be combined with a light general anesthesia. Usually a catheter (a flexible, fine tube) is introduced into the epidural space to allow further anesthetic doses to be given as necessary without more needle puncture.

Epidural *analgesia* is pain relief achieved by injecting narcotics or dilute local anesthetic solutions into the epidural space. Its applications include postoperative analgesia, pain relief during childbirth, and the control of cancer pain that is unresponsive to all other measures.

Administering an epidural anesthetic
The anesthetic is injected into the epidural space (the region surrounding the spinal cord within the spinal canal).

Epiglottiditis

A rare but serious and sometimes fatal infection that mainly affects children between 2 and 6. Caused by the bacterium HEMOPHILUS INFLUENZAE, it results in sudden inflammation and swelling of the epiglottis (the flap of cartilage at the back of the tongue that closes off the windpipe during swallowing). The swollen epiglottis obstructs breathing. If the condition is not recognized and treated promptly, it can cause death by suffocation.

SYMPTOMS

The illness comes on suddenly. The child becomes feverish, breathing becomes noisy (stridor), swallowing is painful, and the child drools because he or she cannot swallow saliva. Breathing becomes increasingly difficult and the child prefers to sit upright in an attempt to make breathing easier. Within a few hours of the onset of the illness, the child may become semiconscious and cyanotic (bluish) due to lack of oxygen.

DIAGNOSIS AND TREATMENT

The symptoms and signs of epiglottiditis resemble those of *croup* (inflammation of the airways); expert assessment by an experienced pediatrician may be necessary to distinguish between them. For this reason, any child who becomes feverish and in whom noisy breathing develops should be seen by a physician as soon as possible. If he or she suspects epiglottiditis, the child will be admitted to a hospital. In the hospital, neck X rays are usually taken to help confirm the diagnosis. A tube is almost always passed through the nose or mouth and into the trachea so breathing can be maintained; often a ventilator is needed. Intravenous antibiotics (usually ampicillin and/or chloramphenicol) are needed to cure the infection. With prompt treatment the prognosis is good; recovery usually takes place within two weeks.

The bacterium H. INFLUENZAE is highly contagious; family members should be screened or treated with antibiotics to prevent its spread.

Epiglottis

The flap of cartilage lying behind the tongue and in front of the entrance to the larynx (voice box). At rest, the epiglottis is upright and allows air to pass through the larynx and into the rest of the respiratory system. During swallowing it folds back to cover the entrance to the larynx, preventing food and drink from being inhaled.

Epilepsy

A tendency to recurrent seizures or temporary alteration in one or more brain functions.

Seizures are defined as transient neurological abnormalities caused by abnormal electrical activity in the brain. Human activities, thoughts, perceptions, and emotions are normally the result of the regulated and orderly electrical excitation of nerve cells in the brain. During a seizure, a chaotic and unregulated electrical discharge occurs. In some cases, a stimulus such as a flashing light sets off this abnormal sequence, but often seizures appear spontaneously.

CAUSES

Seizures are a symptom of brain dysfunction and, like symptoms in other parts of the body, can result from a wide variety of disease or injury. Seizures may occur in association with *head injury*, birth trauma, brain infection (such as *meningitis* or *encephalitis*), *brain tumor*, *stroke*, drug intoxication, drug or alcohol withdrawal states, or metabolic imbalance in the body. A tendency to seizures may develop for no obvious reason or there may be an inherited predisposition.

INCIDENCE

About one person in 200 suffers from epilepsy. The number of epileptics in the US is estimated to be close to 1 million. The disorder usually starts in childhood or adolescence. Many people outgrow epilepsy and do not require medication.

TYPES AND SYMPTOMS

Epileptic seizures can be classified into two broad groups—generalized and partial seizures. The form a seizure takes depends on the part of the brain in which it arises and on how widely and rapidly it fans out from its point of origin. Generalized seizures, which cause loss of consciousness, affect the whole body and may arise over a wide area of the brain. *Temporal lobe epilepsy* is a type of partial seizure. Partial seizures, in which consciousness may be retained, are usually caused by damage to a more limited area of the brain. Though partial seizures begin

in a limited area, the electrical disturbance may spread and affect the whole brain, causing a generalized seizure.

Many people with epilepsy lead normal lives and have no symptoms between seizures. Some can tell when an attack is imminent by experiencing an aura (a restless, irritable, or uncomfortable feeling).

GENERALIZED SEIZURES

There are two main types of generalized seizure—grand mal and petit mal (absence) seizures.

GRAND MAL During a grand mal seizure the person falls down unconscious and the entire body stiffens and then twitches or jerks uncontrollably. There may be an initial cry; breathing is then absent or very irregular during the seizure. Following the seizure, the muscles relax, and bowel and bladder control may be lost. The person may feel confused and disoriented and perhaps have a headache; often he or she will want to sleep. These effects usually clear in several hours. The person usually has no memory of the event. Prolonged seizures, referred to as status epilepticus, can be fatal without emergency treatment.

ABSENCE SEIZURES These seizures, in which there is a momentary loss of consciousness without abnormal movements, occur mainly in children. There is a blank period lasting from a few seconds to up to half a minute or so, during which the sufferer is unaware of anything. To the onlooker, it may appear that the person is simply daydreaming or inattentive, and the attack may even pass unnoticed. Absence seizures may occur hundreds of times daily and can markedly impair school performance.

PARTIAL SEIZURES

Partial seizures are divided into simple seizures (in which consciousness is maintained) and complex seizures (in which it is lost). In simple partial seizures an abnormal twitching movement, tingling sensation, or even hallucination of smell, vision, or taste, occurs without warning and lasts several minutes. When the twitching occurs and spreads slowly from one part of the body to another on the same side, it is referred to as jacksonian epilepsy. Sufferers retain awareness during the event and can recall the details.

During complex partial seizures, the person becomes dazed and may not respond if addressed. Sometimes involuntary actions, such as fumbling with buttons or lip smacking, occur. These actions are called automatisms and can (rarely) take more bizarre forms. The person typically remembers little, if any, of the event.

Both types of partial seizure can sometimes spread to involve the entire brain, in which case generalization is said to have occurred. The symptoms then become the same as those of a grand mal seizure.

PREVENTION

Many epileptics experience seizures at times of extreme fatigue or stress. Infectious illnesses, especially if fever is present, also lower the seizure threshold. By avoiding these situations and taking prescribed medication regularly, epileptics can reduce seizure frequency. Occasionally, epileptics discover a distracting technique that can abort a seizure once the aura has begun.

DIAGNOSIS

In making the diagnosis, the physician seeks as much information as possible about the attacks. Since patients frequently do not have recall, information may be obtained from witnesses. After a complete neurological examination, the physician usually orders an *EEG* to help with the diagnosis. It is important to realize that the EEG cannot always absolutely confirm or refute the diagnosis of seizures, and that the results must be weighed in light of other clinical findings. Sometimes tests of heart function (such as an *ECG* or *Holter monitor*) are obtained to exclude cardiac irregularities as a cause of loss of consciousness in an adult. Patients thought to have seizures are usually given *CT scanning* of the brain and *blood tests* to check for the conditions associated with epilepsy. Opinion is divided on whether a single seizure should be treated; physicians agree that people with recurrent seizures should take *anticonvulsant drugs*.

TREATMENT

Anticonvulsant drugs are the first line of treatment for epilepsy, and, in almost all cases, they lessen the frequency of seizures. The drugs may have unpleasant side effects, including drowsiness and impaired concentration. The physician will attempt to find the one drug that works best, but, with very severe epilepsy, a combination may be needed to control seizures. If no seizures occur for two to three years (depending on their cause), the physician may suggest reducing or stopping drug treatment.

Rarely, surgery may be considered if it is thought that a single area of brain damage (usually in the temporal lobe) is causing the seizures and medication is ineffective.

> **FIRST AID: EPILEPTIC SEIZURE**
>
> **DO NOT**
> - restrain the victim or place anything in the mouth
> - attempt to move the victim unless he or she is in danger of further injury
>
> 1 Carefully loosen tight clothing around the neck.
>
> 2 When the attack is over, place the victim in the *recovery position* and allow him or her to regain consciousness.

OUTLOOK

If epilepsy develops during childhood and there is a strong family history of the disease, the chances are good that the problem will decrease after adolescence; it may even disappear altogether. However, seizure control is likely to be more difficult in temporal lobe epilepsy or if the disorder has been brought about by severe brain damage.

One third of those in whom epilepsy develops eventually grow out of the condition and experience no further seizures. Another third find that the seizures become less frequent in response to drug treatment. The conditions of the remaining third remain the same.

Sufferers from epilepsy usually are able to work, but the disorder may limit their choice of jobs. There are restrictions on obtaining a driver's license (generally an applicant is required to have been seizure-free for several years). It is advisable, unless the seizures are very well controlled, to avoid high-risk jobs involving heights or dangerous machinery and sports such as skiing.

Many epileptics carry a special card, tag, or bracelet that states they have epilepsy. Epileptics are recommended to advise colleagues on what to do if a seizure occurs.

DEALING WITH AN EPILEPTIC SEIZURE

Most major epileptic seizures last only a minute or two and demand little of the bystander. All that is necessary is to let the attack run its course and to ensure that the person is in no physical danger and can breathe while he or she is unconscious.

The person should not be held down, nor should his or her movements be restrained. Any tight clothing around the neck should be loosened and something soft should be placed beneath the head. The mouth should not be forced open and no object should be wedged between the teeth. Once the convulsions have ceased, the victim should be put into the *recovery position*.

An ambulance should be called if the seizure continues for more than five minutes, if another seizure immediately follows the first one, or if consciousness is not regained a few minutes after the epileptic seizure has come to end.

Epiloia

See *Tuberous sclerosis*.

Epinephrine

ALLERGY BRONCHODILATOR
GLAUCOMA DECONGESTANT

Injection Inhaler Eye drops Nose drops

Prescription needed

Available as generic

A naturally occurring hormone, also called adrenaline. Epinephrine has been produced synthetically as a drug since 1900.

Epinephrine is one of two chemicals (the other is *norepinephrine*) released by the adrenal gland in response to signals from the sympathetic division of the *autonomic nervous system*. These signals are triggered by stress, exercise, or by an emotion such as fear.

Epinephrine increases the speed and force of the heart beat and thereby the work that can be done by the heart. It dilates the airways to improve breathing and narrows blood vessels in the skin and intestine so that an increased flow of blood reaches the muscles, allowing them to cope with the demands of exercise.

USE AS A DRUG

Epinephrine is sometimes given by injection as an emergency treatment for *cardiac arrest* (stopped heart beat) and is used to treat *anaphylactic shock* (a severe allergic reaction) and acute *asthma* attacks.

During surgery, it is injected into tissues to reduce bleeding. When combined with a local anesthetic, epinephrine prolongs the effect by slowing down the rate at which the anesthetic spreads into the surrounding tissues.

Epinephrine eye drops are used to treat *glaucoma* and they are used during eye surgery because they reduce pressure in the eyeball. Epinephrine is also used to stop nosebleeds and reduce *nasal congestion*.

POSSIBLE ADVERSE EFFECTS

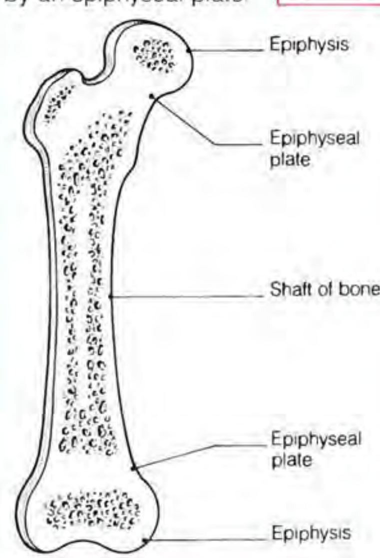
Regular use of epinephrine as eye drops may cause a burning pain and, occasionally, blurred vision or pigment deposits on the eye's surface.

In nose-drop form, epinephrine may cause palpitations, restlessness, and nervousness; newer *decongestant drugs* are now usually preferred.

Epiphora

See *Watering eye*.

Epiphysis



Either of the two growing ends of the long bones (femur, tibia, humerus, ulna, radius, and fibula) of the limbs. The epiphysis is separated from the diaphysis (shaft of the bone) by a layer of cartilage, called the epiphyseal plate or growth plate.

During childhood and adolescence, bones grow as the result of *ossification*, a process in which cartilage cells multiply and absorb calcium to develop into bone. In this way, the cartilage in the epiphyseal plate is gradually replaced by new bone.

LOCATION OF THE EPIPHYSIS

Each epiphysis is situated at the ends of the long bones of the body and is separated from the shaft of the bone by an epiphyseal plate.

Epiphysis, slipped

See *Femoral epiphysis, slipped*.

Episcleritis

A localized patch of inflammation affecting the outermost layers of the sclera (the white of the eye) immediately under the conjunctiva (outer covering layer of the eye).

Episcleritis usually occurs for no known reason and usually affects middle-aged men. It may be a complication of rheumatoid arthritis. The purplish patch of inflammation is oval, slightly raised, and only a fraction of an inch across. It may cause a deep, dull, aching pain that tends to be worse at night. During the day there may be photophobia.

The condition usually disappears by itself within a week or two but may recur. Symptoms may be relieved by corticosteroid eye drops or ointment.

Episiotomy

A surgical procedure in which an incision is made in the perineum (the tissue between the vagina and the anus) to facilitate the delivery of a baby. After delivery, the cut tissues are stitched back together.

WHY IT IS DONE

Episiotomy is used to enlarge the vaginal opening. Some medical practitioners advocate its use almost routinely on the theory that a surgical cut will heal better than a tear, and that women who have had episiotomies will experience less "vaginal relaxation" (stretching of the vagina) later in life. Other practitioners rarely perform episiotomies on the theory that the naturally elastic vagina should not have to be cut to allow a normal delivery, and that small tears cause less damage and pain than does an episiotomy.

If the perineum fails to stretch up over the baby's head and/or a large perineal tear looks likely, an episiotomy is advisable. It prevents a ragged tear that is more painful, more difficult to repair, and more easily leads to complications. When the woman has had a previous vaginal repair (for *prolapse* of the uterus or urinary incontinence), an episiotomy prevents damage to the repair by increasing the size of the vaginal opening. Episiotomy is usually necessary in forceps deliveries because the instruments occupy additional space in the vaginal opening; it is likewise necessary in a breech delivery, when there is little opportunity for gradual stretching of the perineal tissues to occur.

Indications for episiotomy that concern the baby directly include *fetal distress* (when the baby is not receiving enough oxygen during labor), because episiotomy speeds delivery. An episiotomy also reduces pressure on the head of a premature baby.

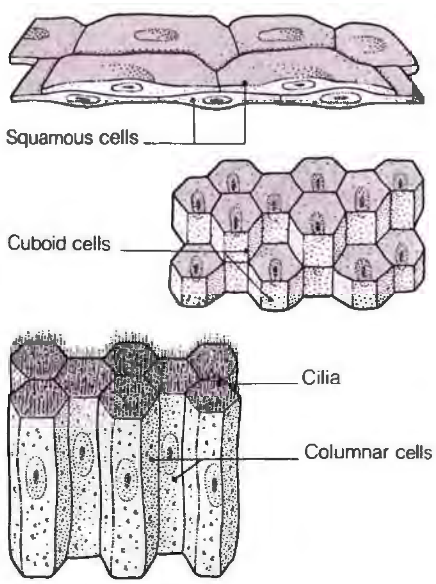
HOW IT IS DONE
As the baby's head descends through the maternal pelvis and begins to distend the perineum, local anesthetic is injected into the area (unless the woman has already been given an epidural or another anesthetic).

Scissors or a scalpel are used to make a cut extending from the back wall of the vagina through the perineal skin and muscles. This cut may be directed to the side of the anus (mediolateral) or in a direct vertical line with the anus (midline).

HOW IT IS REPAIRED
An episiotomy is usually repaired shortly after delivery of the baby. The woman lies on her back with her feet in stirrups. The perineum is thoroughly cleaned and more local anesthetic is injected if necessary. The vagina is then inspected to assess the size of the incision and to see whether further tears have occurred. The wound is repaired in layers, usually with absorbable sutures.

RECOVERY PERIOD
The woman can walk as soon as she wishes. Perineal washes and/or showers are advised. Occasionally, ice packs and analgesics are required. Care is taken to avoid constipation. The sutures dissolve after about 10 days (if catgut is used) and thus do not require removal. In most cases, healing is straightforward. Discomfort in the scar is sometimes noted for up to three months.

Epispadias
A rare congenital abnormality in which the opening of the urethra is not in the glans (head) of the penis, but on the upper surface of the penis. The penis may also curve upward.



Surgery is carried out in infancy, using tissue from the foreskin to reconstruct the urethra and to create a penis that will allow satisfactory sexual intercourse in adult life. Sometimes more than one operation is needed to correct the condition.

Epistaxis
The medical term for a *nosebleed*.

Epithelium
The cells, occurring in one or more layers, that cover the entire surface of the body and that line most of the hollow structures within it. (The blood vessels, lymph vessels, and the inside of the heart are lined with *endothelium*, and the chest and abdominal cavities are lined with mesothelium.)

Epithelium varies in cell type and thickness of layer according to the function it performs. There are three basic cell shapes: squamous (thin and flat), cuboidal, and columnar. These structures may vary further. In the respiratory tract, for example, epithelial cells bear whiplike filaments called cilia that propel dust particles from inhaled air back up the tracheobronchial tree.

Most internal organs lined with epithelium are covered with only one layer of cells, but the skin, which is subjected to more trauma, consists of many layers with a dead outer layer of cells that is constantly being shed.

Types of epithelium
The cells of the epithelium vary in shape and size according to function. The three basic types are squamous, cuboidal, and columnar.

Epstein-Barr virus
A virus that causes infectious *mononucleosis* and is associated with *Burkitt's lymphoma* and nasopharyngeal cancer.

ERCP
The abbreviation for endoscopic retrograde cholangiopancreatography, an X-ray procedure for examining the biliary system and the pancreatic duct. It is used mainly when *ultrasound scanning* or *CT scanning* fails to provide a sufficiently detailed image.

HOW IT IS DONE
ERCP is usually an outpatient procedure and takes 20 to 40 minutes. No food or drink is taken for eight hours before the examination. A sedative and a local anesthetic of the throat are usually given.

An *endoscope* (a flexible viewing tube with a lens and light attached) is passed down the esophagus, through the stomach, and into the duodenum (the upper part of the small intestine). After identifying the ampulla of Vater (the entrance within the duodenum to both the common bile duct and the pancreatic duct), the endoscope operator passes a catheter (fine, flexible tube) through the endoscope and into the ampulla. He or she then passes a radiopaque dye (one that shows up on X-ray film) through the catheter to fill the pancreatic duct and all the ducts of the biliary system. X-ray pictures are then taken to show any abnormalities in the ducts.

If disease is detected, it can sometimes be treated at the same time. For example, stones obstructing the lower end of the common bile duct can be removed by using an attachment on the endoscope to widen the duct. If there is a suspected tumor at the ampulla, the endoscope can be used to perform a *biopsy* (removal of a small sample of tissue for analysis) and/or brushing of cells for cytologic examination (see *Cytology*).

Erection
Hardness, swelling, and elevation of the *penis*. Usually caused by sexual arousal or physical stimulation, it also occurs regularly during sleep and may occur for no obvious reason in very young boys.

The penis contains three cylinders of erectile tissue with a network of blood vessels controlled by the spinal nerves. During an erection, the penis becomes filled with blood as the vessels dilate (widen) to allow increased blood flow. Muscles around the vessels contract and prevent blood from leaving to maintain the erection.

Erection, disorders of
Conditions in which there is total or partial failure to attain or maintain erection (see *Impotence*), persistent erection without any sexual desire (see *Priapism*), or a painfully bowed erection (see *Chordee*).

Ergocalciferol
An alternative name for vitamin D_2 (see *Vitamin D*), also called calciferol.

Ergometer

A machine that measures the amount of physical work done and the body's response to a controlled amount of exercise. It makes continuous recordings, during and immediately after activity, of heart rate and rhythm (using an *ECG*), blood pressure, the rate of breathing, and the volume of oxygen that is taken up from the surrounding air.

The physician-supervised exercise is done on a fixed bicycle, rowing machine, or treadmill, and the effort required is adjusted to suit the particular test being performed. In *fitness testing*, the exercise is vigorous enough to require maximum effort; in a *cardiac stress test*, the exercise is adjusted to a level sufficient to produce a certain predetermined level of heart rate. Symptoms that occur during the exercise, such as chest pain, breathing difficulty, or a fall in blood pressure, terminate the test.

Ergonovine

A drug that is injected after childbirth or termination of pregnancy to control the loss of blood from the uterus. Ergonovine works by causing the muscles of the uterus to contract, which compresses the blood vessels and thus reduces bleeding.

If blood loss remains heavy after the injection and there is no underlying cause (such as a retained placenta or infection) requiring treatment, ergonovine may be prescribed as a tablet for one or two days to help control bleeding.

Ergot

A product of *CLAVICEPS PURPUREA*, a fungus that grows on rye and other grains. Ergot contains several *alkaloids* (nitrogen-containing substances) with medicinal and poisonous effects.

The most important drugs produced from ergot are *ergotamine*, used to treat migraine, and *ergonovine*, used to control blood loss from the uterus following childbirth or an abortion.

Before it was known that ergot was a poison, bread made with contaminated rye caused outbreaks of ergot poisoning. The effects included gangrene of the toes and fingers, seizures, mental disorders, and, in some cases, death.

Ergotamine

A drug used in the prevention and treatment of *migraine*. It works by constricting the dilated blood vessels surrounding the brain and is used as an alternative to *analgesics* (painkillers).

Ergotamine is most effective if taken during the very early warning stages of a migraine attack. Once the headache and nausea of migraine are present, it is less likely to be effective and may even increase the nausea.

Erosion, dental

Loss of enamel from the surface of a tooth as a result of attack by chemicals or acids, such as from gastric juices brought through the mouth in vomiting or from tobacco juice. The first sign of enamel loss is a dull, frosted appearance. As the condition progresses, smooth, shiny, shallow cavities form.

Erosion affecting the outer surfaces of the front teeth is most often caused by excessive consumption of citrus fruits, fruit juices, or carbonated drinks; it also sometimes occurs in workers using acid in industrial processes (such as battery construction). Erosion that mainly affects the inner surfaces of the molar teeth may be caused by frequent regurgitation of acidic fluid from the stomach—for example, in people suffering from *acid reflux* or *bulimia*.

Erosion may be combined with, and also accelerate, *abrasion* (mechanical wearing away of teeth) and attrition (wearing down of the chewing surfaces), leading to extensive damage to many teeth.

Eroticism

A state of sexual excitement. People are usually most easily stimulated by thoughts, but this stimulation may be augmented by touching of the erogenous zones—the breasts, genitals, mouth, and anus. Sexual arousal can also be produced by a variety of other sensations and stimuli (i.e., the look and feel of certain clothes, the scent of a perfume, or the sound of a piece of music).

In *psychoanalytic theory*, eroticism (named for Eros, the Greek god of physical love) is contrasted with *narcissism* (self love). Eroticism is a mature love that can be fulfilled only when the loved one is also satisfied. Narcissism is typical of immature personalities and is a love that merely wishes to satisfy itself.

Eruption

Breaking out or appearing, as in the development of a skin rash or the appearance of a new tooth.

Eruption of teeth

The process by which developing *teeth* move through the bone of the jaws and the covering gum to project into the mouth.

DECIDUOUS DENTITION

Deciduous (primary) teeth (the milk teeth) usually begin to appear at around 6 months of age, with the lower front teeth erupting first, but the timing may vary. Occasionally a baby is born with one or two of these teeth already visible, while in other babies no teeth appear until about 9 months of age. All 20 deciduous teeth usually erupt by age 3. Infants may suffer a mild general upset at the time of eruption (see *Teething*).

PERMANENT DENTITION

Permanent teeth (the secondary teeth) generally begin erupting at 6 years. The first permanent molars erupt toward the back of the mouth, behind the existing deciduous teeth rather than replacing any of them. Children and parents are often unaware that these are permanent teeth. The later eruption of permanent teeth nearer the front of the mouth is preceded by reabsorption of the roots of the deciduous teeth, which become loose and detach. The succeeding permanent tooth emerges a few weeks after its deciduous predecessor falls out. Wisdom teeth (the last molar teeth) usually erupt between the ages of 17 and 21, but in some people never appear. Frequently, wisdom teeth are impacted (blocked from erupting) because of lack of available space in the jawbone (see *Impaction, dental*).

Erysipelas

An infection of the face caused by streptococcal bacteria, which are thought to enter the skin through a small wound or sore. Young children and elderly people are the groups mainly affected.

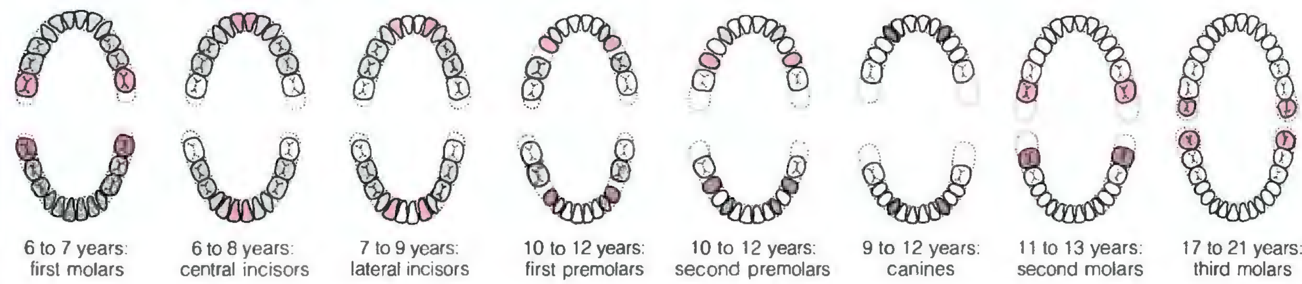
SYMPTOMS AND TREATMENT

The disorder starts abruptly with malaise, fever, headaches, and vomiting. Itchy, red patches appear on the face and spread across the cheeks and bridge of the nose to form an inflamed area with raised edges. Within this area, pimples develop that first blister, then burst, and then crust over.

Treatment is with penicillin, which usually clears the condition within a week. (See also *Cellulitis*.)

Erythema

Redness of the skin. Disorders of which skin redness is one symptom include *erythema multiforme*, *erythema*



TOOTH ERUPTION

The top diagrams show the approximate ages at which particular deciduous teeth usually appear. The ages at which specific types of permanent teeth usually appear are shown in the lower diagrams. Red denotes erupting teeth; gray denotes erupted deciduous teeth; white denotes erupted permanent teeth.

Deciduous teeth
The full deciduous set (left) consists of eight incisors, four canines, and eight molars. They usually start erupting at 6 months.

Permanent teeth
The full set of permanent teeth (below) consists of eight incisors, four canines, eight premolars, and 12 molars.

nodosum, *lupus erythematosus*, and erythema infectiosum (*fifth disease*).

Facial erythema can have many causes, including *blushing*, *hot flashes*, *sunburn*, raised temperature, and skin conditions such as *acne*, *dermatitis*, *eczema*, *erysipelas*, *rosacea*, and *urticaria* (hives).

Erythema ab igne

Red skin that may also be dry and itchy, caused by exposure to strong direct heat. It occurs most commonly in elderly women—on the shins, as the result of sitting too close to a fireplace in cold weather, or on the abdomen, due to hugging a heating pad or a hot-water bottle.

Dryness and itching of the skin can often be relieved by an *emollient* (soothing cream). The redness usually fades in time, although it rarely disappears completely.

Erythema infectiosum

See *Fifth disease*.

Erythema multiforme

An acute inflammation of the skin, and sometimes of the internal mucous membranes (the thin moist tissue that lines bodily cavities). Erythema multiforme is sometimes accompanied by generalized illness. Erythema multiforme means literally "skin redness of many varieties."

CAUSES AND INCIDENCE

The disease can occur as a reaction to certain drugs (including penicillin, sulfonamides, salicylates, and barbiturates), or may accompany certain viral infections (including cold sores) or bacterial infections (such as streptococcal throat infection). Pregnancy, vaccination, and radiation therapy are other possible causes. However, half of all cases occur for no apparent reason. The disease is most common in children and young women.

SYMPTOMS

A symmetrical rash of red, often itchy spots, similar to the rash of measles, erupts on the limbs and sometimes on the face and the rest of the body. The spots may blister or may progress to urticaria (hives), in which there are raised, red, pale-centered wheals. Those affected may have fever, sore throat, headache, and/or diarrhea.

The rash of erythema multiforme
The spots of this rash are usually itchy and have a bull's-eye appearance, with concentric rings of different shades of red around a pale center.

In a severe form of erythema multiforme, called Stevens-Johnson syndrome, the mucous membranes of the mouth, eyes, and genitals become inflamed and ulcerated.

TREATMENT

If treatment for some other disorder is believed to be the cause of the erythema, the treatment will be withdrawn. Similarly, any possible causative illness will be treated. Corticosteroid drugs are sometimes given to reduce inflammation and irritation. Patients suffering from Stevens-Johnson syndrome are given analgesics (painkillers), plenty of fluids (sometimes intravenously), sedatives, and sometimes corticosteroid drugs.

Erythema multiforme usually clears within five to six weeks, although it may recur. The Stevens-Johnson syndrome normally responds to treatment, but in some cases the patient may become seriously ill as a result of shock or of inflammation spreading within the body.

Erythema nodosum

A condition characterized by an eruption of red-purple swellings on the

legs in association with another illness. It is most common between the ages of 20 and 50 and affects women more than men.

CAUSES AND INCIDENCE

The most common cause of erythema nodosum is a throat infection with streptococcal bacteria, but it is also associated with other diseases, most commonly *tuberculosis* and *sarcoidosis*, and may occur as a reaction to certain drugs, including sulfonamides, penicillin, and salicylates. In about one third of cases of erythema nodosum no cause can be discovered.

SYMPTOMS AND TREATMENT

The swellings, which range from 0.5 to 4 inches in diameter, are shiny and tender and occur on the shins, thighs, and, less commonly, the arms. They are usually accompanied by fever and joint and muscle pains.

Effective treatment of any underlying condition clears the swellings. Otherwise, the only treatment that is necessary is bed rest, analgesics (painkillers), and, occasionally, *corticosteroid drugs* to reduce inflammation. The condition usually subsides within a month.

Erythrocyte

The medical name for a red blood cell. See *Blood cells*.

Erythroderma

See *Exfoliative dermatitis*.

Erythromycin

ANTIBIOTIC

Tablet Capsule Liquid Injection Ointment

Prescription needed

Available as generic

A drug used to treat infections of the skin, chest, throat, and ears. Erythromycin is particularly useful in the treatment of *pertussis* (whooping cough) and *legionnaires' disease*. In children under 8 years old, this drug is a useful alternative to tetracycline, an antibiotic that can cause permanent staining of developing teeth.

Erythromycin is destroyed by the acid in the stomach. To overcome this problem, the drug is prepared as a specially coated tablet or as compounds, such as erythromycin estolate and erythromycin stearate, which are more resistant to acid.

POSSIBLE ADVERSE EFFECTS

Adverse effects include nausea, vomiting, abdominal pain, diarrhea, and an itchy rash. Certain brands of erythromycin can be taken with food to reduce the likelihood of irritation of the stomach.

Eschar

A scab on the surface of the skin formed to cover damage caused by a burn, abrasion, severe scratching, or some skin diseases and infections.

Esmarch's bandage

A broad, rubber bandage wrapped around the elevated limb of a patient to force blood out of the blood vessels toward the heart; this enables surgery to be performed more easily in a blood-free area. The Esmarch's bandage is wrapped from the toes or fingers upward, and a pneumatic (inflatable) tourniquet is then applied to the thigh or upper arm to stop blood from returning to the limb. The Esmarch's bandage is removed, leaving the inflated tourniquet in position during surgery.

Esophageal atresia

A rare birth defect caused by a failure of the esophagus to form correctly during embryonic development. A short section of the esophagus is absent, so that its upper part comes to a dead end, and the upward projection of the esophagus from the stomach is also blind-ending. In most cases, there is also an abnormal channel (known as a *tracheoesophageal fistula*) between one of these sections of esophagus and the trachea (windpipe). This abnormality occurs in about one live-born baby in 3,500.

SYMPTOMS, DIAGNOSIS, AND TREATMENT

The infant cannot swallow saliva or milk, and continuous regurgitation from the mouth occurs. If there is an upper tracheoesophageal fistula, milk may be sucked into the lungs; as a result, attempts at feeding provoke attacks of coughing and cyanosis (a blue-purple skin coloration).

A soft tube inserted into the nose can normally be passed down the esophagus; in cases of esophageal atresia, it cannot be passed. The diagnosis is confirmed by a chest X ray.

Immediate surgery is necessary. Using a general anesthetic, the baby's chest is opened, the blind ends of the esophagus are joined, and any tracheoesophageal fistula is closed.

Complications can be prevented by skilled nursing care. Some affected babies do not survive, but usually the operation is successful and the baby is able to lead a normal, healthy life.

Esophageal dilatation

Stretching of the esophagus after it has become narrowed by disease (see *Esophageal stricture*), which prevents normal swallowing. The usual cause of the narrowing is swelling and scarring from *esophagitis* (inflammation of the esophagus), but the narrowing may also be due to cancer (see *Esophagus, cancer of*) or *achalasia* (inability of the muscles in the lower esophagus to relax).

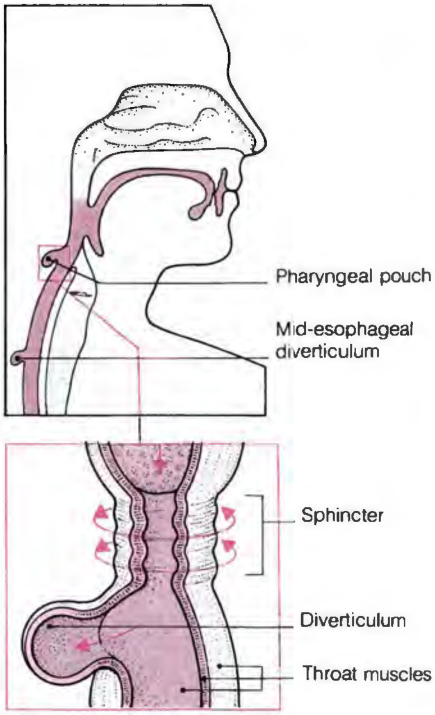
HOW IT IS DONE

The patient must not eat for at least eight hours before the esophageal dilatation, which is usually carried out under sedation.

First, an *endoscope* (a fine, flexible viewing tube) is passed through the mouth and down the esophagus to permit identification of the obstruction. The patient then swallows a length of thread, which anchors in the intestine, and a metal guide is passed over the string.

The next step is to pass a series of *bougies* (cylindrical rods with olive-shaped tips) of increasing size down over the guide wire to stretch the narrowed area. Bougies are being replaced by the *balloon catheter* (a fine tube with a balloon at the end). After being inflated, the balloon is kept in position for three minutes, then deflated and withdrawn; the same procedure is repeated later with a larger balloon. Guide wires are not always used with balloons.

Esophageal diverticulum



A saclike outward protrusion of part of the wall of the esophagus.

TYPES

There are two types of esophageal diverticulum—a pharyngeal pouch (Zenker's or pulsion diverticulum) and a mid-esophageal diverticulum (traction diverticulum).

PHARYNGEAL POUCH This type lies at the top of the esophagus, at its entrance from the pharynx (throat). It usually projects backward. The cause is a failure of the sphincter (circular muscle) at the entrance to the esophagus to relax during the act of swallowing, due to muscular incoordination. Instead, the sphincter resists the passage of food. As the powerful throat muscles used for swallowing work against this resistance, part of the lining of the esophagus is forced through the esophageal wall, thus forming the diverticulum.

Once the diverticulum is formed, it gradually enlarges, and food becomes trapped in it, causing irritation,

Location of esophageal diverticulum
The pharyngeal pouch forms at the top of the esophagus as a reaction to the sphincter's failure to relax during swallowing. The usually symptomless mid-esophageal diverticulum is a pouch that forms further down the esophagus.

difficulty swallowing, *halitosis* (bad breath), and regurgitation. The diagnosis is made by an *esophagogram* and the diverticulum is treated by removal after the surgeon has made an incision in the neck. The sphincter muscle is partly cut at the same time to weaken it and prevent recurrence.

MID-ESOPHAGEAL DIVERTICULUM This disorder consists of a pouch formed further down the esophagus. It rarely causes symptoms and usually requires no treatment.

Esophageal spasm

Uncoordinated contractions of the muscles in the esophagus that fail to propel food effectively down into the stomach. The contractions may be caused by some other esophageal disorder, such as reflux *esophagitis*, but in many cases they occur for no apparent reason. Women are affected more often than men. Pain is felt in the chest or upper abdomen and there is difficulty swallowing, but symptoms are intermittent and do not worsen.

An *esophagogram* will show the irregular contractions of the esophagus and, along with *endoscopy* (passage of a viewing tube down the esophagus) and esophageal *manometry*, can rule out the possibility of a more serious condition, such as a cancer. There is no treatment unless an underlying cause, such as esophagitis, can be treated.

Esophageal stricture

Narrowing of the esophagus, which may cause swallowing difficulty.

CAUSES AND SYMPTOMS

Narrowing may be due to a cancer (see *Esophagus, cancer of*) or to any of numerous noncancerous causes. These include persistent reflux *esophagitis*, in which constant irritation from gastric acid causes inflammation and swelling followed by the formation of fibrous scar tissue and narrowing. Prolonged use of a *nasogastric tube* may inflame the esophagus, leading to a stricture, as may the accidental swallowing of a corrosive liquid.

The symptoms of a stricture are difficulty swallowing, pain, weight loss, and regurgitation of food.

DIAGNOSIS AND TREATMENT

A barium swallow (see *Barium X-ray examinations*) shows a smooth narrowing of the esophagus. *Endoscopy* (passage of a viewing tube down the esophagus) is used to look at the narrowed area, and a *biopsy* (removal of a small piece of tissue for analysis) is performed to exclude cancer.

In most cases, the narrowed area is widened by *esophageal dilatation*. In cases of very severe narrowing over a long segment of the esophagus (usually due to swallowing corrosives), the affected area may require surgical removal. A loop of colon may be substituted for the removed section, or the ends of the esophagus may be joined and the stomach brought up into the chest. These operations are rarely required.

Patients too old or frail for surgery may be treated by the insertion of a soft, pliable, plastic tube through the stricture or by a feeding *gastrostomy*.

Esophageal varices

Dilated, incompetent veins in the walls of the lower part of the esophagus and, at times, the upper part of the stomach. They arise as a consequence of *portal hypertension* (increased blood pressure in the portal vein due to liver disease). Blood passing from the intestines to the liver via the portal vein meets increased resistance and is instead diverted through the veins in the walls of the esophagus and stomach, where the pressure causes the veins to balloon outward.

SYMPTOMS, DIAGNOSIS, AND TREATMENT

The affected veins are thin-walled and contain blood at high pressure; they may rupture, causing recurrent episodes of torrential hematemesis (vomiting of blood) and melena (tarry, black feces). Most patients also have other symptoms of chronic liver disease.

Endoscopy (passage of a viewing tube down the esophagus) or a barium swallow (see *Barium X-ray examinations*) shows the affected veins bulging from the esophageal walls.

Acute bleeding may be controlled by means of a specially designed *balloon catheter*, which is passed into the esophagus and stomach; the balloon is blown up to press on the bleeding varices. Later, the varices may be treated with intravenous pitressin and/or by injection of a sclerosant—a solution that clots the blood and permanently hardens and seals off the affected veins. Surgery may be performed to lower the pressure in the blood supply to the liver. Recurrent bleeding can also sometimes be controlled by drugs such as propranolol.

Esophagitis

Inflammation of the esophagus.

TYPES

There are two main types—corrosive esophagitis, caused by the swallowing of caustic chemicals (acid or lye) accidentally or in a suicide attempt, and reflux esophagitis, caused by regurgitation of the stomach contents into the esophagus.

CORROSIVE ESOPHAGITIS The severity of the inflammation depends on the amount, concentration, and type of caustic chemical swallowed. Chemicals likely to cause very severe corrosive esophagitis include cleaning or disinfectant solutions.

Immediately after swallowing such a chemical, there is severe pain with *shock* and *edema* (swelling) in the throat and mouth. Antidotes are of limited value and gastric lavage (washing out the stomach) must be avoided as this may only increase the damage. Treatment consists mainly of reducing pain and providing nursing care until the esophagus heals. Sometimes a severe *esophageal stricture* (narrowing of the esophagus) develops, requiring prolonged dilatation and/or extensive surgery later.

REFLUX ESOPHAGITIS This is a very common condition. The cause is poor function of the musculature of the lower esophageal segment, which permits reflux of the stomach's con-

tents. Poor lower esophageal segment function may be associated with a *hiatal hernia*, in which the top part of the stomach slides back and forth between the chest and the abdomen. Symptoms may be worsened by alcohol, smoking, and obesity.

The stomach content is usually acid but, after certain operations, such as partial *gastrectomy*, the stomach contains bile. If this bile flows backward into the esophagus, it causes an alkaline type of esophagitis, which tends to be more severe and difficult to treat. Severe, chronic esophagitis can cause an esophageal stricture.

The main symptom of reflux esophagitis is heartburn—a burning pain in the chest—which worsens on bending over.

Barrett's esophagus is a complication of reflux esophagitis in which stomach lining is found in the esophagus. It may lead to cancer.

DIAGNOSIS AND TREATMENT

A barium swallow (see *Barium X-ray examinations*) will show reflux of stomach contents, and *endoscopy* (passage of a viewing tube down the esophagus) will show inflammation. In doubtful cases, special tests may be required. A small tube may be swallowed and a probe positioned in the lower esophagus to record the acidity over a 24-hour period; alternatively, a dilute acid solution may be introduced into the stomach to see if it reproduces the symptoms.

The treatment for most cases of persistent esophagitis is for the sufferer to change his or her life-style—to reduce weight and alcohol consumption, stop smoking, and avoid heavy meals. *Antacid drugs* may be given to reduce the acidity of the stomach contents. Elevation of the head of the bed with blocks may be employed. Sometimes, surgical treatment may be needed for a hiatal hernia.

Esophagogastroscopy

See *Gastroscopy*.

Esophagogram

A type of barium swallow of the esophagus (see *Barium X-ray examinations*) that is documented by still or motion X-ray films. The films show alterations in function and motility (muscular activity) of the esophagus. In addition, the pictures can reveal structural anatomic disorders such as a tumor, stricture, ulcer, diverticulum, or hernia. (See also *Esophagus, cancer of; Hiatal hernia; Esophageal diverticulum.*)

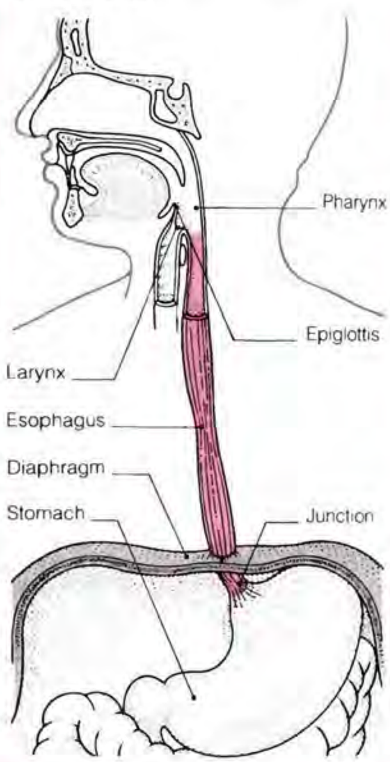
Esophagoscopy

Examination of the esophagus by means of an *endoscope*, a thin, flexible viewing instrument with a light and lenses attached. (See *Gastroscopy*.)

Esophagus

The muscular tube that carries food from the throat to the stomach.

STRUCTURE



The top end of the esophagus is the narrowest part of the entire digestive tract and is encircled by a sphincter (circular muscle) that is normally closed but can open to allow the passage of food. There is a similar sphincter at the point where the esophagus enters the stomach. The walls of the esophagus consist of strong muscle fibers arranged in bundles, some circular and others longitudinal. The inner lining of the esophagus consists of smooth, squamous epithelium (flattened cells).

FUNCTION

The esophagus acts as a conduit by which liquids and food (once it has been chewed) are conveyed to the stomach and intestines for digestion. Food is propelled downward toward the stomach by a peristaltic action, powerful waves of contractions passing through the muscles in the esophageal wall. Gravity plays little part in getting food into the stomach—making it possible to drink while upside down. (See also *Swallowing*.)

ANATOMY OF THE ESOPHAGUS

A muscular tube that propels food to the stomach from the throat. The upper and lower ends are bounded by sphincters – muscular valves that open to allow food to pass through.

Esophagus, cancer of

A malignant tumor of the esophagus, which ultimately causes difficulty in swallowing. Most esophageal cancers develop in the middle or lower sections of the esophagus.

CAUSES AND INCIDENCE

The causes of esophageal cancer are mainly unknown, but a high alcohol consumption and smoking are thought to play a role.

The incidence varies throughout the world, but there are about seven to 10 new cases diagnosed per 100,000 population in the US each year, mainly in people over 50. The cancer is more common in men than women and more common in blacks than whites. There is a particularly high incidence in parts of the Far East and Iran, where the cancer is linked to chemicals in certain foods.

SYMPTOMS

Difficulty in swallowing is noticed first with solids and later with fluids (even saliva) and becomes progressively worse. If food cannot pass it is immediately regurgitated. Rapid weight loss occurs, but no pain develops until the cancer is well advanced. Respiratory infections are common, because regurgitated fluid spills over into the trachea.

DIAGNOSIS

A barium swallow (see *Barium X-ray examinations*) can indicate the site and often the nature of the obstruction of the esophagus. Definite diagnosis is provided by examination of a *biopsy* sample (small piece of tissue) obtained through an *endoscope* (viewing tube with a tissue-collecting attachment).

TREATMENT AND OUTLOOK

Esophagectomy (removal of the esophagus) provides the best hope of cure but is a major undertaking. Incisions are made in the abdomen, chest, and sometimes in the neck. Most of the esophagus is then removed and the stomach or sometimes a portion of the colon is pulled up into the chest and joined to the upper esophagus.

For older patients who might not survive this operation, *radiation therapy*, sometimes combined with

DISORDERS OF THE ESOPHAGUS

Despite its apparently simple structure, the esophagus is prone to a number of disorders, most of which lead to difficulty, or completely prevent, swallowing and/or cause a pain in the chest.

CONGENITAL DEFECTS

Esophageal atresia is an absence from birth of a section of the esophagus, with the remaining sections ending in dead ends. It requires urgent surgical correction. Rarely, babies are born with weblike constrictions of the esophagus. These are rarely serious enough to require treatment, but may, if necessary, be broken down with a rubber dilator.

INFECTION AND INFLAMMATION

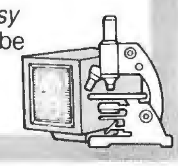
Infections of the esophagus are uncommon, but can occur in severely immunosuppressed patients whose defenses against infection are weakened. The most common infections are *herpes simplex* infection or *candidiasis* (thrush) extending downward from the mouth. Both cause pain on swallowing.

Esophagitis (inflammation of the esophagus) is usually due to reflux of the contents of the stomach, causing heartburn (a burning sensation in the chest). A more severe form—corrosive esophagitis—can occur as a result of swallowing caustic chemicals. Either of these types of esophagitis may lead to formation of an *esophageal stricture* (narrowing of the esophagus).

INJURY

Apart from the damaging effects of swallowing corrosive chemicals, the most common cause of injury to the esophagus is severe vomiting and retching, which occasionally tear the esophageal lining (and result in bleeding) or in extreme cases lead to rupture. A hard, swallowed *foreign body* can also cause injury and sometimes perforation if it lodges in the esophageal wall.

TUMORS



Tumors of the esophagus are not rare. About 90 percent are malignant (see *Esophagus, cancer of*); the remainder are benign. With both types, the initial symptom is usually difficulty swallowing.

OTHER DISORDERS

An *esophageal diverticulum* is an outwardly protruding sac, formed usually at the top end of the esophagus, in which food may collect and cause halitosis (bad breath) and sometimes difficulty swallowing. *Esophageal spasm* consists of uncoordinated and uncontrollable contractions of the esophagus, which may make swallowing difficult. In *achalasia*, the sphincter muscle at the junction between esophagus and stomach fails to relax to allow the passage of food, causing pain on swallowing and sometimes regurgitation of food. (See also *Swallowing difficulty*.)

INVESTIGATION

Esophageal disorders are investigated by barium swallow (see *Barium X-ray examinations*) and by *endoscopy*. Occasionally, a *biopsy* (tissue sample) may be taken for pathologic examination.

chemotherapy (particularly cisplatin), can sometimes provide a significant regression of the cancer, relief from symptoms, and even an occasional cure. Some relief from starvation can also be achieved by intubation—the insertion of a rigid tube through the tumor to allow swallowing of liquid or semiliquid food.

The overall outlook is poor, with only about 5 percent of patients surviving for five years; if the cancer is diagnosed early, the outlook is better.

Esotropia

Convergent squint, or "cross-eye," in which only one eye looks directly at the object while the other turns inward. (See also *Strabismus*.)

ESR

The abbreviation for erythrocyte sedimentation rate, measurement of the rate at which red blood cells sink toward the bottom of a test tube. Because the ESR is increased in certain disorders, it is a useful aid to diagnosis and can also be used to monitor the effect of treatment.

HOW IT IS DONE

Whole blood from the patient is mixed with anticoagulant (which prevents the blood from clotting) in a test tube and left undisturbed at a constant temperature for one hour.

The red blood cells, which can be seen as a dark red clump, settle toward the bottom of the tube, leaving the clear, straw-colored plasma at the top. The ESR is the number of millimeters the red cells fall in one hour.

RESULTS

The ESR is high when the red cells are sticky due to abnormal levels of fibrinogen or *globulins* (types of protein) in the blood. Globulins are usually produced in response to serious infection, inflammation of blood vessels (as in *temporal arteritis*), and some types of cancer, such as *myeloma*. Fibrinogen is produced in response to inflammation.

Estradiol

ESTROGEN

Tablet Injection Cream

Prescription needed

Available as generic

The most important of the *estrogen hormones* (female sex hormones). They are essential for the healthy functioning of the reproductive system and for breast development.

In its synthetic form, estradiol is prescribed as a tablet to treat symptoms of the *menopause* (see *Hormone replacement therapy*), to treat *osteoporosis*, and to stimulate sexual development in *hypogonadism* (underdeveloped ovaries). Estradiol is also prescribed as a cream to treat atrophic *vaginitis* (dryness of the vagina).

Estriol

One of the *estrogen hormones* (female sex hormones).

Estrogen drugs

COMMON DRUGS

Conjugated estrogens Diethylstilbestrol Dienestrol Estradiol Estrone Ethinyl estradiol

WARNING

Tobacco smoking while taking estrogen drugs significantly increases the risk of abnormal blood clotting, which may cause myocardial infarction, pulmonary embolism, or stroke.

A group of drugs produced synthetically for use in the birth-control pill (see *Oral contraceptives*) and to supplement or replace the naturally occurring estrogen hormones in the body (see *Ovary*). Estrogen drugs are often used in conjunction with *progesterone drugs*.

Estrogens suppress the production of *gonadotropin hormones* (hormones that stimulate cell activity in the ovaries). High doses of estrogens may be given as postcoital contraception (see *Contraception, postcoital*).

Synthetic estrogens are used to treat, and in some cases to prevent, symptoms and disorders related to the *menopause*, including atrophic *vaginitis* (dryness of the vagina) and *osteoporosis* (a bone disorder).

Estrogens may also be used to treat certain forms of infertility, *hypogonadism* (underdeveloped ovaries), menstrual disorders in which there is abnormal bleeding from the uterus, prostate cancer, and certain types of breast cancer.

POSSIBLE ADVERSE EFFECTS

Estrogen drugs may cause breast tenderness and enlargement, bloating, weight gain, nausea, reduced sex drive, depression, migraine, and bleeding between periods. Side effects often settle after two or three months, but, if they persist or are troublesome, a different estrogen drug may be prescribed. Vaginal creams containing estrogen should be used sparingly and usually only for a short time to reduce the risk of adverse effects throughout the body.

Estrogen drugs increase the risk of abnormal blood clotting and are therefore not recommended for people with a history (or family history) of *stroke*, *pulmonary embolism*, or deep-vein *thrombosis*, or for people about to undergo surgery. Estrogen drugs may increase a person's susceptibility to *hypertension* (high blood pressure) and are not usually prescribed if a person has suffered from this disorder in the past. Estrogens should not be taken during pregnancy as they may adversely affect the fetus.

Estrogen hormones

A group of hormones essential for normal female sexual development and for the healthy functioning of the reproductive system. In women, they are produced mainly in the ovaries. Estrogen hormones are also formed in the placenta during pregnancy and, in both men and women, in small amounts in the adrenal glands. In men, estrogens have no known specific function. (See also *Ovary*.)

Estrone

One of the *estrogen hormones*. Estrone is also prepared synthetically and given by injection or as a tablet in the treatment of symptoms of the menopause (see *Hormone replacement therapy*) and osteoporosis. It is also prescribed as a cream for the treatment of atrophic *vaginitis* (dryness of the vagina).

ESWL

Extracorporeal shock wave lithotripsy. See *Lithotripsy*.

Ethambutol

A drug used in conjunction with other drugs in the treatment of *tuberculosis*. Ethambutol rarely causes side effects, although occasionally it may cause inflammation of the optic nerve, resulting in blurred vision.

Ethanol

The chemical name for the *alcohol* in alcoholic drinks; it is also sometimes called ethyl alcohol.

Ether

The first general anesthetic. Ether was commonly used for surgery until the 1930s, but has now largely been replaced by other anesthetic agents. Ether (full name, diethyl ether) is a colorless liquid administered on a gauze mask placed over the patient's nose and mouth. When inhaled, ether fumes produce unconsciousness.

Ether is among the safest of all anesthetics, but it is so flammable that even static electricity can cause it to explode. Ether has therefore been superseded by other agents (see *Anesthesia, general*), although these require more skill to administer.

Ethical drug

A drug that requires a physician's prescription for purchase.

Ethics, medical

A code of behavior that addresses the relationships between the patient and physician, and among physicians.

The characteristic that distinguishes a profession, such as medicine, from a trade, such as repairing automobiles, is that the members establish and maintain standards of training, competence, and professional behavior. These standards are enforced by professional organizations, such as the American Medical Association, which has a Council on Ethical and Judicial Affairs.

Traditionally, medical ethics covers a wide range of behavior, including the physician's involvement with patients and their families, and his or her competence, public image, and commercial behavior.

Physicians must not abuse the relationship of trust they develop with patients. In particular, they must not enter into sexual relationships with patients and they must maintain in confidence information learned from patients. They must give clear priority to their patients' interests.

Physicians are expected to maintain their skills and to update their knowledge to the standard of their colleagues. They should not refer patients to unlicensed practitioners of alternative medicine. Fees should conform to recognized schedules; all forms of fee splitting or rebates are unacceptable. In addition, it is against ethical standards for a physician to be dependent on alcohol or drugs.

The physician should ensure that the patient not only consents to all procedures, investigations, and treatments, but that this consent is based on an unbiased and full explanation of any risks, drawbacks, and alternatives that might be considered.

Any time a patient is asked to enroll in a research study, the investigator should see that consent is full and free, and that patients do not feel pressured to agree because of a sense of gratitude owed to the physician for previous treatment. Research on children or on patients with mental handicap should, in general, be considered only when there is a reasonable prospect that the person concerned will benefit from the investigation and that the risks and any discomfort inherent in the research are minimal.

Ethical considerations are also important in the care of the dying, in termination of pregnancy, in the care of children born with major physical and mental handicaps, and in the care of patients with mental disorders.

Ethinyl estradiol

ESTROGEN

Tablet

Prescription needed

Not available as generic

A synthetic form of the female sex hormone estradiol. It is most commonly used in *oral contraceptives*, where it is combined with a *progesterone drug*.

Ethinyl estradiol is also prescribed to stimulate sexual development in female *hypogonadism* (underdeveloped ovaries) and in the treatment of symptoms caused by the *menopause*, such as hot flashes and sweating (see *Hormone replacement therapy*). It is also used to treat menstrual disorders.

Ethosuximide
An *anticonvulsant drug* used to treat petit mal (a form of *epilepsy*). Ethosuximide is often prescribed in preference to other anticonvulsant drugs because, unlike some of them, it rarely causes drowsiness or liver damage. Ethosuximide may, however, cause nausea and vomiting and in rare cases affects the production of blood cells in the bone marrow and causes aplastic anemia (see *Anemia, aplastic*).

Ethyl alcohol
Another name for ethanol, the *alcohol* in alcoholic drinks.

Ethyl chloride
A colorless, flammable liquid once used as a general anesthetic and now as a local anesthetic.

WHY IT IS USED

Applied to the skin as a spray, ethyl chloride quickly evaporates and, as a result, makes the skin feel so cold that any pain or irritation is reduced. It may be used to numb an area of skin before a minor surgical procedure, such as lancing a boil, and is sometimes used to alleviate the pain that arises from sprained or strained muscles or ligaments.

Ethyl chloride is also used in the treatment of *larva migrans*, a hookworm infection acquired from cats and dogs. (See also *Anesthetics, local*.)

Etiology
The study of the causes of disease. In some cases a specific cause may be found. For example, the cause of *meningitis* may be identified as tuberculosis bacillus after examining a sample of cerebrospinal fluid under a microscope. Many disorders have a multifactorial etiology. The causative factors of degenerative arthritis, for example, include genetic susceptibility, being overweight, and repeated joint injuries. Many disorders, such as osteoarthritis and cancer of the intestine, are of unknown etiology.

Eunuch
A man whose testicles have been removed or destroyed so that he is sterile. The term was used especially to describe boys who were castrated before puberty to preserve their high-pitched singing voices or to make them suitable for guarding harems. A male castrated before puberty has eunuchoid body proportions (i.e., undeveloped male secondary sexual characteristics with a small penis, sparse body hair, broad hips, narrow shoulders, and a feminine distribution of body hair).

Euphoria
A state of confident well-being. A normal reaction to personal success, it can also be induced by drugs.

Feelings of euphoria with no rational cause may indicate the presence of brain disease or damage caused by *head injury* (particularly damage to the frontal lobes), *dementia*, *brain tumors*, or *multiple sclerosis*. In these cases, the euphoria results from the victim's general lack of awareness.

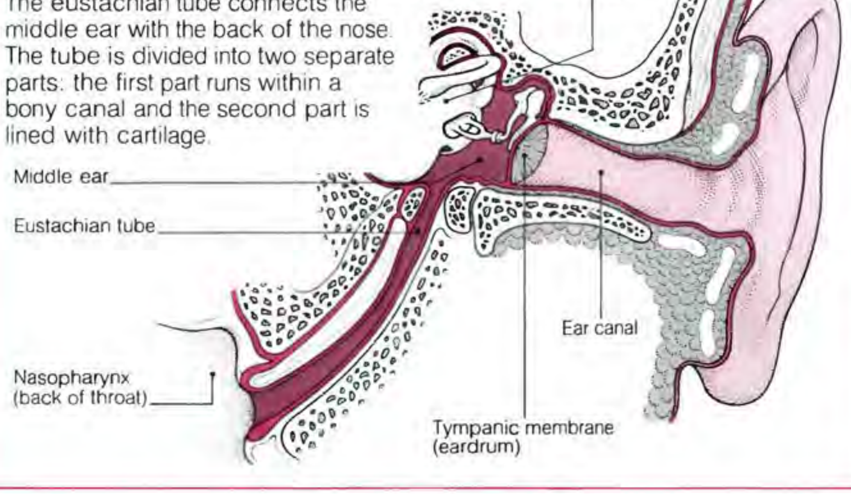
Eustachian tube
The passage that connects the middle ear and the back of the nose. It acts as a drainage passage from the middle ear and maintains hearing by opening periodically to regulate air pressure.

STRUCTURE

The tube is about 1.33 inches (36 mm) long in an adult. From the middle ear it runs forward, downward, and in toward the middle of the head; it ends in the space at the back of the nose just above the soft *palate* (part of the roof of the mouth). A smooth, wet, mucous membrane lines the tube.

FUNCTION

The lower end of the eustachian tube opens during swallowing and yawning, thus allowing air to flow up to the middle ear and equalizing air pressure on both sides of the eardrum. If a change in external pressure is large and rapid, pressure may build up on one side of the eardrum, pushing it inward or outward; this is uncomfortable and dulls hearing. Most people have experienced this sensation when taking off in a plane (reduced pressure) or going into a tunnel in a car or train (increased pressure). Symptoms can usually be relieved by swallowing hard to open the tube.



A person with a blocked eustachian tube who is subjected to rapid changes in pressure may suffer from *barotrauma* (pressure damage to the eardrum or other structures).

When a head cold blocks the eustachian tube, equalization cannot occur, which may cause severe pain. Because the displaced eardrum cannot vibrate properly, hearing may be temporarily impaired.

DISORDERS

Persistent *middle-ear effusion* (chronic accumulation of secretions in the middle ear) or chronic *otitis media* (middle-ear infection) may occur if the eustachian tube becomes blocked, preventing adequate drainage from the middle ear. These conditions, which often cause partial hearing loss, are more common in children because their adenoids are larger and more likely to block the tube if they become infected. Children's eustachian tubes are shorter, making it easier for bacteria to travel from infected areas in the throat to the middle ear.

ANATOMY OF THE EUSTACHIAN TUBE
The eustachian tube connects the middle ear with the back of the nose. The tube is divided into two separate parts: the first part runs within a bony canal and the second part is lined with cartilage.

E

Euthanasia

The act of killing a person painlessly to relieve suffering. Even when it is requested by a patient with incurable disease, euthanasia (the literal meaning is "easy death") is against the law in most Western countries. There are groups attempting to change the law to allow patients to ask physicians to give a fatal dose of drugs.

Euthanasia is distinct from nonintervention, which is the physician's recognition that, if a patient has an advanced or incurable disease, he or she has a right to refuse medical treatment that would simply prolong the process of dying.

Euthyroid

The term used to describe a person whose *thyroid gland* is functioning normally, or to describe a person who has been successfully treated for *hypothyroidism* (underactive thyroid) or *hyperthyroidism* (overactive thyroid) so that the gland functions normally.

Eversion

A turning outward. The term is commonly applied to a type of ankle injury or deformity in which the foot is turned outward.

Evoked responses

The tracing of electrical activity in the brain in response to a specific external stimulus. The responses are much smaller than the impulses recorded by electroencephalography (see *EEG*) and are a refinement of that technique. Evoked responses were first demonstrated in 1947. Today, with the increased sophistication of computerized electronic technology, it is a widely used diagnostic tool.

WHY IT IS DONE

The functioning of various sensory systems—for example, sight, hearing, and touch—can be checked by this technique. The information obtained can be used to reveal abnormalities in the system caused by inflammation, pressure from a tumor, or other pathological changes, and to confirm the diagnosis of *multiple sclerosis*. The test is extremely sensitive and can often pinpoint the location of a fault.

HOW IT IS DONE

The method for testing each sensory system is similar, painless, and takes 30 to 60 minutes, depending on whether more than one system is being assessed.

A set of small disk electrodes is attached to the scalp in the same way as in electroencephalography. The electrodes are attached to different parts of the scalp, depending on which sensory system is being tested. The output from the brain is linked to a computer, which produces a printout after a specific period of stimulation (e.g., 100 flashes from a light).

Analysis is based on the time lapse between stimulus and response; the computer is used to extract this information from the background brain activity that shows up on an EEG.

For testing the visual system, a series of flashes from a stroboscopic light may be used. An example of a more demanding stimulus for the brain, which gives more consistent results, is a board made up of black and white squares constructed so that the colors alternate every second.

To test hearing, the ears are subjected to different sounds. To test touch and pain sensations, small electrical stimuli are applied, for example, to a nerve at the wrist.

RESULTS

This test does not necessarily give an unequivocal diagnosis and is used as a supplement to other tests of the nervous system (e.g., EEG or *EMG*), other investigations, and radiological tests such as *CT scanning*.

Ewing's sarcoma

A rare malignant tumor of bone. The sarcoma (cancer of connective tissue) arises in a large bone, most commonly the femur (thigh bone), tibia (shin), humerus (upper arm bone), or one of the pelvic bones, and spreads to other parts of the body at an early stage.

The condition is most common in children between 10 and 15; it affects twice as many boys as girls and is rarely seen in black children.

SYMPTOMS

The affected bone is painful and tender and part of it may swell. It may also become weakened and fracture easily (called a pathologic fracture). Other possible symptoms include weight loss, fever, and anemia.

DIAGNOSIS

The sarcoma is diagnosed by X rays and a bone *biopsy* (removal of a small piece of bone for analysis). If cancer is found, the complete skeleton is examined by X rays and *radionuclide scanning*, and the lungs by *CT scanning*, to determine if, and how far, the cancer has spread. Spreading by the time of diagnosis is found in 15 to 20 percent of cases.

TREATMENT

Treatment is by *radiation therapy* and *chemotherapy*. Before the introduction of chemotherapy, death usually occurred within two to three years of diagnosis. Today, the chances of survival have improved considerably; 65 percent of those affected are still alive five years after diagnosis and most of those remain well.

Examination, physical

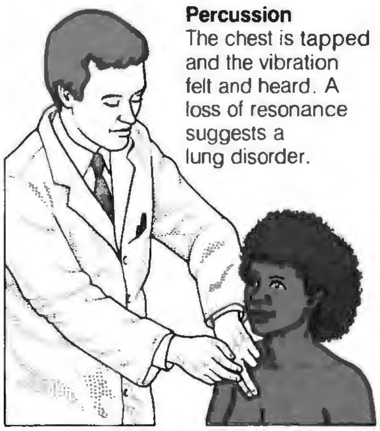
The inspection, palpation, percussion, and auscultation of the various body parts and organs. Physical examination is the second stage of most medical consultations; it follows history-taking, in which the physician listens to the patient's complaints and then asks questions. Aside from history-taking, the physical examination is the physician's most important means of making a diagnosis or of finding the clues that aid him or her in selecting the appropriate diagnostic studies. If there are generalized symptoms, such as loss of energy, the physician examines the patient's entire body. The physician also performs a complete physical examination during the patient's initial visit and usually annually thereafter. Examination may be limited to a certain part of the body (such as when a patient has a localized injury).

Excision

Surgical cutting out of diseased tissue from surrounding healthy tissue, such as the removal of a breast lump or gangrenous skin.

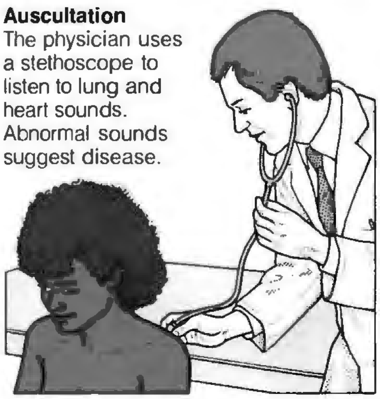
Excoriation

Injury to the surface of the skin or of a mucous membrane (the thin, moist tissue that lines parts of the body, such as the mouth) caused by physical abrasion (such as scratching) or chemical action. The loss of surface cells causes a raw area to develop. (See also *Ulcer*.)



Excretion

The discharge of waste material from the body. To maintain health, the body must dispose of the by-products of digestion (such as food residues and an excess of salt or other substances), waste products from the repair of body tissues, medication or its breakdown products, poisonous substances, and water (to maintain the correct volume of fluid and to remove solid wastes in solution).



ORGANS OF EXCRETION

The *kidneys* excrete excess nitrogen in the urine in the form of urea, along with excess water, salts, some acids, and most prescribed drugs.

TYPES OF PHYSICAL EXAMINATION
Examination may include looking for skin changes and feeling organs for size, consistency, and shape. Assessment is made of muscle strength, coordination, joint mobility, and skin sensation. The state of the eyes, ears, mouth, throat, and teeth is checked.

Percussion
The chest is tapped and the vibration felt and heard. A loss of resonance suggests a lung disorder.

Auscultation
The physician uses a stethoscope to listen to lung and heart sounds. Abnormal sounds suggest disease.

Tendon reflexes
One test of the nervous system is to tap a stretched tendon. If the reflex is normal, the muscle should contract.

The *liver* excretes bile, which, as well as containing salts that help emulsify fats in the small intestine, consists of waste products and bile pigments formed from the breakdown of red blood cells. Part of the bile is passed from the body in the feces, which it colors brown.

The large *intestine* excretes undigested food, some salts, and some excess water in the form of feces.

The *lungs* discharge carbon dioxide and water vapor into the atmosphere.

Sweat glands excrete salt and water onto the surface of the skin as a method of regulating the body's temperature.

Exenteration
The surgical removal of all organs and soft tissue in a body cavity in the hope of arresting a cancerous process. Exenteration is an operation that is occasionally performed for cancer in the orbit (the bony structure surrounding the eye) or the pelvis.

Exercise
The performance of any physical activity that improves health or that is used for recreation or correction of physical injury or deformity (see *Physical therapy*). Different types of exercise affect the body in one or more of the following ways: some improve flexibility, some improve muscular strength, some improve physical endurance, and some improve the efficiency of the cardiovascular and respiratory systems. (See illustrated box, next page.)

BENEFITS OF EXERCISE
There is an established association between high levels of aerobic exercise and low incidence of *coronary heart disease*. Regular exercise usually leads to a reduction in blood pressure. It also increases the amount of high-density lipoprotein in the blood, which is thought to help protect against *atherosclerosis* (fat deposits in arteries) and *myocardial infarction* (heart attack). Exercise has also been shown to be valuable in relieving the symptoms of peripheral vascular disease and of some psychological disorders such as depression.

Vigorous work with a muscle or a group of muscles, even if it is of short duration, leads to an increase in the size, strength, and possibly the number of the muscle cells, and an increase in the strength of their ligamentous attachment to bones. Improving the strength of muscles in the back and abdomen can help prevent or ease lower back pain. The increased strength of the muscles and tendons is also an insurance against damage due to an unexpected strain.

Elderly people are especially inclined to become inactive and lose joint mobility. Regular, gentle, rhythmic movements can help maintain the range of movement of important joints. Coordination and balance deteriorate with age; exercise helps maintain muscle strength and reduce the risk of falls. (See also *Aerobics; Fitness; Fitness testing*.)

Exfoliation
Flaking off, shedding, or peeling from a surface in scales or thin layers, as in *exfoliative dermatitis*.

Exfoliative dermatitis
Inflammation, marked redness, and scaling of the skin of most of the body, also called erythroderma.

Exfoliative dermatitis may be the result of a drug reaction (an allergic response to a particular drug) or may be caused by the worsening of a skin condition, such as *psoriasis* or *eczema*. Sometimes, exfoliative dermatitis occurs in *lymphoma* and *leukemia*.

There is a widespread rash with severe flaking of the skin. The loss of surface skin, with exposure of its deeper layers, results in increased loss of water and protein from the body surface. Water loss may result in a rise in body temperature; protein loss may cause *edema* (a buildup of fluid in tissues) and muscle wasting. Further complications are infection and *heart failure* (reduced pumping efficiency of the heart).

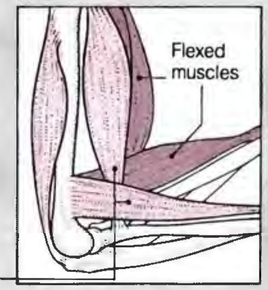
The treatment and outlook depend on the cause. About 60 percent of sufferers recover within two to three months, but about 30 percent die as a result of complications; in the remainder the disease takes a chronic form unresponsive to treatment.

Exhibitionism
The habit of deliberately exposing the genitals to strangers.

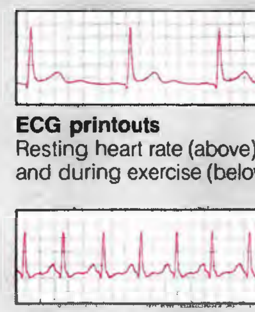
This form of behavior is almost always confined to men. The exhibitionist displays his penis to a female passerby, usually in a secluded spot (such as a side street) or from a car or house window with the aim of surprising or frightening the victim.

In 80 percent of cases, a single court appearance puts an end to the exhibitionist's behavior. *Psychotherapy* can help those who relapse; the outlook is poor for persistent offenders.

THE EFFECTS OF EXERCISE



There are many changes in different body organs during exercise. Muscles require an increase in blood flow because of their greater energy requirements; the heart and lungs work faster and more efficiently. These changes are controlled by the release of the chemicals epinephrine and norepinephrine from the sympathetic nervous system.



The lungs
The rate and depth of breathing increase to ensure sufficient flow of oxygen from the lungs into the blood. This also aids in the removal of additional carbon dioxide produced by muscle cells during exercise.

The joints
Regular exercise helps maintain the mobility of joints. Increased strength in the muscles and tendons around joints makes them more resistant to injury.

The muscles
There is a rise in the chemical activity within muscle cells. The rate of consumption of oxygen and glucose increases.

The heart and circulation
The heart beats more rapidly and more powerfully to provide an increased flow of blood to the working muscles. Blood vessels in the stomach and beneath the skin are narrowed to compensate for the increased requirements of the muscles.

ECG printouts
Resting heart rate (above) and during exercise (below).

COMMON TYPES OF EXERCISE

Aerobic

Exercise in which the body continuously needs to take in additional oxygen to meet the muscles' increased demands. Regular aerobic exercise improves the performance of the cardiovascular and respiratory systems. Jogging, swimming, and cycling are examples of aerobic exercise.

Isometric

Exercise without movement in which one group of muscles exerts pressure against an immovable object or an opposing group of muscles. It is an effective means of increasing muscle strength, but does not exercise the cardiovascular system or aid in muscular endurance.

Isotonic

Exercise with movement in which muscle tension remains more or less constant and the body works against its own weight or against external weights. Isotonic exercise includes weight training and calisthenics (repetitious movements with little or no equipment). Isotonic exercise increases muscle strength, size, and endurance.

Isokinetic

Isokinetic exercise involves both isotonic and isometric exercise. The muscles move reasonably heavy loads, but are also put through their full range of movement. Isokinetics combines strength training with some aerobic exercise, but requires special equipment.

Exocrine gland

A gland that secretes substances through a duct onto the inner surface of an organ or onto the outer surface of the body. Examples include the *salivary glands*, which release saliva into the mouth, *lacrimal* glands, which release tears, and *sweat glands*. The release of exocrine secretions can be triggered by a hormone or by a neurotransmitter, released by nerve endings. (See also *Endocrine gland*.)

Exomphalos

A rare birth defect in which a part of the intestines, covered by a thin membrane, protrudes through the umbilicus (navel). In mild cases only one or two loops of intestine protrude, but in severe cases most of the abdominal organs are exposed.

Also called omphalocele, exomphalos is associated with other birth defects, especially *anencephaly*. Many babies with the condition are stillborn or die soon after birth. Exomphalos is treated by surgery.

Exophthalmos

Protrusion of one or both eyeballs caused by a swelling of the soft tissue in the bony orbit (eye socket). The eyeball is pressed forward, exposing an abnormally large amount of the front of the eye, forcing the eyelids apart and causing a staring appearance.

CAUSE

The most common cause of exophthalmos is *thyrotoxicosis* (overactive thyroid gland). Other causes include an *eye tumor*, an *aneurysm* (swelling of an artery) behind the eye, or inflammation of eye tissues; in these cases only one eye is affected.

SYMPTOMS AND SIGNS

Exophthalmos may restrict eye movement and cause double vision. In severe cases, the pressure in the orbit

Appearance of exophthalmos
An affected eye protrudes markedly compared with a normal eye. In most cases, both eyes are affected.

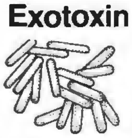
may be so high that the blood supply to the optic nerve may be restricted; blindness results. The lids may be prevented from closing, and vision may become seriously blurred due to drying of the cornea.

TREATMENT AND OUTLOOK

In thyroid exophthalmos, treatment of the thyroid disorder may sometimes relieve the exophthalmos, but often it does not. Early treatment usually returns the vision to normal. Surgery to decompress the orbit may be required to relieve pressure on the optic nerve.

Exostosis

A type of benign *bone tumor* in which there is an outgrowth of bone. It occurs most commonly at the end of the femur (thigh bone) or tibia (shin).



Exostoses account for 90 percent of all bone tumors; they affect twice as many men as women. In about 65 percent of cases the condition is due to hereditary factors; another cause is prolonged pressure on a bone.

SYMPTOMS AND TREATMENT

In most cases, exostosis produces no symptoms and goes unnoticed. Often it is recognized (as a hard swelling) only after an injury. Occasionally the bony outgrowth presses on a nerve, causing pain or weakness in the affected area (usually when it is beneath a fingernail or toenail).

A preliminary diagnosis of the condition is confirmed by X ray. Treatment may be by surgical removal of the growth, but usually surgery is performed only if the exostosis causes symptoms or is unsightly.

Exotoxin

A poison released by some types of bacteria into the bloodstream, from where it causes widespread effects throughout the body. Exotoxins are among the most poisonous substances known. They are produced by bacteria such as tetanus bacilli, which enter the body through a wound and produce an exotoxin that affects the nervous system to cause muscle spasms (lockjaw) and paralysis, and diphtheria bacilli, which initially infect the throat, but release an exotoxin that damages the heart and nervous system.

Immunization with vaccines consisting of detoxified exotoxins can prevent dangerous symptoms from bacterial diseases that are potentially fatal due to the effects of exotoxins. If such an infection occurs, treatment usually includes antibiotics and an antitoxin to neutralize the exotoxin. (See also *Endotoxin*; *Enterotoxin*.)

Exotropia

Divergent squint, in which one eye is used for detailed vision; the other is directed outward. (See *Strabismus*.)

Expectorants

A group of *cough remedies* used to promote the coughing up of phlegm.

Expectoration

The coughing up and spitting out of sputum (phlegm). See also *Cough*.

Expiration

The act of breathing out air from the lungs. See *Breathing*.

Exploratory surgery

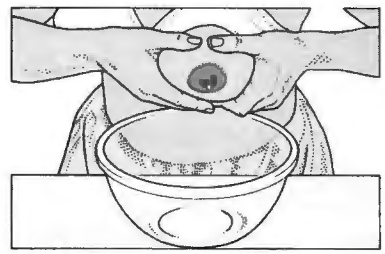
Any operation to investigate or thoroughly examine part of the body to discover the extent of known disease or to establish a diagnosis. Exploratory thoracotomy is performed on the chest and exploratory laparotomy on the abdomen.

Explosive disorder

A mental condition characterized by uncontrolled violent behavior that is completely out of proportion to any known cause. There may be several separate acts of aggression or a single violent outburst; in any case, the resulting damage to people or property may be very serious.

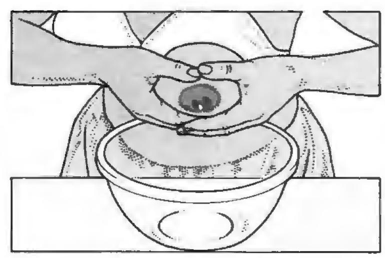
Similar behavior may occur in people with *epilepsy*, *brain damage*, *schizophrenia*, or an *antisocial personality disorder*, but in these cases there are also other symptoms.

Exposure



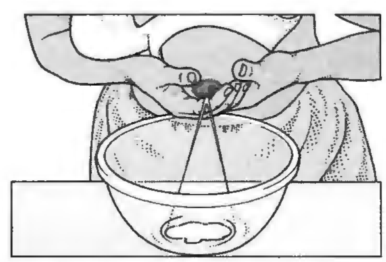
The effects on the body from being subjected to very low temperatures, or to a combination of cold, wet, and high winds. The primary danger comes from the lowering of body temperature in these conditions (see *Hypothermia*). The term also applies to being subjected to radiation or a variety of environmental pollutants.

Expressing milk



A technique used by breast-feeding women for removing milk from the

EXPRESSING MILK BY HAND



Wash your hands thoroughly before starting, then follow the method below. Repeat the sequence twice on each breast, alternating between breasts. If the breasts are engorged, bathe them in hot water first to help milk flow.

1 Cup the breast in both hands, thumbs on top and fingers underneath. Squeeze the outer part of the breast firmly. Repeat 10 times, moving around the breast.

2 Move hands closer to the nipple area and repeat the squeezing movement 10 more times.

3 Hold the breast in one hand. With the thumb and forefinger of the other hand, squeeze the edge of the areola in and up so that milk squirts out. Move your hand around the areola, squeezing gently and rhythmically for about five minutes.

breasts. Expressing milk may be necessary when the breasts are engorged (overfull), which often happens several days after delivery when the milk supply arrives quickly and forcibly. Not only is engorgement painful for the mother, but the tightly swollen nipples are impossible for the baby to suckle.

A woman may also want to express milk from her breasts so that the milk can be given to the baby in her absence. In this case, the milk should be expressed into a sterilized container and sealed and stored in the refrigerator; it will keep for 48 hours. When properly prepared, milk may be frozen and stored in a freezer. Milk may be kept up to six months in the back or bottom of a deep freeze unit. Most women find it easier to express milk by hand, but a *breast pump* can also be used.

Exstrophy of the bladder

A rare birth defect in which the bladder is turned inside out and is open to the outside of the body through a space in the lower abdominal wall.

Usually, there are also other defects, such as *epispadias* (emergence of the urethra through a hole in the shaft of the penis) in males, and failure of the pubic bones to join at the front.

Untreated, an affected child constantly leaks urine. Surgical treatment consists of reconstructing the bladder and closing the abdominal wall.

Extraction, dental

The removal of one or more teeth.

WHY IT IS DONE

Extraction may be performed when a tooth is severely decayed, when an abscess has formed, or when a tooth is too badly broken to be repaired by crowning or root-canal treatment. Teeth that are causing crowding or malocclusion (incorrect bite), teeth that are loose because of advanced gum disease, or teeth that are preventing another tooth from erupting may also require extraction.

HOW IT IS DONE

For most extractions, local anesthesia is used. General anesthesia may be used to extract badly impacted wisdom teeth, to extract several teeth at once, or for extremely anxious patients or young children.

Most teeth are extracted with dental forceps, which are designed to grasp the root of the tooth. When gentle but firm pressure is applied, the blades cut through the periodontal ligaments (the tough fibrous membranes supporting the tooth in its socket), the socket is gradually expanded, and the tooth is removed. Occasionally the root of the tooth fractures during this procedure, especially if the bone is dense (as in older people) and may need to be removed separately.

If the tooth is especially difficult to remove—for example, if it is impacted, the crown is missing, or the roots are very curved—it may be necessary to cut a small flap into the gum and remove a small amount of bone nearby. The tooth is then extracted and the gum sewn up.

COMPLICATIONS

Most extractions take place without complications. Occasionally, if a blood clot fails to form in the empty tooth socket, or if the blood clot is dislodged, *dry socket* (infection in the tooth socket) develops. Dislodging a clot can also cause bleeding from the wound to begin again; this can be eased by placing a tightly folded handkerchief or a gauze pad on the wound and biting on it gently for about 30 minutes. If bleeding continues, suturing of the tissue around the socket may be necessary.

Extradural hemorrhage

Bleeding into the space between the inner surface of the skull and the external surface of the dura mater, the outer layer of the meninges (protective covering of the brain).

CAUSES AND SYMPTOMS

An extradural hemorrhage usually results from a blow to the side of the head that fractures the skull and ruptures an artery running over the surface of the dura mater. The person may momentarily lose consciousness and then apparently recover.

A hematoma (collection of clotted blood) forms and rapidly enlarges, increasing pressure within the skull (which is the main cause of symptoms occurring a few hours to days after the injury). A headache that gradually increases in severity develops in the affected person; other symptoms include drowsiness, vomiting, seizures, and paralysis on one side of the body. The patient eventually lapses into a coma and, without treatment, may die.

DIAGNOSIS AND TREATMENT

CT scanning confirms the diagnosis. Surgical treatment consists of drilling burr holes in the skull (see *Craniotomy*), draining the blood clot, and clipping the ruptured blood vessel. If the bleeding is diagnosed early (before serious symptoms develop), the outlook is excellent; hence the importance of seeking medical advice and investigation following even a moderate blow to the head (see *Head injury*).

Extrapyramidal system

A network of nerve pathways that links nerve nuclei in the surface of the *cerebrum* (the main mass of the brain), the *basal ganglia* deep within the brain, and parts of the *brain stem*. The system influences and modifies electrical impulses that are sent from the brain to the skeletal muscles.

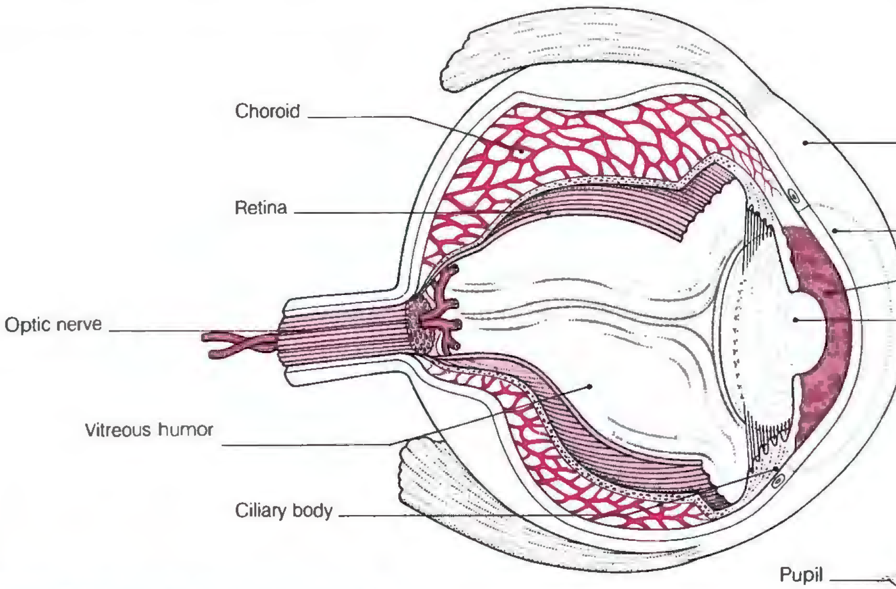
Damage or degeneration of components in the extrapyramidal system can cause a disturbance in the execution of voluntary (willed) movements and in muscle tone, and can also cause the appearance of involuntary (unwanted) movements such as tremors, jerks, or writhing movements. Such disturbances are seen in *Huntington's chorea*, *Parkinson's disease*, some types of *cerebral palsy*, and can also occur as a side effect of taking phenothiazine drugs, which are used to treat some psychiatric disorders.

Extrovert

A person whose interests are constantly directed outward, to other people and the environment. Extroverts are active, energetic, sociable, easy to talk to, and have many outside interests and concerns. (See also *Personality*.)

Exudation

The discharge of fluid from blood vessels into a tissue or onto the tissue's surface. An exuded fluid (called an exudate) contains cells, pus, and/or a large amount of protein (or a combination of these) and is usually produced as a result of *inflammation*. When tissue is inflamed, its small blood vessels become wider and the tiny pores in the vessel walls become enlarged, which allows fluid and cells (mainly white blood cells) to escape.

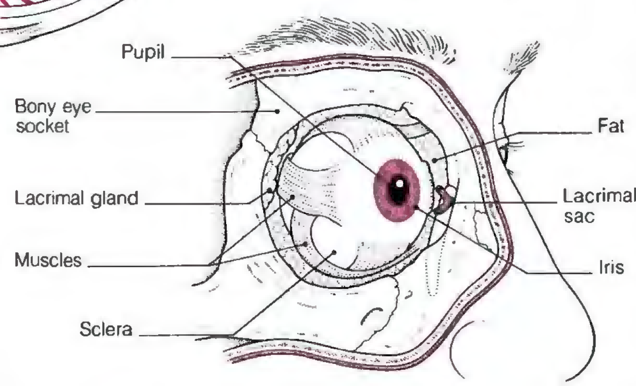


Eye

The organ of sight. It consists of structures that focus an image onto the retina at the back of the eye and a network of nerves that convert this image into electrical impulses recorded in a region of the brain.

The two eyes work in conjunction under the control of the brain, aligning themselves on an object so that a clear image is formed on each *retina*. If necessary, the eyes sharpen images by altering focus in an automatic process known as *accommodation*.

ANATOMY OF THE EYE



The eye is a complex organ that focuses light rays to form an image on the retina, which then converts this image into a pattern of nerve impulses that are transmitted to the brain. The cornea and lens focus the light, the pupil controls the amount of light entering the eye, the ciliary body alters the shape of the lens to adjust the focus, and the retina contains millions of nerve cells that respond to light.

Movement of the eye
Movement of each eyeball occurs as the result of contraction of one or more of the muscles attached around it. There are six of these muscles, each one of which pulls the eye in a specific direction.

The external eye
Behind the brilliant transparency of the cornea is the fluid-filled front chamber of the eye. At the back is the iris, with the round pupil in the center.

The pattern of light falling on the retina stimulates a complex flow of impulses along the optic nerves to the brain. The two optic nerves pass into the skull, meet, partially cross over, and run back, at first on the underside of the brain, and then through its substance to the visual cortex—the area of the back surface of the brain concerned with vision.

STRUCTURE

EYEBALL The eyeball lies in pads of fat within the orbit, the bony eye socket that provides protection from injury. Each eyeball is moved by six delicate muscles, the action of these muscles for both eyes being coordinated by a nerve network in the brain stem.

The eyeball has a tough outer coat, the *sclera* (the white of the eye). The front, circular part of the outer coat, the *cornea,* is transparent and protrudes slightly. The cornea is the main lens of the eye and performs most of the focusing. Behind the cornea is a shallow chamber full of aqueous humor (watery fluid), at the back of which is the *iris* (colored part) with its *pupil* (central hole). The pupil appears black and its size is altered with changes in light intensity to control the amount of light entering it.

Immediately behind the iris, and in contact with it, is the crystalline *lens,* suspended by delicate fibers from a circular muscle ring called the ciliary body. Contraction of the ciliary body alters the shape of the lens to allow focusing power. Behind the lens is the main cavity of the eyeball, filled with a clear gel called the vitreous humor.

On the inside of the back of the eye is the retina, a complex structure of nerve tissue on which the image formed by the cornea and the crystalline lens falls. The retina requires a constant supply of oxygen and sugar. To meet this need, a thin network of branching blood vessels, the choroid plexus, lies immediately under it. The *choroid* is continuous at the front with the ciliary body and the iris. These three parts constitute the uveal tract.

CONJUNCTIVA The eyeball is sealed off from the outside by a flexible membrane called the *conjunctiva,* which is firmly secured around the margin of the cornea but lies freely on the sclera over the front third of the globe. It is attached to the skin at the corners of the eye and forms the inner lining of the lids, with a deep cul-de-sac above and below. This arrangement provides a permanent seal while allowing free mobility of the eyeball.

The conjunctiva contains many tiny tear-secreting and mucus-producing glands. They, along with an oily secre-

tion from the meibomian glands in the eyelids, provide the important, three-layer tear film that must constantly cover the cornea and conjunctiva to protect them from damage due to drying out of the cells.

EYELIDS Each lid contains about 30 meibomian glands, with their openings along the lid margin just behind the roots of the lashes. The glands secrete an oil that prevents lid margin adhesion during sleep and forms the outer layer of the tear film—a layer that retards evaporation and helps maintain the continuity of the tear film. The blink reflex is protective and helps to spread the tear film evenly over the cornea. This is essential for clear vision. Should the tear film dry out, corneal abrasion is more likely.

Just under the skin of the lid is a flat but powerful muscle that can, in an emergency, contract to push the globe back into the orbit and interpose a bunched-up mass of tissue to protect the eye; this occurs as a rapid, reflex response to danger. (See also *Vision*.)

Eye, artificial

A prosthesis to replace an eye that has been removed. It is worn for cosmetic and psychological reasons.

Often wrongly called a "glass eye," the ocular prosthesis is actually a slim plastic shell. The artificial iris behind the transparent artificial cornea may be produced by hand painting or by a photograph.

The eye fits neatly behind the eyelids within the cavity left when the natural eye has been removed. Movement is achieved by attaching the eye-moving muscles to the conjunctiva, or by using a buried magnetic implant.

Eye drops

Medication in solution for the treatment of eye disorders or to aid in diagnosis. To use eye drops, the lower lid is held away from the eye and the drop allowed to fall behind it. Care should be taken to avoid touching the skin or eye with the dropper to reduce the risk of contamination.

Common examples of drugs given in this form are antibiotics, corticosteroids, antihistamines, drugs to control glaucoma (raised pressure in the eye), and drugs to dilate or constrict the pupil.

Eye, examination of

An inspection of the external and internal appearance of the eyes either as part of a standard vision test or to make a diagnosis.

WHY IT IS DONE

Eye examinations are performed to determine the cause of vision disturbance or other symptoms relating to the eye, and to assess whether or not glasses or contact lenses are necessary. Some serious eye disorders, such as glaucoma, are symptomless in the early stages and can be detected only by an eye examination.

HOW IT IS DONE

The examination begins with an inspection of the external appearance of the eyes, the lids, and the surrounding skin. A check of eye movements is usually performed. The examiner looks for *strabismus*, using the cover test to demonstrate that a squinting eye will move to align itself when the other eye is covered. A check of the visual acuity (sharpness of vision) in each eye using a Snellen's chart (the standard eye testing wall chart) follows. Refraction testing (using lenses of different strengths) may be done to determine the requirement for glasses or contact lenses.

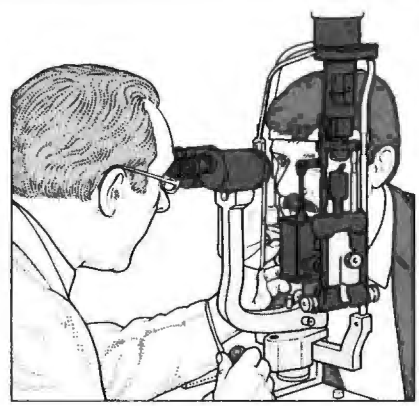
A test of the visual fields (extent of the peripheral vision) may also be performed, especially in suspected glaucoma or neurological conditions. Color vision may also be checked because it is disturbed in certain conditions affecting the retina.

To check for abrasions or ulcers, the cornea and conjunctiva may be stained with fluorescein (a yellow dye); any abrasions or ulcers are then revealed as green areas under light.

Applanation tonometry (measurement of the pressure within the eye) is an essential test for glaucoma. It is done using a slit lamp microscope.

EQUIPMENT

The retina can be examined with an *ophthalmoscope*. The slit lamp microscope, with its brilliant illumination and lens magnification, allows meticulous examination of the conjunctiva, cornea, front chamber of the eye, iris, and crystalline lens.



By means of special corneal contact lenses, the magnified view may be extended to include the vitreous gel behind the lens and the retina. These contact lenses incorporate mirrors to allow examination of structures at the base of the iris and the front edge of the retina. For a full view of the crystalline lens and the structures behind it, the pupil must be widely dilated with drops, such as tropicamide or phenylephrine.

CONDUCTING AN EYE EXAMINATION

During an eye examination, the physician checks external appearance, eye movement, visual acuity, visual field, and color vision. The eyes are checked for the presence of strabismus, abrasions, and ulcers. Applanation tonometry and a refraction test are also done.

View of retina through ophthalmoscope
The retina (inner back surface of the eye) is examined to assess conditions such as hypertensive *retinopathy*, as seen here

Applanation tonometry
Measurement of the pressure within the eye is a routine test for glaucoma.

Snellen's chart
The chart is used to check visual acuity of each eye: the patient's ability to read letters of different sizes from the same distance is assessed

E

DISORDERS OF THE EYE

Many eye disorders are minor, but some lead to serious complications unless treated. (See also *Cornea* disorders box; *Retina* disorders box; *Eye, painful red*.)

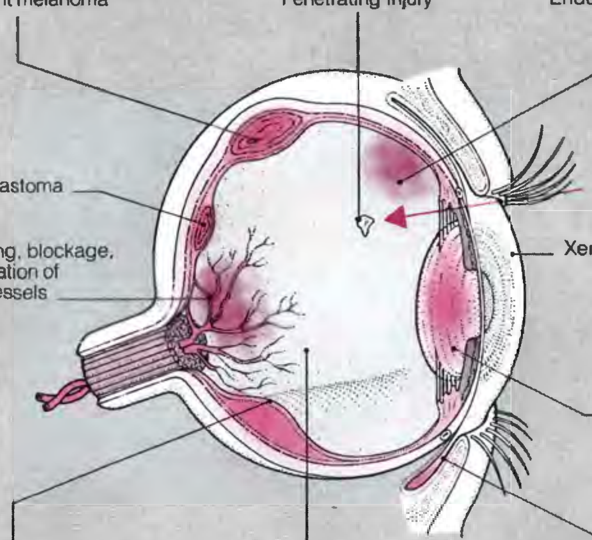
CONGENITAL DEFECTS

Strabismus (squint or malalignment of the eyes) is often congenital (present at birth). *Cataracts* (opacity of the lens of the eye) can occur in infants, when the cause may be maternal *rubella* infection early in pregnancy. Very rarely, babies are born with microphthalmos (abnormally small eye) on one or both sides. Vision in a microphthalmic eye is usually very poor. *Nystagmus* (rapid, uncontrollable movement in the eyes) can be congenital.

Retinoblastoma is a malignant tumor of the retina that appears in early life and may occur in one or both eyes. Other congenital disorders affecting the eye include *albinism* (absence of pigment) and abnormalities of development of the cornea and retina.

INFECTION

Conjunctivitis, the most common infection, rarely affects vision. In the late stages of neglected conjunctival infection, such as *trachoma* or severe bacterial conjunctivitis, vision can be impaired.



Corneal infections are more serious and can lead to blurred vision or corneal perforation if not treated early. Endophthalmitis (infection within the eye), which may make it necessary to remove the eye surgically, can occur after a penetrating injury, after severe ulceration, in rare cases after major eye surgery, or from infections elsewhere in the body.

IMPAIRED BLOOD SUPPLY

Narrowing, blockage, inflammation, or other abnormalities of the blood vessels of the retina may cause partial or total loss of vision.

TUMORS

Malignant *melanoma* of the choroid (middle layer of the eye) is the most common primary malignant eye tumor. It can be found in the eyes of people who do not have symptoms (during routine examinations) or it can cause a decrease in vision.

NUTRITIONAL DISORDERS

Various vitamin deficiencies (particularly vitamin A deficiency) can affect the eye. This may lead to xerophthalmia (dryness of the cornea and conjunctiva), night blindness, or, ultimately, *keratomalacia* (corneal softening and destruction) and total loss of vision.

AUTOIMMUNE DISORDERS

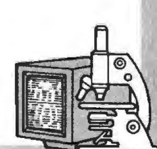
Uveitis (inflammation of the uveal tissues—iris, choroid, and/or ciliary body), when not caused by an infectious agent, may have an autoimmune basis (when the defense mechanisms of the body attack its own tissues). It is commonly encountered in people with *ankylosing spondylitis* (crippling and deforming arthritis of the spine) and *sarcoidosis.*

DEGENERATION

Macular degeneration of the retina is common in the elderly. It causes loss of fine, detailed vision, although peripheral vision remains.

Cataract is also common in elderly people; although the exact cause of the condition is unknown, the process is thought to be degenerative.

OTHER DISORDERS



Glaucoma (a condition in which the pressure in the fluid that maintains the normal shape of the eye is raised) may take various forms. If untreated, glaucoma can lead to permanent loss of vision.

In *retinal detachment,* the retina lifts away from the underlying layer of the eye; this may have various causes.

Ametropia is a general term that means the eye has a refractive error (an error in focusing), such as *myopia* (nearsightedness), *hyperopia* (farsightedness), *astigmatism,* or *anisometropia.* None of these is a disease in the ordinary sense of the word; they are caused simply by variations of shape and focusing ability of the eye. *Presbyopia* is the progressive loss of accommodation (ability to focus at near range) with age. *Amblyopia* (poor vision in one eye without any obvious structural abnormality) is often due to strabismus.

INVESTIGATION

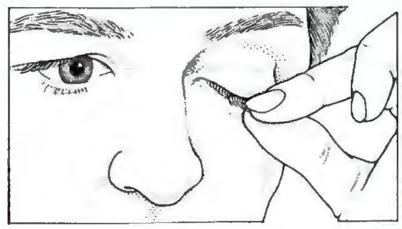
Because of the transparency of its structures, the eye is particularly accessible for examination. Many of the disease processes affecting it can be viewed directly by use of the *ophthalmoscope* and *slit lamp.* Photography of the retina and *fluorescein* angiography are also used. (See also *Eye, examination of.*)

E

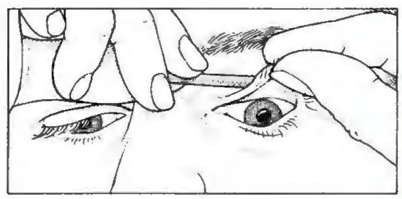
FIRST AID: FOREIGN BODY IN THE EYE

WARNING
Never attempt to remove a particle embedded in the eyeball. Do not remove a foreign body if it is resting on the iris (colored part of the eye).

LOWER LID

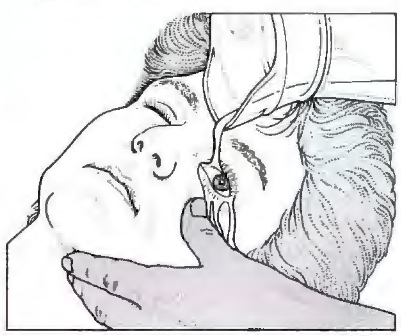


1 Wash your hands. Ask the victim to look up while you separate the lids and examine the eye.



2 First try floating an object out with water; then try lifting it out with the moistened corner of a cloth.

UPPER LID



1 Grasp the lashes and carefully draw the upper lid outward and downward. If this does not dislodge the object, try floating it off by having the victim blink under water.

2 If these measures fail, ask the victim to look down while you place a matchstick across the upper lid and fold the lid up over it. Then pick off the object with a clean cloth.

CORROSIVES IN THE EYE

Flush with continuously running water – some alkalis penetrate deeply and take longer to wash out.

Eye, foreign body in

Any material on the surface of the eye or under the eyelid, or an object that penetrates the eyeball.

INCIDENCE AND CAUSES

Most people get something in their eye at least once in their lives. Usually it is a particle of dust; occasionally it is a metal, plastic, or wood fragment that has been deflected into the eye while doing some home or car maintenance. Rarely, an object traveling at high speed actually penetrates the eyeball—for example, a piece of metal in an industrial accident.

SYMPTOMS

A foreign body under the eyelid or on the cornea or conjunctiva irritates the eye, causing pain, redness, and tearing. It usually causes blepharospasm (uncontrollable eyelid contractions). These symptoms may improve even if the foreign body remains. Occasionally, there will not be any symptoms, especially if the eye has been penetrated.

COMPLICATIONS

Some foreign bodies left within the eyeball may dissolve to release pigment into the substance of the eye, causing blindness. Other foreign bodies may remain whole but cause infection, again leading to blindness.

DIAGNOSIS

If a foreign body is suspected, a physician should be consulted. He or she will examine the eye and both eyelids. Fluorescein (a yellow stain) is used to show up abrasions or sites of penetration. Imaging procedures are used if a penetrating injury is suspected.

TREATMENT

Superficial foreign bodies may be removed at home. Use the corner of a clean cloth, or pull the upper lid down over the lower lid or irrigate the eye using an eyecup.

Objects on the iris or pupil or embedded in the eye should be removed by a physician. A sharp spatula is often used after the surface of the eye has been anesthetized with local anesthetic eye drops. The eye is then stained with fluorescein to assess the area of damage to the cornea. Antibiotics as drops or ointment will be prescribed and the eye is then protected with a patch (see also *Corneal abrasion*). Metallic objects that have penetrated the eye can sometimes be extracted using a powerful magnet.

Eye injuries

The greatest danger to the eye arises from objects of relatively small size traveling at high speed, such as BB gun pellets, slingshot missiles, or small stones sometimes thrown up by rotary lawnmowers. Many industrial activities, such as drilling, sawing, hammering, or grinding, can cause objects from high-speed machinery to penetrate the eye. Penetrating injuries also can occur from windshield glass in automobile accidents. Foreign bodies within the eye can cause serious problems.

The serious injuries are generally those that damage both the cornea and the crystalline lens. Central corneal wounds impair vision by causing scarring (see *Corneal abrasion*). Damage to the lens may cause a *cataract* to form, with resultant loss of vision in that eye. The most serious injuries also extend to the back of the eye to include the retina and posterior sclera (outer lining).

Blunt trauma to the eyeball, such as a blow from a stick, may cause tearing of the iris or may cause rupture of the sclera, with collapse of the eyeball and permanent blindness. Lesser degrees of injury that do not cause penetration may lead to a vitreous hemorrhage (bleeding behind the lens), *hyphema*

(bleeding into the front chamber of the eye), retinal detachment, or injury to the trabeculum (fluid outflow drain of the eye), which can lead to glaucoma. Hyphema affects vision until the blood absorbs, unless other vision-threatening damage occurred with it. (See also *Eye, foreign body in*.)

Eyelashes, disorders of

Eyelashes are arranged in two rows at the front edge of each lid and curve outward. Growth in an abnormal direction may be due to injury to the lid or, more commonly, infection. Occasionally, lashes grow in an abnormal direction for no obvious reason. With age, the lashes become finer.

Severe *blepharitis* (eyelid infection) may cause the lid margins to be so damaged that lash roots are destroyed. *Trachoma*, an eye infection in which the lid is distorted by scarring, may lead to trichiasis, a condition in which the lashes turn inward. They may rub against the cornea, causing corneal abrasion.

Eye, lazy

A popular term for *amblyopia*, in which normal vision has failed to develop, usually in one eye.

Eyelid

One of a pair of complex structures that lies on the upper and lower edges of the eye socket. The eyelids are held in position by ligaments attached to the socket's bony edges. They consist of thin fibrous tissue, called the tarsal plate, covered by muscle and a very thin layer of skin. The inner layer is covered by part of the *conjunctiva*.

Along the edge of the eyelid are two rows of eyelashes, which are strong, curved hairs. Immediately behind the eyelashes are the openings of the ducts leading from the meibomian glands, which secrete the oily part of the tear film from within the tarsal plate (see also *Tears*).

The eyelids act as protective shutters, closing very rapidly as a reflex action in response to anything approaching the eye. A squeezing action of the eyelids pushes the eyeball back into the socket as an additional protective measure. The eyelids also act as wipers to smear the tear film across the cornea.

DISORDERS

Disorders include a *chalazion* (a swelling of a meibomian gland), *blepharitis* (inflammation of the edge of the eyelid), and a *stye* (an abscess at the root of one of the eyelashes).

The shape and position of the eyelids are abnormal in a number of disorders, including *entropion* (the eyelid margin turning inward), *ectropion* (the eyelid margin turning outward), *ptosis* (a drooping eyelid covering all or part of the eye), and baggy eyelids due to dermatochalasis (excess lid skin) or blepharochalasis (excess fat under the lid skin).

Myokymia (twitching of the eyelid) is a common phenomenon usually due to fatigue. *Blepharospasm* (rapid contractions of the eyelid) is usually caused by a foreign body in the eye.

The skin of the eyelid is a common site for a *basal cell carcinoma*.

Eyelid, drooping

See *Ptosis*.

Eyelid surgery

See *Blepharoplasty*.

Eye, painful red

A very common combination of eye symptoms that can be due to several different eye disorders. The presence of pain and redness in one or both eyes requires examination and treatment by a physician.

The most common eye disorder that causes pain and redness is *conjunctivitis*. The redness is due to dilation of the superficial (conjunctival) blood vessels. The pain is similar to that caused by grit in the eye. Conjunctivitis can be due to viral or bacterial infections, irritants (such as chemicals), or allergies. Viral conjunctivitis usually eventually affects both eyes and precautions should be taken to prevent infecting others.

Uveitis (inflammation of all or a portion of the uvea, such as the iris) is another common cause. The dull, aching pain may be due to swelling within the front of the eye and spasm in muscles around the iris. The redness is caused by widening of blood vessels around the iris.

A serious cause of pain and redness in one eye is acute closed-angle *glaucoma* (sudden, highly increased pressure within the eyeball). The pain is severe and may be accompanied by nausea, vomiting, halos, and blurred vision. There is redness of the white of the eye due to increased blood flow in the surrounding vessels.

Other important causes of painful, red eye include a *corneal ulcer*, *keratitis* (inflammation of the outer protective layer of the eye), or the presence of a foreign body on the surface of the eye or under one of the eyelids.

Eyestrain

A term often used to describe aching or discomfort in the eye. Eyestrain is not a medical term, and physicians do not accept the popular belief that the eyes can be damaged by being used.

Eye teeth

A common name for canine *teeth*.

Eye tumors

Tumors of the eye are rare. When eye tumors do occur, they are usually malignant and painless.

TYPES AND TREATMENT

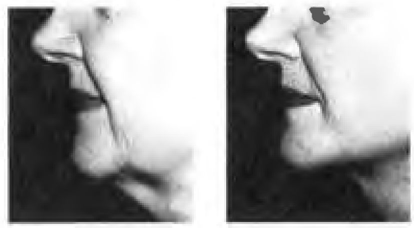
RETINOBLASTOMA This is a *congenital* malignant tumor of the retina that occurs in one or both eyes. If the central vision in only one eye is affected, the child may have strabismus (squint). If the tumor is not discovered in its early growth, it may be seen as a white or yellowish reflection in one pupil. Retinoblastoma may sometimes be treated by *radiation therapy*, *laser treatment*, or freezing, but the eye may require removal to prevent spread of the tumor.

MALIGNANT MELANOMA A form of skin cancer, this is a tumor of the choroid layer that usually affects the middle-aged and elderly. It is the most common eye tumor. Often there are no early symptoms, but the tumor eventually causes detachment of the retina and distortion of vision. Small malignant melanomas can be destroyed by laser treatment, but removal of the eye is often advised to avoid spread of the tumor to the brain or elsewhere.

SECONDARY EYE TUMORS These occur when cancer in another part of the body spreads to the eye, where it produces effects similar to those of the primary tumor. If the secondary tumors grow behind the eyeball, they may cause bulging of the eye. Their effect on vision varies, depending on the location and growth rate. Secondary tumors may sometimes be controlled by radiation therapy; separate treatment is necessary for the primary tumor.

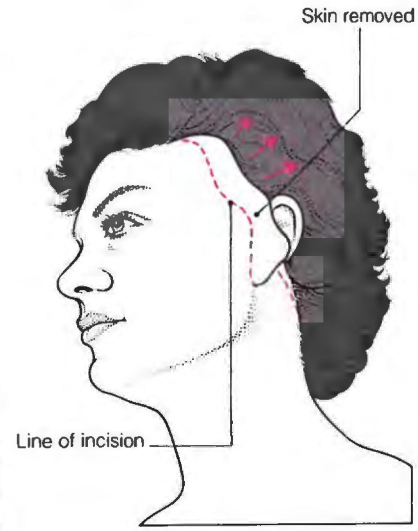
BASAL CELL CARCINOMA This is the most common eyelid tumor. Like other basal cell carcinomas, it is related to excessive exposure to sunlight. The tumor usually has a small crusty central crater and a hard rolled edge. Although it may grow large, it very rarely spreads to other parts of the body. In the early stages, basal cell carcinoma of the lids may be treated by surgery, radiation therapy, or freezing. Extensive plastic surgery or removal of the eye may be necessary.

F



Face-lift
A cosmetic operation to smooth out wrinkles and lift sagging skin on an aging face to make it look younger. A face-lift is usually performed as an outpatient procedure using a local anesthetic. The two sides of the face are treated during the same operation.

OUTLOOK

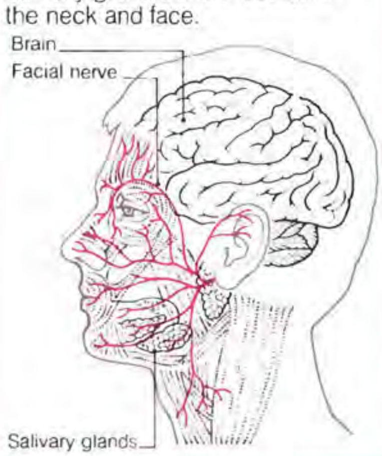


Some bruising of the face is common, but there is usually no pain. The stitches are removed three to five days after the operation. In most cases, the scars, which fade within a year, are hidden by natural crease lines or by the hair. The effect of a face-lift usually lasts about five years.

Occasionally, satisfactory healing does not occur as a result of *hematoma* (bleeding under the skin) or infection, leading to severe scarring; in the worst cases, a *skin graft* may be necessary.

FACE-LIFT
A face-lift is really a skin-lift. It is a serious surgical operation and its effects are not always permanent. There is some discomfort after a face-lift and the cosmetic effects are not immediately apparent. Care should be taken in choosing a highly reputable surgeon.

Before and after treatment
The results of most face-lifts are excellent. However, it should be realized that the outcome may not be exactly as expected, and there is always some risk associated with any operation.



How it is done
An incision is made where shown. The skin is undercut as far as the crease running from the nose to the corner of the mouth It is then pulled upward and backward, and its margins are sewn near the hairline

Facial nerve
The seventh *cranial nerve*. It arises from the pons and medulla oblongata (parts of the brain stem) and sends branches to the face, neck, salivary glands, and outer ear.

The facial nerve performs both motor and sensory functions. It controls the muscles of the neck and of facial expression (including muscles in the forehead); it also stimulates secretion by the submandibular and sublingual salivary glands. In addition, the facial nerve conveys taste sensations from the front two thirds of the tongue and carries sensations from the outer ear.

Damage to the facial nerve causes weakness of the facial muscles (see *Facial palsy*) and, in some cases, loss of taste. Such damage is most commonly due to a virus infection. It may also be a feature of a *stroke*; more rarely, it may occur as a result of surgery (typically for a tumor) to the parotid gland (one of the salivary glands).

LOCATION OF THE FACIAL NERVE
Arising from the brain stem, the facial nerve has branches that connect to the outer ear, tongue, salivary glands, and muscles of the neck and face.

Facial pain
Pain in the face may be caused by injury, infection, or a nerve disorder, may be referred from elsewhere in the body (see *Referred pain*), or may occur for no known reason.

INJURY

In addition to pain in the face from a direct injury, pain may be caused indirectly by *teething* problems in a baby, wisdom tooth problems in an adult (see *Impaction, dental*), or partial dislocation of the jaw.

INFECTION

Sinusitis (inflammation of the air spaces around the nose) can cause pain around the eyes and in the cheek bones. The onset of *mumps* also can cause pain in the cheeks before any swelling appears in front of and/or below the ears. Pain from a boil in the nose or ear may radiate to the face, as may pain from a tooth abscess (see *Abscess, dental*) or dental *caries*.

NERVE DISORDERS

Damage to a nerve that supplies the face can result in severe pain. Examples include the knifelike pain that precedes the one-sided rash in *herpes zoster* (shingles), and the intermittent shooting pain of *trigeminal neuralgia* (tic douloureux), which usually affects only one side of the face and is often brought on by touching the face or chewing.

REFERRED PAIN

In *angina pectoris* (pain in the chest due to lack of oxygen to the heart), pain may be felt in the jaw. With *migraine* headaches, pain may occur on one side of the face. When facial pain or headache occurs for no reason, it may be a symptom of *depression*.

TREATMENT

Analgesics (painkillers) can provide temporary relief, but, if the pain is severe or persistent, a physician or dentist should be consulted.

Facial palsy
Also known as Bell's palsy (for the Scottish surgeon Sir Charles Bell), paralysis of the facial muscles, usually

one-sided and temporary, due to inflammation of a facial nerve. Facial palsy is common and usually comes on suddenly. The cause is unknown, although, rarely, it may be associated with *herpes zoster* (shingles).

SYMPTOMS

The eyelid and corner of the mouth droop on one side of the face and there may be pain in the ear on that side. It may be impossible to wrinkle the brow or to close the eye, and smiling is distorted. Depending on which branches of the nerve are affected, taste may be impaired or sounds may seem unnaturally loud.

TREATMENT

Corticosteroid drugs or *ACTH* is sometimes given to reduce inflammation of the nerve, along with analgesics (painkillers) if the ear is painful. Exercising the facial muscles may facilitate recovery. Electrostimulation of the nerve is of unproved value. It may be necessary to tape the eyelid shut at bedtime to avoid corneal abrasion. In most cases, the condition clears up with or without treatment.

Facial spasm

An uncommon disorder in which there is frequent twitching of facial muscles supplied by the *facial nerve*. (This condition is often called a tic, but, in fact, tic is a general term that can refer to spasmodic twitching in any part of the body.) The disorder, which affects mainly middle-aged women, is of unknown cause.

Facies

A medical term for the appearance of the face, as in adenoid facies, the dull, open-mouthed expression seen in many children whose nasal passages are blocked due to enlarged adenoids.

Factitious disorders

A group of disorders in which symptoms mimic a true illness, but actually have been invented and are under the control of the patient. This is done willingly and for no apparent reason other than the wish to receive the attention given to a patient.

The most common type of factitious disorder is characterized by real physical symptoms and is known as *Munchausen's syndrome*. In a second form, called *Ganser's syndrome*, there is a psychological disturbance.

These disorders differ from malingering, in which the person claims to be ill for a particular purpose, such as obtaining time off from work or claiming compensation.

Factor VIII

One of the blood proteins (coagulation factors) that takes part in the "coagulation cascade"—an important process in *blood clotting*. Some people with the inherited condition *hemophilia* have a reduced level of factor VIII in their blood and, consequently, have a tendency to abnormal bleeding and prolonged bleeding when injured.

Freeze-dried concentrates of factor VIII are given to hemophiliacs by regular intravenous injection (some hemophiliacs administer the treatment themselves at home), which reduces the bleeding tendency and improves the quality of life.

Fahrenheit scale

A temperature scale in which the melting point of ice is 32° and the boiling point of water is 212°. On this scale, normal body temperature is 98.6°F (37°C). The scale is named for the German physicist Gabriel Fahrenheit.

To convert Fahrenheit to Celsius, subtract 32 and then multiply by 0.56 (or 5/9). To convert a Celsius temperature to a Fahrenheit temperature, multiply by 1.8 (or 9/5) and then add 32. (See also *Celsius scale*.)

Failure to thrive

Lack of expected growth in an infant, usually assessed by comparing the rate at which a baby gains weight with a standardized growth chart. Babies who fail to thrive are not growing enough in relation to birth weight.

The undernourishment may be due to some problem at home, often an unsatisfactory relationship between parent and child. In some cases, the child is actually neglected. Deprived children often have delayed emotional and intellectual development as well as failure to thrive.

If a baby fails to gain weight despite receiving an adequate diet and having a stable family background, other conditions may be responsible. Failure to thrive can indicate a serious problem, such as congenital *heart disease*, *renal failure*, or *malabsorption*.

A baby who fails to thrive is often observed (along with a parent) for a week or two to see how the parent feeds and handles the baby. The baby's diet and weight are carefully monitored. If there are social problems, support for the family can be initiated. (See also *Short stature*.)

Fainting

Temporary loss of consciousness due to insufficient oxygen reaching the brain. A fainting attack, known medically as syncope, is often preceded by dizziness, nausea, or a feeling of extreme weakness.

CAUSES

One common cause of fainting is a vasovagal attack, overstimulation of the *vagus nerve* (which helps control breathing and blood circulation). Usually such an attack is due to severe pain, stress, or fear; more rarely it may be caused by prolonged coughing, or by straining to defecate, urinate, or blow a wind instrument. In such cases, unconsciousness is usually accompanied by profuse sweating or

FIRST AID: FAINTING

1 Anyone who feels faint should sit down and lean forward, head between the knees.

2 If a fainting victim is unconscious and breathing normally, lay the person down and raise his or her legs above chest level.

paleness of the skin. A common cause of fainting is being in a stuffy atmosphere that has little oxygen.

Standing still for a long time, or standing up suddenly, can cause fainting. This is due to blood pooling in veins in the legs and reducing the amount available for the heart to pump to the brain, with a resultant drop in blood pressure (postural *hypotension*). It is common in the elderly, in sufferers from *diabetes mellitus*, and in people taking *antihypertensive* or *vasodilator drugs*.

In some people, episodes of fainting may be associated with temporary difficulty in speaking or weakness in the limbs; this may indicate a disorder called *vertebrobasilar insufficiency*, in which there is an obstruction to the blood flow in vessels that pass through the neck to the brain. This is one form of a *transient ischemic attack*.

Fainting may be a symptom of *Stokes-Adams syndrome*, in which the blood flow to the brain temporarily is inadequate due to an *arrhythmia* (irregularity of the heart beat) usually associated with a form of *heart block* (interruption of electrical impulses in the heart).

TREATMENT

Recovery from syncope takes place when normal blood flow to the brain is restored. This usually happens within minutes because falling to the ground places the head at the same level as the heart. To ensure another attack does not occur, the person should remain lying down for 10 to 15 minutes after regaining consciousness.

A person who experiences warning signs of a faint can sometimes prevent fainting by sitting with the head between the knees or, if possible, lying flat with the legs raised.

If a person fails to regain consciousness within a minute or two of fainting, medical help should be obtained promptly and appropriate first aid given (see *Unconsciousness*) until help arrives. Repeated attacks require investigation by a physician.

Faith healing

The supposed ability of certain people to cure disease by their possession of a healing force inexplicable to science. The healer usually transmits this supposed force to the sufferer by direct contact, placing his or her hands on the body ("laying on of hands"). Often the healer and patient have a deep religious faith and believe the force to be divine, but in many cases no religious faith is involved—only a firm

FEELING FAINT AND FAINTING

A sudden feeling of weakness and unsteadiness that may result in brief loss of consciousness.

? Was the feeling of faintness accompanied by a spinning sensation?
- **YES** → See • *Dizziness*
- **NO** ↓

? Did you stand up suddenly after sitting, lying down, or stooping, or had you just gotten up after a few days in bed?
- **YES** → The faintness was probably caused by a temporary drop in blood pressure. See • *Hypotension*
- **NO** ↓

? Are you pregnant?

- **YES** → Fainting or feeling faint during pregnancy is a common occurrence. It is caused by a lowering of blood pressure as a result of relaxation of the muscles surrounding the blood vessels. This is normal during pregnancy.
- **NO** ↓

? Did the faintness follow an emotional shock?
- **YES** → Emotional stress can affect blood pressure, causing a drop in pressure that leads to faintness.
- **NO** ↓

? Are you taking drugs for high blood pressure?
- **YES** → Your blood pressure may have fallen too low. Discuss with your physician. See • *Hypertension*
- **NO** ↓

Continued on next page

? Are you a diabetic OR has it been an unusually long time since you last ate something?

YES → Low blood sugar is probably causing your faintness. If you are diabetic and have had several such attacks, consult your physician.

See • *Hypoglycemia*

NO ↓

? Had you spent several hours in strong sunshine or in very hot or stuffy conditions before you felt faint?

YES → You may have heat exhaustion. Lie down and rest in a cool room and drink plenty of fluids.

See • *Heat exhaustion*

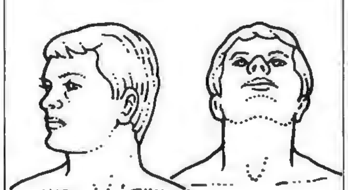
NO ↓

? Have you noticed one or more of the following symptoms since the attack of faintness?
- numbness and/or tingling in any part of the body
- blurred vision
- confusion
- difficulty speaking
- loss of movement in your arms or legs

YES → Have these symptoms now disappeared?

- **YES** → ☎ **Consult your physician without delay!** A temporary decrease in the blood supply to the brain may have caused your symptoms.

  See • *Transient ischemic attack*



- **NO** → ☎ **Consult your physician without delay!** A disruption in the blood supply to the brain, caused by a blocked or burst blood vessel, may be the cause of these symptoms.

  See • *Stroke*

NO ↓

? Are you over 60 years old?

YES → Does turning your head or looking upward suddenly bring on a feeling of faintness?

- **YES** → Osteoarthritis of the bones in the neck can cause a feeling of faintness due to pressure on blood vessels passing to the brain. Consult your physician.

  See • *Cervical osteoarthritis*

- **NO** ↓

NO ↓

Continued on next page

Do you have any form of heart disease AND/OR did you notice your heart beat speed up or slow down before you felt faint?

YES → Did you lose consciousness?

YES → **Consult your physician without delay!** This may indicate a disorder of your heart rhythm.

See • *Heart block*

NO → You may have arrhythmia. Discuss this with your physician.

See • *Arrhythmia, cardiac*

NO ↓

Have you been passing black, tarry feces?

YES → **Call your physician without delay!** Bleeding in the digestive tract is a possibility.

NO ↓

If you are unable to make a diagnosis from this chart, consult your physician.

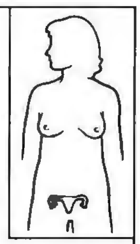
Fainting in children
Many children faint from time to time. This is usually caused by anxiety or hunger. Consult your physician if your child suffers from a frequent loss of consciousness or attacks during which he or she has uncontrolled movements of the body or limbs.

belief, by healer and sufferer alike, in the healer's powers.

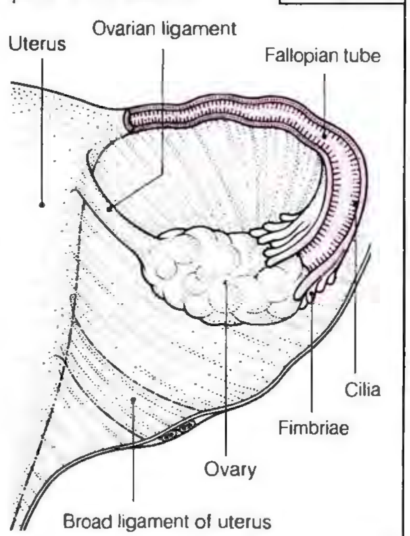
The existence of cures by faith healing is not in doubt—they have been demonstrated many times to the satisfaction of medical observers; in addition, the cures do not involve any of the risks that may accompany medical or surgical treatment. However, the medical profession tends to argue that most such cures are due not to a divine or otherwise inexplicable force, but to the fact that the disorders were hysterical in origin (see *Hysteria*) and therefore susceptible to *autosuggestion*. Physicians also believe that people who turn to faith healing rather than seek medical advice are depriving themselves of effective treatment of the underlying problem.

Fallen arches

A cause of *flatfoot*, which can develop as a result of weakness of the muscles that support the arches of the foot.



Fallopian tube



The tube that extends from the *uterus* to the *ovary*. The fallopian tube transports eggs and sperm and is where *fertilization* takes place.

STRUCTURE

The funnel-shaped tube is about 3 inches long. The narrow end opens into the uterus and the free, expanded end, divided into fimbriae (fingerlike projections), lies close to the ovary. Its muscular wall is lined by cells with cilia (hairlike projections).

LOCATION OF THE FALLOPIAN TUBES
Situated in the pelvic portion of the abdominal cavity, each tube extends from an ovary and becomes the upper part of the uterus.

FUNCTION

The fimbriae sweep up the egg after it is expelled from the ovary. The beating cilia and waves of muscular contractions propel the egg toward the uterus. After intercourse, sperm swim up the fallopian tube from the uterus. The lining of the tube and its secretions sustain the egg and sperm. They also encourage fertilization and nourish the egg until it reaches the uterus.

DISORDERS

Salpingitis is inflammation of the fallopian tube, usually following bacterial infection. It accounts for almost 15 percent of cases of *infertility*.

Ectopic pregnancy (development of an embryo outside the uterus) usually occurs in the fallopian tube. A delay in the transport of the fertilized egg along the tube results in implantation within the tube wall, which is too thin to sustain growth. The tube then ruptures and may hemorrhage.

Fallot's tetralogy

See *Tetralogy of Fallot*.

Fallout

See *Radiation hazards*.

Falls in the elderly

The tendency to fall increases steadily with age. Although the majority of

falls produce no permanent injury, a significant number of the injuries that do result are ultimately fatal.

CAUSES AND INCIDENCE

Reflex actions in the elderly are much slower than in the young, and an elderly person who trips or stumbles is often too slow to prevent a fall.

Half of all falls are accidental and half have a medical cause. Poor sight, walking disorders, arrhythmias (see *Arrhythmia, cardiac*), *hypotension* (reduced blood pressure), dizziness for various reasons, and the effect of drugs are causes. Falls sometimes herald the onset of serious illness such as pneumonia, stroke, myocardial infarction (heart attack), or internal hemorrhage. Epilepsy, Parkinson's disease, alcohol consumption, the hangover effects of some sleeping tablets, and use of daytime tranquilizers may also increase the likelihood of a fall.

RISKS AND COMPLICATIONS

Broken bones as a result of falls are particularly common in the elderly. Women are more vulnerable to broken bones than men. Not only do women have more falls, they are also more likely to suffer fractures because their bone strength is reduced as a result of calcium loss after the menopause (see *Osteoporosis*). The incidence of fractures of the neck of the femur (thigh bone) doubles approximately every seven years after the age of 65, and, by the age of 90, one woman in four has suffered this type of fracture.

Apart from injuries, there may be serious indirect consequences of the fall. The outlook is particularly grave for those who fall and lie on the floor for more than an hour, particularly if it is cold. This may lead to *hypothermia* (low body temperature) or pneumonia. In this group, 50 percent die within three months of the fall.

A serious fall, or fear of such a fall and the helplessness and dependence it could bring, can have bad psychological effects on an elderly person, sometimes causing a previously active person to become demoralized and housebound.

ACTION AFTER A FALL

Immediate medical help should be obtained if the person is unconscious, is in severe pain, is bleeding profusely, is burned, has suspected broken bones, or is showing signs of shock. First-aid measures (for bleeding, burns, or fractures) and *cardiopulmonary resuscitation* (if the heart and/or breathing have stopped) may be necessary.

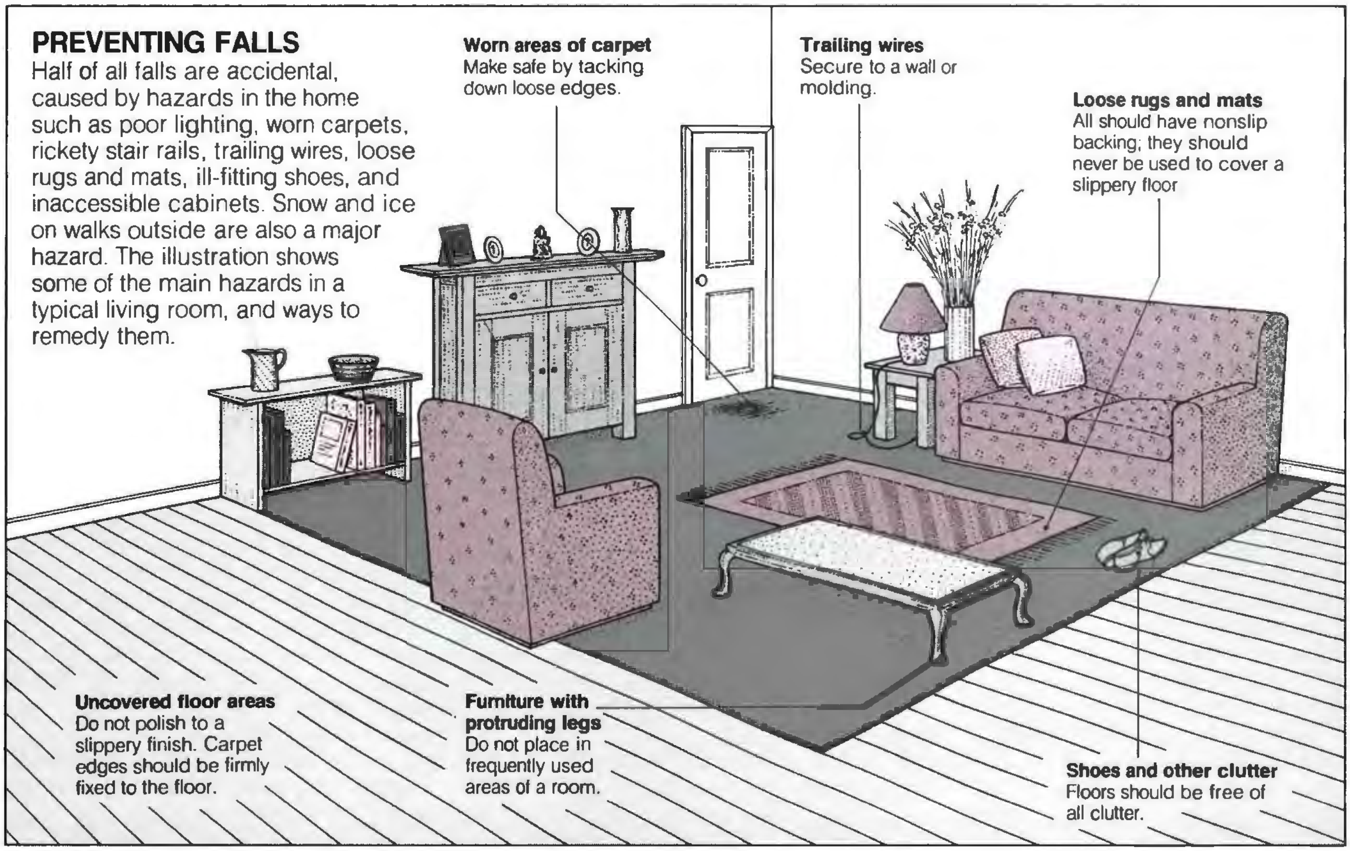
PREVENTION AND OUTLOOK

These measures can be taken to guard against falls: ensure that handles in bathrooms and on stairs are secure, good lighting is available, suitable footwear is worn, floor coverings and wiring are safe, and that there is minimal clutter on the floor. Elderly people who live alone can arrange for an alarm system to be installed or for a regular visit by a neighbor. It is also helpful to teach the elderly person several different ways of getting up from the floor.

False teeth

See *Denture*.

Familial



A term applied to a characteristic or disorder that runs in families (that is, it occurs in more members of a particular family than would be expected from the occurrence in the population as a whole). An example of a familial characteristic is male pattern baldness (see *Alopecia*); an example of a familial disorder is *hyperlipidemia* (abnormally high levels of fat in the blood).

Familial Mediterranean fever

An inherited condition that affects certain Sephardic Jewish, Armenian, and

PREVENTING FALLS

Half of all falls are accidental, caused by hazards in the home such as poor lighting, worn carpets, rickety stair rails, trailing wires, loose rugs and mats, ill-fitting shoes, and inaccessible cabinets. Snow and ice on walks outside are also a major hazard. The illustration shows some of the main hazards in a typical living room, and ways to remedy them.

F

Arab families. Its cause is unknown. Symptoms usually begin between the ages of 5 and 15 years. The main symptoms are recurrent episodes of fever, abdominal pain, arthritis, and chest pain. Red swellings in the skin sometimes occur, and affected people may also suffer psychiatric problems.

Attacks usually last between 24 and 48 hours, but may last longer. Between attacks there are usually no symptoms. There is no specific treatment, but known sufferers are able to reduce the incidence of attacks by taking colchicine, a drug usually used to treat gout. Death may eventually occur from *amyloidosis*, which is a complication of the condition.

Family planning

Limitation of the number or spacing of children through choices made by sexually active people. In some countries, financial and taxation incentives are used by the state to encourage couples to have more or fewer children; in other countries, penalties are imposed on those who do not conform to government recommendations.

In most countries the factors governing family size are economic and social. In many developing countries few older people have pensions, and those too frail to work rely on support from their adult children. Under these circumstances, having many children is seen as a provision for care in old age. In the past 20 years, however, most nations have experienced the economic ill effects of rapid population growth and large families are no longer encouraged.

The number of children born to a couple may be limited by social factors—late marriage for both men and women reduces the reproductive period, and economic barriers to marriage may restrict childbearing to a fraction of the population.

Strategies for restricting family size include contraceptive techniques (see *Contraception*) and elective abortion (see *Abortion, elective*).

Family practitioner

A physician who provides comprehensive medical services for individuals, regardless of sex or age, on a continuing basis. The family practitioner (FP) often cares for all members of a family.

Emphasis is placed on treatment of all problems experienced by the person and on coordination of care, with referrals to specialists as necessary. Care by an FP may range from stitches and sniffles to management of long-term conditions (e.g., terminal cancer, congestive heart failure, or diabetes mellitus), including the delivery of a baby and care afterward. Family practitioners have replaced the former general practitioner (GP), but the training for the FP is broader.

Family therapy

Treatment of the family as a whole rather than individual treatment of one or more members. Family therapy is based on the belief that a troubled or mentally ill person cannot be seen in isolation from the family unit. Disturbed children may merely reflect parental conflicts. This approach has become popular in recent years for dealing with the problems of children and adolescents.

Usually the therapist arranges regular meetings with the family to find out what feelings lie behind the way parents and children deal with each other. Through discussion and confrontation, these feelings can gradually be changed, leading to greater harmony and understanding.

Famotidine

A recently released (1986) *ulcer-healing drug* related to the *antihistamine drugs*. Famotidine reduces the secretion of acid in the stomach and, by doing so, promotes healing of *peptic ulcers* and reduces *esophagitis* (inflammation of the esophagus).

Fanconi's anemia

A rare type of aplastic *anemia*, characterized by a severely reduced production of all types of blood cells by the bone marrow.

Fanconi's syndrome

A rare kidney disorder, occurring mainly in childhood, in which various important nutrients and chemicals such as amino acids, phosphate, calcium, and potassium are lost in the urine; this leads to failure to thrive, stunting of growth, and bone disorders such as *rickets*.

Fanconi's syndrome has a wide variety of possible causes, including a number of rare inherited abnormalities of body chemistry; it may also occur as a side effect of some drugs, such as the ingestion of outdated tetracycline. In some cases there is no obvious cause.

The child may resume normal growth if an underlying chemical abnormality can be corrected. Alternatively, he or she may benefit from a *kidney transplant*. In some cases, neither of these measures is possible or beneficial and kidney function progressively worsens, leading to death in childhood or early adolescence. Fanconi's syndrome in adults has a much brighter outlook.

Fantasy

The process of imagining events or objects that are not actually occurring or present. The term also refers to the mental image itself. Fantasy can give the illusion that wishes have been met. In this sense, it provides satisfaction and can be a means of helping people to cope when reality becomes too unpleasant. Fantasy can also be creative, stimulating ideas and activities by presenting mental images in new combinations.

Psychoanalysts believe that some fantasies are unconscious and represent certain primitive instincts; these fantasies are always presented to the conscious mind in symbols. For example, the fantasy of returning to the womb might be represented by the image of a cave deep within the earth.

Farmers' lung

An occupational disease affecting the lungs of farm workers in whom *hypersensitivity* (an excessive allergic reaction) develops when exposed to certain molds or fungi that grow on hay, grain, or straw.

CAUSES AND INCIDENCE

Farmers' lung is an example of an allergic *alveolitis*—a reaction of the lungs to inhaled dust containing fungal spores. The causative fungi grow on hay or grain that has been stored in warm, damp conditions. Outbreaks of farmers' lung often occur toward the end of a winter following a wet summer in areas with a high rainfall.

SYMPTOMS

Typical symptoms develop about six hours after exposure to dust containing fungal spores. The symptoms may include shortness of breath and flulike symptoms of fever, headache, and muscle aches. In single acute attacks, the symptoms persist for one or two days. Repeated exposure to the molds or fungi that provoked the attack may lead to a chronic form of the disease, causing permanent scarring of the lung tissues.

DIAGNOSIS AND TREATMENT

The physician takes a full occupational history and listens through a stethoscope for crackles. A chest X ray may show abnormalities; *pulmonary func-*

tion tests show that the efficiency of the lungs is reduced. Specific blood tests, indicating that the patient has antibodies to the fungus, can confirm the diagnosis.

The sufferer should avoid further exposure to moldy hay or grain; if symptoms persist, *corticosteroid drugs* may be prescribed. Complete recovery can be expected, provided the disease is diagnosed before permanent lung damage has occurred.

PREVENTION

Farmers can reduce their own and their workers' chances of developing the condition by reducing the water content of hay and grain before storage and by ensuring that storage conditions are cool and dry (to discourage growth of fungi). Well-ventilated work areas help prevent a buildup of fungal spores in the air; wearing protective masks may help.

Farsightedness

See *Hyperopia*.

Fascia

Fibrous *connective tissue* that surrounds many structures in the body. One layer of the tissue, known as the superficial fascia, envelopes the entire body just beneath the skin. Another layer, the deep fascia, encloses muscles, forming a sheath for individual muscles and separating them into groups. The deep fascia also holds in place soft organs, such as the kidneys. Thick fascia in the palm of the hand and sole of the foot have a cushioning, protective function.

Fasciculation

Spontaneous, irregular, and usually continual contractions of a muscle apparently at rest. Unlike *fibrillation*, a similar condition, fasciculation is visible under the skin and is described as fine or coarse.

A minor degree of fasciculation is common and is no cause for concern. However, persistent fasciculation with weakness in the affected muscle indicates damage to (or disease of) nerve cells in the spine that control the muscle or nerve fibers that connect the spinal nerves to the muscle; *motor neuron disease* is one such disorder.

Fasciitis

Inflammation of a layer of *fascia* (fibrous connective tissue), causing pain and tenderness. Fasciitis is usually the result of straining or injuring the fascia surrounding a muscle; it most commonly affects the sole of the foot (a condition called plantar fasciitis). It may occur in people who suffer from *ankylosing spondylitis* (rheumatism of the spine) or *Reiter's syndrome* (inflammation of the urethra with conjunctivitis and arthritis).

Treatment consists of resting the affected area and protecting it from pressure (i.e., by wearing cushioned pads in the shoes if the foot is affected). In some cases, injections of *corticosteroid drugs* have been given in an attempt to relieve pain.

Fasciotomy

An operation to relieve pressure on muscles by making an incision in the fascia (connective tissue) that surrounds them.

WHY IT IS DONE

Fasciotomy is usually performed to treat *compartment syndrome*, a painful condition in which a group of muscles is constricted with consequent obstruction of their blood flow. The condition can result in damage to, or even the death of, affected muscles. Fasciotomy gives the muscles space in which to expand.

The operation is also sometimes performed as a surgical emergency to treat a crush injury in which the muscle group has swollen or there is bleeding into the muscle compartment, raising the pressure within it.

HOW IT IS DONE

Fasciotomy is performed using a general anesthetic. An incision is made in the skin over the affected muscle group and then in the underlying fascia to allow the muscles to bulge through. For compartment syndrome, only a small incision is usually required; in an emergency procedure, a much larger incision may be needed.

Once the muscles have expanded through the opening, the wound is sewn up. In some cases, the muscle bulges out so much that a *skin graft* is required to repair the incision.

Fasting

Abstaining from all food and drinking only water. In temperate conditions and at moderate levels of physical activity, a person can survive on water alone for more than two months; without food or drink, death usually occurs within about 10 days (survival times are shorter in hot or cold conditions and at high levels of activity).

EFFECTS ON THE BODY

Without food, the energy needed to maintain essential body processes, such as *metabolism*, is supplied by substances stored in the body.

About six hours after the last meal, the body starts to use glycogen (a carbohydrate stored in the liver and muscles). This continues for about 24 hours, after which, while the body adapts to obtaining energy from stored fat, protein from the breakdown of muscles is also used as an energy source.

After a few days, most energy is obtained from fat, although some continues to come from muscle breakdown. If fasting continues, the body's metabolism slows to conserve energy. As a result of this slowdown, the fat and protein from muscles is consumed more slowly.

In the initial stages of fasting, weight loss is rapid. Later it slows, not only because metabolism slows down, but also because the body starts to conserve its salt supply, which causes water retention. Water that would normally be excreted in the urine is absorbed by the tissues. The accumulated fluid causes edema (swelling), mainly of the legs and abdomen.

In prolonged fasting, the ability to digest food may be impaired or lost entirely because the stomach gradually stops secreting digestive juices. If this occurs, medical supervision may be necessary when eating resumes. Prolonged fasting also halts the production of sex hormones, causing *amenorrhea* (absence of periods) in women. In addition, the body's ability to fight infection deteriorates, which, along with degeneration of the heart muscle, may be fatal.

FASTING TO REDUCE WEIGHT

Omitting a main meal each day for a limited period, or occasionally not eating anything for up to 24 hours, may be an effective means of losing weight. However, nobody should go without any food for more than a day without consulting a physician.

Fatigue

See *Tiredness*.

Fats and oils

Nutrients that provide the body with its most concentrated form of *energy*; 1 gram of fat provides nine Calories, whereas 1 gram of carbohydrate produces only four to five Calories.

Fats are compounds containing *carbon* and hydrogen with very little *oxygen*. Chemically, they consist mostly of *fatty acids* combined with an oily alcohol, *glycerol*. They are divided into two main groups, saturated and unsaturated, depending on the proportion of hydrogen atoms. If the fatty

F

acids contain the maximum quantity possible of hydrogen, they are said to be saturated. If there are some sites on the carbon atom unoccupied by hydrogen, they are unsaturated; when many sites are vacant, they are polyunsaturated. Animal fats, such as those found in meat and dairy products, are highly saturated with hydrogen, while vegetable fats tend to be unsaturated to varying degrees.

There is no difference between fats and oils except in consistency. Saturated fats are solid at room temperature (but liquid when heated); oils are liquid at room temperature.

TYPES

Dietary fats are sources of the fat-soluble vitamins A, D, E, and K and of essential fatty acids. They are mainly triglycerides (combinations of glycerol and three fatty acids) but also contain other types of fats. Sources in the diet include not only the visible fats (such as butter, margarine, and vegetable oils) but also the so-called invisible fats found in meat, fish, poultry, and dairy products. The oils of certain cold-water ocean fish are being investigated for their potential ability to protect against coronary heart disease.

Structural fats (referred to as lipids) include triglycerides, phospholipids, and sterols. Triglycerides are the main form of fat found in stores of body fat. These stores act as an energy reserve as well as providing insulation and a protective layer for delicate organs. Phospholipids are structural fats found in cell membranes. Sterols, such as *cholesterol*, are found in animal and plant tissues; they have a variety of functions within the body, often being converted by chemical actions into hormones or vitamins.

FAT METABOLISM

Dietary fats are first dissolved by the action of bile salts and then broken down into fatty acids and glycerol by lipase, a pancreatic enzyme. They are absorbed via the lymphatic system before entering the bloodstream.

The lipids are carried in the blood bound to a protein, when they become known as lipoproteins. There are four classes of lipoprotein—chylomicrons, very low-density lipoproteins (VLDLs), high-density lipoproteins (HDLs), and low-density lipoproteins (LDLs). LDLs and VLDLs contain large amounts of cholesterol, which they carry through the bloodstream and deposit in cells. The HDLs pick up cholesterol and carry it back to the liver for processing and excretion. (See also *Nutrition*.)

Fatty acids

Organic acids, containing *carbon*, hydrogen, and *oxygen*, that are constituents of fats. There are over 40 different fatty acids found in nature, distinguished by their number of carbon atoms.

Certain fatty acids cannot be synthesized by the body and must be provided by the diet. These fatty acids are linoleic, linolenic, and arachidonic acids, sometimes referred to collectively as the essential fatty acids. (See also *Nutrition*.)

Favism

A disorder characterized by an extreme sensitivity to the broad bean *VICIA FABA* (fava). If an affected person eats these beans, a chemical in the bean causes rapid destruction of his or her red blood cells, leading to a severe type of anemia (see *Anemia, hemolytic*).

Favism is uncommon except in some areas of the Mediterranean, especially lowland Greece, where up to 10 percent of the population is affected. Favism is an inherited condition caused by a sex-linked *genetic disorder*. Affected people have a defect in a chemical pathway within their red blood cells that helps to protect the cells from injury. This defect is called glucose-6-phosphate dehydrogenase deficiency or *G6PD deficiency*.

Children in any family with a history of favism should be screened for the condition at an early age. If the disorder is found, they must avoid broad beans and certain drugs (including some antimalarials and antibiotics) that can have a similar destructive effect on their red blood cells. A list ot drugs to avoid can be obtained from a physician when the disorder is diagnosed. With these precautions, affected people are able to remain in good health.

FDA

See *Food and Drug Administration*.

Febrile

Feverish or related to *fever*, as in febrile seizures—convulsions that occur mainly in young children who have high temperatures.

Fecal impaction

A large mass of hard feces that cannot be evacuated from the rectum. The condition usually is associated with long-standing *constipation*, along with dehydrated feces. Fecal impaction is most common in very young children and the elderly, especially those who are bedridden.

The main symptoms are an intense desire to have a bowel movement, pain in the rectum, anus, and center of the abdomen, and, in some instances, watery feces (which may be mistaken for diarrhea) that are passed around the impacted mass.

To diagnose the condition, the physician inserts a gloved finger into the rectum. Treatment consists of giving enemas (see *Enema*). If this is ineffective, the fecal mass may require removal manually.

Fecalith

A small, hard, almost stonelike piece of impacted feces that occasionally forms in a diverticulum (an outpouching, usually in the large intestine). A fecalith is harmless unless it blocks the entrance to the appendix, causing *appendicitis*, or a diverticulum, causing diverticulitis (see *Diverticular disease*).

Feces

Waste material from the digestive tract that is expelled through the anus. Solidified in the large intestine, feces consists of indigestible food residue (roughage, or dietary *fiber*), dead bacteria (which may account for as much as half the weight of the feces), dead cells shed from the intestinal lining, secretions from the intestine (such as mucus), bile from the liver (which colors the feces brown), and water.

Examination of the feces—for color, odor, consistency, or the presence of blood, pus, fat, parasites, or unusual microorganisms—is important in the diagnosis of digestive tract disorders. (See also *Feces, abnormal*.)

Feces, abnormal

Feces that differ from normal in color, odor, consistency, or content. The changes may be the result of a harmless condition, but in some cases they are due to a disorder of the digestive tract or a disorder of a related organ, such as the liver.

Liquid or very loose feces, passed frequently (see *Diarrhea*), may be due simply to anxiety but may also be caused by an intestinal infection (see *Gastroenteritis*); by an intestinal disorder such as *ulcerative colitis* or *Crohn's disease*; or by the *irritable bowel syndrome*. Loose stools may also reflect various states of *malabsorption*. At the other extreme, feces may be very hard and infrequently passed (see *Constipation*). Constipation is usually harmless but may be associated with rumbling

and gurgling (*borborygmi*), bloating, and abdominal discomfort attributable to an irritable colon.

Pale feces may be due to diarrhea, to a lack of bile in the intestine as a result of *bile duct obstruction*, or to a disease that causes malabsorption (such as *celiac sprue*). In malabsorption, the paleness of the feces is due to the high fat content. Such feces may be oily, frothy, foul-smelling, and difficult to flush away.

Dark feces may simply be the result of unusually large amounts of iron or red wine in the diet. However, if feces are black, there may be bleeding in the stomach, duodenum, small intestine, or cecum.

Slimy feces, which contain excessive mucus, may be passed normally, but are sometimes associated with constipation or the irritable bowel syndrome. *Enteritis*, *dysentery*, or a tumor of the intestine (see *Intestine, tumors of*) may also cause slimy feces, often accompanied by blood.

Blood in the feces varies in appearance according to the site of bleeding. When blood is in the stomach or duodenum, it usually shows only as black, tarry feces; blood from a disease of the colon, such as ulcerative colitis or a tumor, is red and can usually be seen separate from the feces. Bleeding from the rectum, which occurs with *hemorrhoids* or rectal tumors, often streaks the feces, is visible only on toilet paper, or drips into the toilet bowl. This blood is usually bright red.

INVESTIGATION

Blood in the feces and any other persistent abnormality should be reported immediately to a physician, who may ask for a sample of the feces. (See also *Rectal bleeding*.)

Feces, blood in the

See *Feces, abnormal*; *Rectal bleeding*.

Feeding, artificial

Administration of nutrients other than by mouth, usually through a tube inserted into the stomach or small intestine. Occasionally, a tube is inserted directly into the stomach or jejunum (upper part of the small intestine) by surgical means. This is called enteral nutrition. If the gastrointestinal tract is not functioning, food must be sent into the bloodstream by *intravenous infusion*. This technique is known as total parenteral nutrition.

WHY IT IS DONE

Tube feeding may be necessary for people with disorders of the gastrointestinal tract, *malabsorption*, or neurological or renal disorders. Premature babies often require tube feeding if their sucking reflexes are undeveloped, as do burn or fever patients because of their increased nutritional requirements.

Intravenous feeding is usually necessary when there has been damage to the small intestine as a result of disease or surgical removal of large areas of the absorbing surface.

HOW IT IS DONE

TUBE FEEDING Suitable food mixtures or preparations of predetermined levels of nutrients are administered via a narrow plastic tube. The tube is passed through the patient's nose (guided via the nasopharynx to the esophagus) and into either the stomach or the duodenum.

If tube feeding is the sole means of nutrition, it must provide all of the essential nutrients (and adequate fluids) to meet the person's daily needs, which can vary markedly. There are two alternative methods of tube feeding—bolus feeding and continuous drip feeding.

Bolus feeding involves the rapid administration of a set amount of nutrients at intermittent periods throughout the day. Continuous drip feeding is, however, more widely preferred because it is tolerated better by the patient. In both methods the rate of flow can be controlled by a pump. The tube is left in place for adults and older children, but, for infants and young children, it is removed and reinserted for each feeding.

INTRAVENOUS FEEDING This method is generally used only when tube feeding is impractical or ineffective; its main drawback is the risk of introducing infection directly into the bloodstream or of blocking a blood vessel. Some problems with the liver or gallbladder have occurred.

The nutrient preparations are given directly into a large central vein near the heart via a catheter (thin, flexible tube) inserted using an anesthetic and strict *aseptic techniques*. Intravenous feeding is sometimes used to supplement feeding by mouth, but can if necessary provide all the nutrients needed to meet a patient's requirements. Essential vitamins and minerals are included.

Feeding, infant

During a baby's first year, it grows more rapidly than at any other time in its life. A good diet is essential for healthy growth.

BREAST- OR BOTTLE-FEEDING

NUTRITIONAL REQUIREMENTS During the first four to six months, most babies' nutritional requirements are met by milk alone, whether by *breast-feeding* or *bottle-feeding*. Both human milk and artificial milk (modified dried cow's milk) contain carbohydrate, protein, fat, vitamins, and minerals in similar proportions (see *Milk* for components), but human milk is the food of choice because it provides these nutrients in the perfect blend as well as containing antibodies and white blood cells that protect the baby against infections.

After the baby is 6 months old, vitamin D supplements should be given to breast-fed babies and to bottle-fed babies whose locations or backgrounds pose a risk of rickets. At 6 months a baby can safely be taken off artificial milk and fed with natural cow's milk. Supplementary vitamin D should be given until the baby is established on a mixed diet. Drops containing vitamins A, C, and D, although often given, are usually not required by most infants.

If a baby seems unable to tolerate milk of any kind (see *Food allergy*; *Food intolerance*), the pediatrician should be consulted; he or she may recommend a preparation based on soybeans, vegetable oils, sucrose, corn sugar, modified meat protein, and other substances. Babies should not be fed skim milk, which has relatively too much protein and minerals and insufficient calories compared with whole milk.

EMOTIONAL REQUIREMENTS For healthy emotional development, a baby requires warmth, security, and contentment; the act of feeding plays an important part in meeting these needs. Breast-feeding is again preferable in this respect because it establishes an intimate bond between mother and child, but bottle-feeding is a perfectly satisfactory alternative if the baby is cuddled and talked to while he or she is fed.

INTRODUCING SOLIDS

Solid foods, initially in the form of purees and cereals, should be introduced into an infant's diet at some time between the ages of 3 and 6 months, depending on the baby's birth weight and rate of growth. By 6 months the baby should be eating some true solids, such as chopped up meat and vegetables. The accompanying chart gives the optimum times for the introduction of solids, but a baby's general contentment also provides some guide. A rapidly growing baby

who is unable to drink enough milk to satisfy his or her hunger needs the more concentrated calories found in solid food.

Many parents prefer to give their infants home-prepared purees rather than prepared foods. In this case, salt and other additives should not be used, since an overconcentration of salt and other minerals can dangerously overburden a baby's kidneys. Sugar, too, should be kept to a minimum in the diet; a baby easily learns to have a "sweet tooth," which will lead to future dental decay; for the same reason, babies should not be given bottles of sweetened drinks to comfort them.

A baby can live healthily on a vegetarian diet (one that contains no meat or fish) provided eggs are included, but a baby fed on a vegan diet (one that also excludes all animal products, such as dairy produce and eggs) runs the risk of severe malnutrition. A vegan diet makes it very hard to obtain enough calories, essential fatty acids, vitamins (especially B_{12}), and protein. Overall, it is a very bad diet for infants and growing children whose nutrient requirements are much greater than adults.

FEEDING PROBLEMS

Any difficulties associated with milk usually appear within the first month.

Some babies have an intolerance to certain foods; reactions can include vomiting, diarrhea, or allergic rashes. For this reason, solids should be introduced one by one so that any that cause problems can be identified.

Prolonged crying after feedings may mean that the baby needs help bringing up gas, that artificial milk is not being digested properly, or that the baby has colic (see *Colic, infantile*). See also *Nutritional disorders*.

APPROXIMATE AGES FOR INTRODUCING SOLIDS

4 months	At second breast- or bottle-feeding offer one or two teaspoons of vegetable or fruit puree or cereal.
4½ months	At second breast- or bottle-feeding offer two teaspoons of cereal. At third breast- or bottle-feeding offer two teaspoons of vegetable or fruit puree.
5 to 6 months	*Early morning* Breast- or bottle-feeding. *Breakfast* Two teaspoons of cereal and lightly boiled egg yolk, followed by breast- or bottle-feeding. *Lunch* One teaspoon of meat or fish puree with three teaspoons of strained vegetables. Offer water or well-diluted fruit juice instead of milk. *Mid-afternoon* Mashed banana or other soft fruit followed by usual milk feeding. *Dinner* Breast- or bottle-feeding if the baby is still hungry.
6 to 7 months	*Early morning* Breast- or bottle-feeding. *Breakfast* Two teaspoons of cereal with lightly scrambled egg. Offer cow's milk from a cup. *Lunch* Offer minced or mashed food instead of pureed. Give meat or fish with some vegetables, then offer yogurt and fruit. Give a drink of water or well-diluted fruit juice.
7 to 8 months	*Early morning* Offer a drink of water or diluted juice instead of the milk. *Breakfast* Cereal and boiled egg with whole-grain bread and butter. A drink of cow's milk. *Lunch* Cheese, fish, or minced meat with mashed vegetables. Pudding or fresh fruit. A drink of water or well-diluted fruit juice. *Late afternoon/dinner* Whole-grain bread and butter with peanut butter or cheese. Fresh fruit and a drink of cow's milk.
9 to 12 months	*Early morning* A drink of water or well-diluted fruit juice. *Breakfast* Cereal, then egg or fish with whole-grain toast and butter. A drink of cow's milk. *Lunch* Chopped meat or fish, or cheese, with vegetables. Pudding or fresh fruit. A drink of water or well-diluted fruit juice. *Late afternoon/dinner* Meat or cheese sandwiches. A drink of cow's milk.

Fee for service

The traditional financial arrangement between patient and physician. The patient is charged for each service he or she receives; the physician is compensated for each service he or she provides. (See also *Health maintenance organization*.)

Femoral epiphysis, slipped

Displacement of the upper *epiphysis* (growing end) of the femur (thigh bone). Such displacement is rare, usually affects those between the ages of 11 and 13, and occurs more often in boys, in obese children with delayed sexual and physical development, and in children who grow rapidly.

While the bone is still growing, the epiphysis is separated from the shaft of the bone by a plate of cartilage. This constitutes a zone of relative weakness in the bone, so that a fall or other injury, even a minor one, can cause the epiphysis to slip out of position.

SYMPTOMS

A limp develops and the child feels pain in the knee rather than in the hip. The leg tends to turn outward and hip movements are restricted.

TREATMENT

An operation is performed using general anesthetic to manipulate the displaced parts of bone and fix them together with metal pins. To prevent possible damage to the other thigh, it, too, may be strengthened with pins during the same operation.

OUTLOOK

Surgery usually provides an effective repair and prevents further accidents of the same type. However, after the injury, the hip tends to be more susceptible than normal to *osteoarthritis*. In rare cases, the hip becomes stiff and painful, sometimes permanently so.

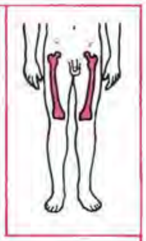
Femoral nerve

One of the primary nerves of the leg. It is made up of fibers from nerves in the second, third, and fourth segments of the lumbar spinal cord. The nerves emerge from the lower back region of the spine and run down into the thigh, where they branch to supply the skin and muscles of the front of the thigh. The nerve branches that supply the skin convey sensation; the branches that supply the muscles stimulate contraction of the *quadriceps muscle* of the thigh, causing the knee to straighten.

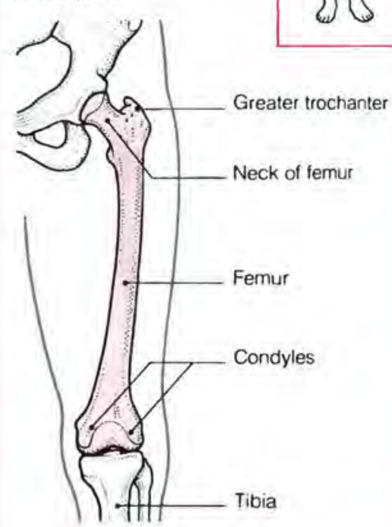
Damage to the femoral nerve (which impairs the ability of the knee

to straighten) is usually caused by a slipped disk in the lumbar region of the spine (see *Disk prolapse*). Damage may also occur as the result of a backward dislocation of the hip or, rarely, as a result of a *neuropathy*.

Femur



The medical name for the thigh bone, the longest bone in the body. The lower end hinges with the tibia (shin) to form the knee joint. The upper end is rounded into a ball (head of the femur) that fits into a socket in the pelvis to form the hip joint. The head of the femur is joined to the bone shaft by a narrow piece of bone called the neck of the femur. While it gives the hip joint a wide range of movement, the neck of the femur is a point of structural weakness and a common fracture site (see *Femur, fracture of*).



The femur can be felt through the skin at two sites. At the lower end, the bone is enlarged to form two lumps (the condyles) that distribute the weight-bearing load on the knee joint. On the outer side of the upper end of the femur is a protuberance (called the greater trochanter).

The shaft of the femur is surrounded by powerful muscles whose principal functions are to move the hip and knee joints. The shaft is also well supplied with blood vessels; because of this, a fracture can result in considerable blood loss.

LOCATION OF THE FEMUR

The femur extends from the hip joint, down the thigh, to the knee joint.

Femur, fracture of

The nature, symptoms, treatment, and possible complications of a fractured femur (thigh bone) depend on whether the bone has broken across its neck (the short section between the top of the shaft and the hip joint) or across the shaft.

NECK OF FEMUR

This type of fracture is very common in elderly people suffering from *osteoporosis* (thinning of the bone) and is usually associated with a fall. The broken ends of the bone are often considerably displaced; in such cases there is usually severe pain in the hip and groin (made worse by movement) and the leg cannot bear any weight. Occasionally, the broken ends of bone become impacted (wedged together). In this case there is less pain and walking is often still possible, which may delay reporting of the injury and detection of the fracture.

DIAGNOSIS AND TREATMENT Diagnosis of a suspected fracture is confirmed by X ray. If the bone ends are displaced, an operation using general anesthesia is necessary, either to realign the bone ends (a procedure called reduction) and to fasten them together with metal screws, plates, or nails, or to replace the entire head and neck of the femur with a metal or plastic substitute (see *Hip joint replacement*). Both procedures produce a stable repair, and hip and knee movement can be resumed immediately.

If the bone ends are impacted, the person is kept in bed for a few weeks to prevent any jarring movement that might dislodge the bones. The fracture heals naturally without surgery, but supervised exercise is necessary to maintain hip and knee mobility. X rays are taken periodically to determine how well the fracture is healing.

With either type of repair, walking is started with the aid of crutches, progresses to walking with a walker, walking with a cane, and, finally, walking without aid.

COMPLICATIONS These depend on the site of the fracture. A break at the union of the neck and shaft may result in hip deformity (see *Coxa vara*). A fracture across the neck itself may damage the blood supply to the head of the femur, causing the head to crumble (osteonecrosis). As a result, the bone ends may fail to fuse, or *osteoarthritis* may develop. In either case, more surgery (usually hip joint replacement) is required. Osteoarthritis may also develop even if avascular necrosis does not occur.

SHAFT OF FEMUR

This type of fracture usually occurs when the femur is subjected to extreme force, such as in an automobile accident. In most cases, the bone ends are considerably displaced, causing severe pain, tenderness, and swelling.

DIAGNOSIS AND TREATMENT Diagnosis of this injury is confirmed by X rays. With a fractured femoral shaft there is often substantial blood loss from the bone. In most cases, the fracture is repaired by an operation (using general anesthesia) in which the two ends of the bone are realigned and fastened together with a long metal pin. However, sometimes the bone ends can be realigned by manipulation, and surgery is not necessary. After realignment of the bones, the leg is supported with a *splint* and put in *traction* to hold the bone together while it heals.

Following both types of treatment, supervised exercise and massage of the knee, ankle, and foot is started to prevent the joints from becoming stiff. The progress of healing is checked regularly by X rays; when it is complete, weight bearing and walking is started gradually.

COMPLICATIONS These include failure of the bone ends to unite or successful fusion of the broken ends at the wrong angle, infection of the bone, or damage to a nerve or artery. All of these complications usually require more surgery. A fracture of the lower end of the shaft can result in permanent stiffness of the knee.

Fenoprofen

A *nonsteroidal anti-inflammatory drug* (NSAID). Fenoprofen is used to relieve pain and stiffness caused, for example, by *rheumatoid arthritis*, *osteoarthritis*, and *gout*. Fenoprofen is also used in the treatment of muscle and ligament sprains; it reduces pain and helps speed recovery.

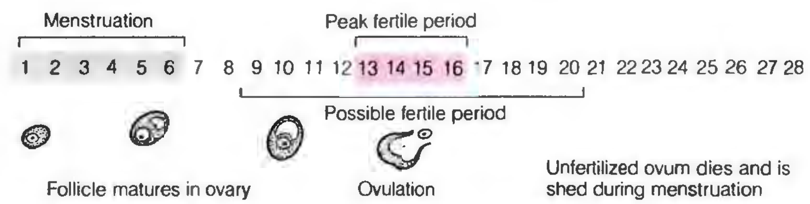
Ferrous sulfate

An alternative name for iron sulfate (see *Iron*).

Fertility

The ability to reproduce children without undue difficulty.

MALE FERTILITY

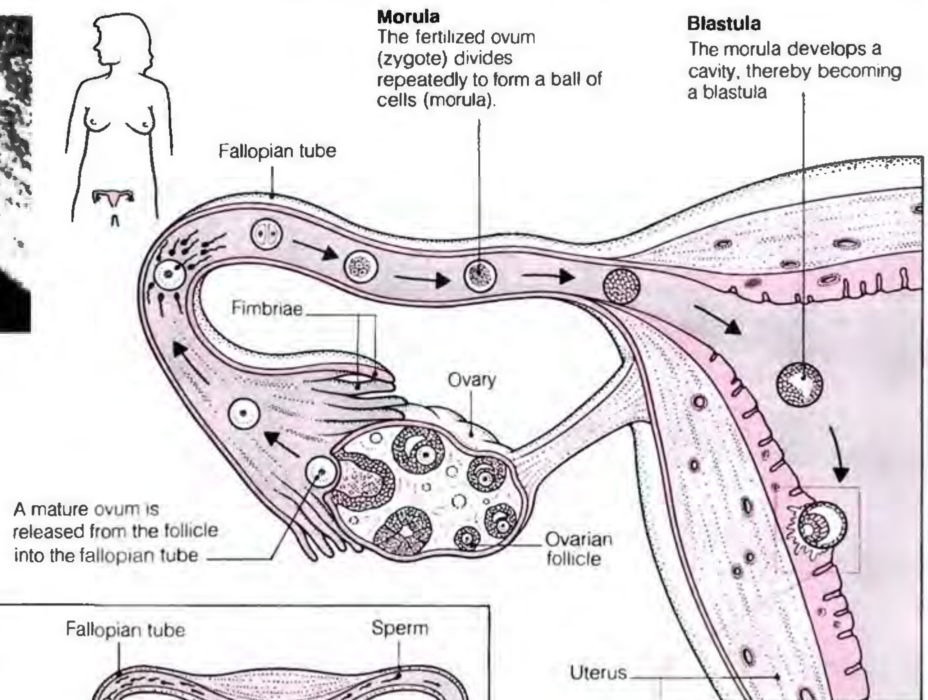


A man's fertility depends on the production of normal quantities of healthy *sperm* in the testes, and on the ability to achieve *erection* and to ejaculate *semen* into the vagina during *sexual intercourse*.

THE PROCESS OF FERTILIZATION

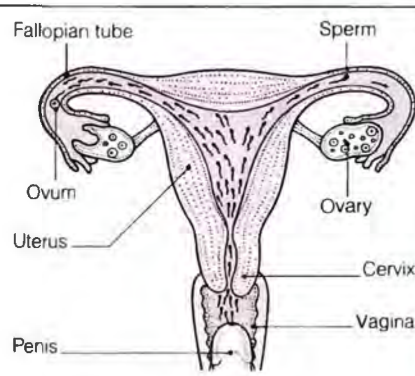
Fertilization occurs when the head of a sperm penetrates a mature ovum in a fallopian tube. After penetration, the nuclei (which contain the genetic material) of the sperm and ovum fuse, and the body and tail of the sperm drop off. The newly fertilized ovum, called a zygote, then forms an outer layer that is impenetrable to other sperm. The zygote undergoes repeated cell divisions as it passes down the fallopian tube, so that, by the time it reaches the uterus, it has grown into a solid ball of cells called a morula. It then develops an inner cavity with a small cluster of cells to one side; this is called a blastula.

FERTILE PERIOD

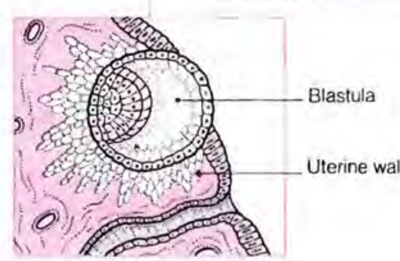


Ovulation occurs about halfway through the menstrual cycle (14 to 16 days before the start of a period), after which the released ovum is available for fertilization for about two days. Sperm can also live for approximately two days, so the actual fertile period is about four days.

Actual and possible fertile periods
Although the actual fertile period is about four days, the possible fertile period may last seven to 12 days, due to variations in how long the ovum and sperm can survive and the timing of ovulation. The illustration shows the actual and maximum possible fertile periods in a 28-day cycle.



Sperm and ovum
A single sperm penetrates the ovum, thereby fertilizing it. To achieve this, the sperm releases enzymes that dissolve a path through the ovum's outer layers.



JOURNEY OF THE SPERM

When semen is ejaculated into the vagina, as many as 500 million sperm are released, most of which are capable of fertilizing an ovum. But, as they travel upward (propelled by their whiplike tails), more than half are killed by acidic vaginal secretions; many more die during the journey up through the cervix and uterus and into the fallopian tubes. The journey can take from one to five hours, and, in the end, only a few thousand sperm have survived.

Life span of sperm
A sperm can live in a fallopian tube for up to 48 hours, during which time it is capable of fertilizing an ovum.

Blastula
The blastula embeds in the uterine wall (implantation), where it develops into an embryo and also forms the placenta

The testes—under the influence of *gonadotropin hormones* from the pituitary gland—produce hundreds of millions of sperm. The large output is necessary for normal fertility because only about one in 80,000 sperm ejaculated into the vagina reaches a fallopian tube (see *Fertilization*).

Normal fertility also requires a large proportion of the sperm to be healthy. After ejaculation, the sperm must be able to pass through the hostile environment of acid secretions in the vagina, penetrate a barrier of mucus around the cervix, and swim upward into the fallopian tubes.

Men become fertile at puberty and usually remain so (although to a lesser degree) well into old age.

FEMALE FERTILITY

The ability of a woman to conceive depends on normal *ovulation* (the monthly production of a healthy *ovum* by one of the ovaries) and the egg's unimpeded passage down a fallopian tube toward the uterus, on thinning of the mucus surrounding the mouth of the cervix to enable sperm to penetrate more easily, and on changes in the lining of the uterus that prepare it for the implantation of a fertilized ovum. These processes are in turn dependent on normal production of gonadotropins by the pituitary, and on production of the sex hormones *estrogen* and *progesterone* by the ovaries.

Women become fertile at puberty and remain so until *menopause*, which usually occurs during a woman's 40s or 50s. (See also illustrated box, left; *Fertility drugs*; *Infertility*.)

Fertility drugs

A diverse group of hormonal or hormone-related drugs used to treat female and male *infertility*. In women, fertility drugs may be prescribed when abnormal hormone production by the pituitary gland or ovaries disrupts *ovulation* or causes mucus around the cervix to become so thick that sperm cannot penetrate it. In men, fertility drugs may be used when abnormal hormone production by the pituitary gland or the testes interferes with normal sperm production. (See also *Clomiphene*; *Gonadotropin hormones*; *Infertility*.)

Fertilization

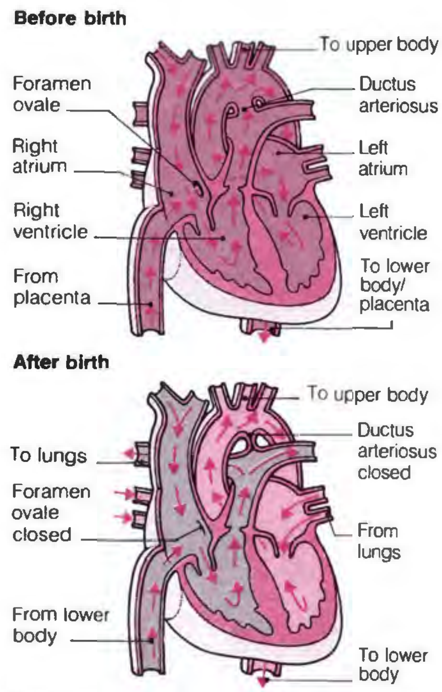
The union of a *sperm* and an *ovum*. In natural fertilization, this occurs after *sexual intercourse* (see box). Fertilization may also occur as a result of semen being artificially introduced into the cervix (see *Artificial insemination*), or may take place in the laboratory (see *In vitro fertilization*).

Fetal alcohol syndrome

A combination of birth defects resulting from high alcohol consumption by the mother during pregnancy.

Even small amounts of alcohol may be harmful in pregnancy, since (like tobacco) alcohol seems to affect fetal growth. The risks of miscarriage and congenital physical defects may also be increased. Fetal alcohol syndrome, however, normally occurs only if there is persistent alcohol consumption during pregnancy. Fetal alcohol syndrome has been reported in babies of women who consistently drank 30 milliliters of alcohol per day (equal to two mixed drinks or two to three bottles of beer or glasses of wine). While there is no evidence that an occasional glass of wine or beer is dangerous, it is best to abstain completely from alcohol during pregnancy.

The affected baby is abnormally short, has small eyes with epicanthic folds (vertical folds of skin extending from the upper eyelid to the side of the nose), and a small jaw. He or she may have a small brain, a cleft palate, heart defects, a dislocated hip, and other joint deformities. As a newborn, the baby sucks poorly, sleeps badly, and is irritable. In effect, he or she is suffering from alcohol withdrawal.



Almost one fifth of affected babies die during the first few weeks of life; many who survive are physically and mentally retarded to some degree. (See also *Alcohol dependence*.)

Fetal circulation

Blood circulates differently in the fetus than it does after birth (see *Circulatory system*). The fetus neither breathes nor eats, so oxygen and nutrients are obtained—via the *placenta* and *umbilical cord*—from the mother's blood. The other fundamental difference in circulation is that blood bypasses the lungs in the fetus.

Oxygen and nutrients enter the fetal blood in the placenta, an organ embedded in the inner lining and wall of the uterus and connected to the fetus by the umbilical cord. The oxygenated blood flows to the fetus along a vein in the umbilical cord, then enters the right atrium (right upper chamber) of the heart, after which, instead of flowing to the lungs, it bypasses them. It does this by passing into the left atrium through a hole called the foramen ovale.

The blood then passes to the left ventricle (left lower chamber), from where it is pumped to the upper parts of the body to provide the tissues with oxygen. It then returns to the heart, flowing into the right atrium and from there into the right ventricle. (After birth, blood pumped from this ventricle passes via the pulmonary artery to the lungs for reoxygenation and elimination of carbon dioxide and other wastes.) However, in the fetus, the blood is only partly deoxygenated at this stage and has more tissues to supply with oxygen. Bypassing the lungs again, it flows from the pulmonary artery into the aorta; it does this through a channel called the ductus arteriosus which, like the foramen ovale, closes after birth.

Fetal heart circulation

In the fetus, blood passes from the right atrium of the heart to the left atrium through the foramen ovale. Another channel, the ductus arteriosus, allows blood to pass from the pulmonary artery to the aorta. Both channels close after birth.

The aorta carries the blood to the lower parts of the body, from where, completely deoxygenated, it is carried by two arteries in the umbilical cord to the placenta. There, carbon dioxide and other waste products diffuse into, and are carried away by, the mother's blood and are excreted by the mother.

In rare cases, the foramen ovale or ductus arteriosus fails to close after birth, causing a congenital heart disorder (see *Heart disease, congenital*).

F

Fetal distress

Physical stress experienced by a fetus during labor as the result of not receiving enough oxygen. The most stressful period of labor for a baby is during a contraction, when the uterus tightens to squeeze it out and thus reduces its supply of oxygen from the placenta. If, in addition, there are problems with the labor, such as the mother losing blood or having a pelvis too small for the size of the baby's head, the amount of oxygen reaching the baby may be inadequate.

MONITORING

Fetal distress causes the baby's heart rate to slow, which can be seen as a dip on a cardiotocograph (see *Fetal heart monitoring*). Alternatively, a distressed baby may show no variability in heart rate. This is in contrast to a healthy baby, whose heart rate varies within a normal range of from 120 to 160 beats per minute. The obstetrician keeps a close watch on the heart rate and, if necessary, may obtain a blood sample from the baby's scalp for analysis. High acidity indicates that the baby is not getting enough oxygen. In addition, the fluid around the baby is examined for signs of meconium (fetal feces), which a distressed baby often passes.

DELIVERY

A fetus in distress needs to be delivered promptly—by *cesarean section* if oxygen shortage occurs during the first stage of labor, and by *forceps delivery* or *vacuum extraction* during the second stage.

Fetal heart monitoring

Use of an instrument to record and/or listen to an unborn baby's heart beat during pregnancy and labor. Some form of monitoring of fetal well-being is performed during labor in all hospitals. In its simplest form the nurse or obstetrician uses a special fetal stethoscope to listen to the baby's heart beat. A more sophisticated version is the electronic fetal heart monitor, which is used to make a continuous paper or sound recording of the heart beat.

WHY IT IS DONE

In pregnancy, monitoring is carried out at intervals if tests indicate that the placenta is not functioning normally or if the baby's growth has been slow. Uterine contractions or other stimuli, such as the baby kicking, increases the heart rate in a healthy fetus; the obstetrician can detect this using a fetal heart monitor.

During labor, monitoring can detect *fetal distress*, caused by the baby not receiving enough oxygen. A fetus deprived of oxygen has an abnormal heart rate. Fetal monitoring can detect this abnormality and, at an early stage, allows the attending physician to take appropriate action.

HOW IT IS DONE

An electronic fetal monitor is used to make a continuous recording of the baby's heart beat. The beat is picked up either externally by an ultrasound transmitter strapped to the mother's abdomen or, as an alternative during labor, internally by an electrode attached to the baby's head and linked to the recording device by a wire inserted through the mother's vagina. The fetal heart beat is amplified and heard as a beeping noise or printed as a paper trace. Electronic monitors also have a pressure gauge for measuring and recording contractions. Contractions of the uterus can also be measured by an external gauge that is strapped to the mother's abdomen or by an internal plastic tube that is inserted through the vagina into the amniotic fluid.

ADVANTAGES AND DISADVANTAGES

Electronic fetal monitoring has the advantage of giving the physician a minute-by-minute assessment of the baby's condition. Many obstetricians are convinced that babies are less likely to become hypoxic (deprived of oxygen) during labor with continuous monitoring and therefore feel that the monitoring results in healthier babies.

However, routine electronic fetal monitoring has been controversial for a number of reasons. Critics have claimed that it limits maternal mobility during labor and that it leads to overdiagnosis of fetal distress and therefore to unnecessary cesarean sections. Critics also claim that external monitoring unnecessarily exposes the healthy baby to ultrasound and that internal monitoring may increase the risk of infection during labor without resulting in improvement in the outcome of low-risk pregnancies.

Fetishism

Reliance on special objects for achieving sexual arousal. Fetishism is thought to be rare and restricted to men; because of the nature of the practice, there are no reliable statistics.

The objects need not have an obvious sexual meaning; they include shoes, gloves, rubber or leather garments, and parts of the body such as the feet or ears. It seems that once a particular fetish has led to successful orgasm, it becomes increasingly difficult to obtain sexual satisfaction without it. Nevertheless, many fetishists are able to have a stable sexual relationship, provided their partners join in the practice.

CAUSES

Fetishism usually has no obvious cause, although it may, rarely, result from certain forms of brain damage. According to psychoanalysts, the origin may be a childhood *fixation* of sexual interest upon some aspect of the mother's body or appearance.

TREATMENT

As long as fetishism does not impair sexual or social life, there is no reason for any form of medical interference. Treatment is needed only if the behavior is causing distress or if there are persistent criminal acts, such as stealing underwear.

Fetoscopy

A procedure for directly observing a fetus inside the uterus by means of a fetoscope, a type of *endoscope* (flexible viewing tube). The fetoscope can also be used to take samples of fetal blood and tissue for *biopsy* and to permit treatment of some fetal disorders.

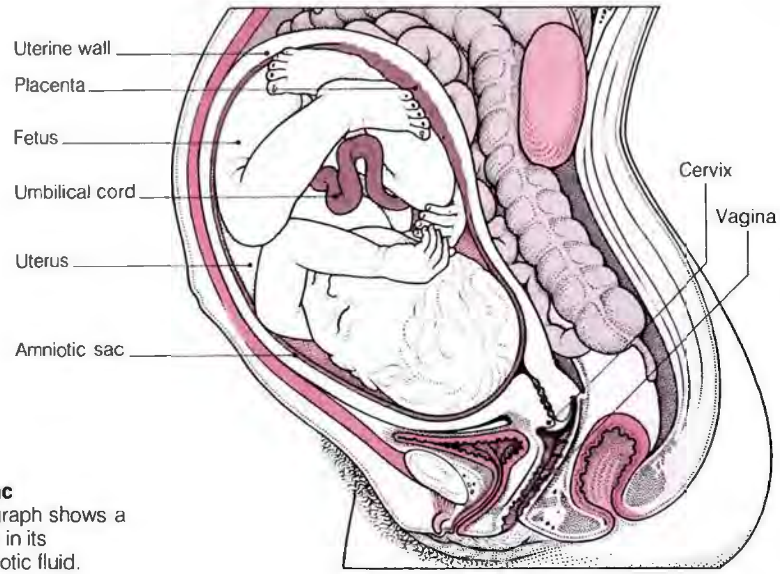
WHY IT IS DONE

Fetoscopy is used to diagnose various congenital abnormalities and genetic defects before the baby is born. Because the technique carries some risks, it is attempted only if there is a higher-than-normal chance that the baby will have some abnormality (for example, if the mother has already had an abnormal baby or if there is a family history of genetic defects).

Fetoscopy allows a close-up look at the developing fetus, particularly the face, limbs, genitals, and spine, and can detect abnormalities, such as spinal column defects, facial clefts, and limb defects. By attaching additional instruments, the fetoscope can also be used to surgically correct some defects, such as certain urinary system disorders. (See also *Amniocentesis*; *Chorionic villus sampling*.)

Fetus

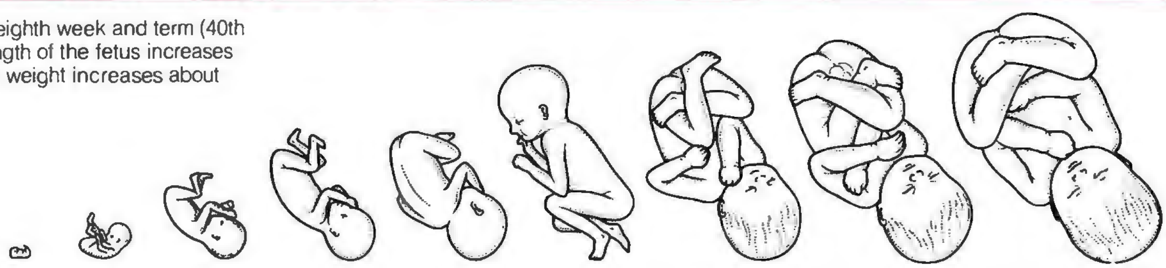
The unborn child from the end of the eighth week after fertilization until birth. For the first eight weeks, the unborn child is called an *embryo*.



The fetus develops in the mother's uterus in a sac filled with *amniotic fluid*, which cushions it against injury. The oxygen and nutrients the fetus needs are supplied through the *placenta*, an organ embedded in the inner wall of the uterus and attached to the fetus by the umbilical cord (see box).

DEVELOPMENT OF THE FETUS

By the 32nd week of pregnancy, the internal organs of the fetus are almost fully mature and it is perfectly formed. In most cases, the fetus has turned to lie head-down in the pelvis.



Fetus in sac
This photograph shows a young fetus in its sac of amniotic fluid.

GROWTH OF THE FETUS FROM 8 TO 40 WEEKS

Between the eighth week and term (40th week), the length of the fetus increases twentyfold; its weight increases about 1,700 times.

Week	8	12	16	20	24	28	32	36	40
Length	1.0 in.	3.0 in.	6.5 in.	10.0 in.	13.0 in.	14.5 in.	16.0 in.	18.0 in.	20.0 in.
Weight	0.07 oz.	0.6 oz.	5.0 oz.	12.0 oz.	1.3 lbs.	2.0 lbs.	3.5 lbs.	5.5 lbs.	7.5 lbs.

Fever

Known medically as pyrexia, a fever is defined as a body temperature above 98.6°F, measured in the mouth, or 99.8°F, measured in the rectum.

A fever may be accompanied by other symptoms, such as shivering, headache, sweating, thirst, a flushed face, hot skin, and faster than normal breathing. In some cases there may be rigors (attacks of severe shivering followed by drenching sweats and a sudden fall in body temperature). Confusion or delirium sometimes occurs with fever, especially in the elderly; a very high fever may also cause seizures or coma.

CAUSES

Most fevers are caused by bacterial or viral infections, such as typhoid, tonsillitis, influenza, or measles. In these cases, proteins called pyrogens are released when the white blood cells of the body's defense system fight the microorganisms responsible for the illness. These pyrogens act on the temperature-controlling center in the brain, causing it to raise body temperature in an attempt to destroy the invading microorganisms.

Fever may also occur in noninfectious conditions, such as dehydration, thyrotoxicosis (a condition that results from overactivity of the thyroid gland), myocardial infarction (heart attack), and tumors of the lymphatic system. Its function is not understood in such cases. (See also *Fever* chart, next page.)

TREATMENT

A physician should be consulted if a fever lasts longer than three days or if there are atypical accompanying symptoms, such as severe headache with stiff neck, abdominal pain, or painful urination. Medical advice is also necessary if the sufferer is a baby less than 6 months old, a child with a history of febrile seizures (see *Seizures, febrile*), or an elderly person.

Antipyretic (temperature-lowering) drugs may be given to treat fevers due to infections; such drugs also help relieve any aches and pains accompanying the fever. Otherwise, treatment is directed toward the underlying cause (for example, giving the appropriate antibiotics for a bacterial infection).

Febrile seizures can often be prevented by cooling the entire body as soon as the fever starts, either in a lukewarm bath or by sponging with lukewarm water.

Fever blister

Also known as a cold sore, a blister caused by the *herpes simplex* virus, usually on the face. The term dates from the preantibiotic era, when such blisters would often appear during feverish infectious illnesses.

FEVER Temperature of about 100°F (38°C) or above. Consult your physician if your temperature remains raised for longer than 48 hours or rises above 104°F (40°C).

? Do you have a cough?

- YES → Are you short of breath even when resting AND/OR have you been coughing up brownish sputum (phlegm)?
  - YES → ☎ **Call your physician without delay!** A chest infection such as pneumonia is a possibility. This may be serious, especially in the elderly and those in poor health.
    See • *Pneumonia*
  - NO → Have you been coughing up gray-yellow sputum (phlegm) AND/OR have you been wheezing?
    - YES → Infection of the airways in the lung is a possibility. Consult your physician.
      See • *Bronchitis*
    - NO → Do you have one or more of the following symptoms?
      • headache
      • aching limbs
      • runny nose
      • sore throat
      - YES → A generalized viral infection such as the flu is a strong possibility. Take analgesics (painkillers) as required and drink plenty of fluids.
      - NO → go to next question
- NO → go to next question

? Do you have a severe headache?

- YES → Do you have two or more of the following symptoms?
  • pain when you bend your head forward
  • nausea or vomiting
  • dislike of bright light
  • drowsiness or confusion
  - YES → ☎ **Call your physician without delay!** Inflammation of the membranes surrounding the brain due to infection may be the cause of such symptoms.
    See • *Meningitis*
  - NO → Do you have one or more of the following symptoms?
    • aching limbs
    • runny nose
    • sore throat
    - YES → A generalized viral infection such as the flu is a strong possibility. Take analgesics (painkillers) as required and drink plenty of fluids.
    - NO → go to next question
- NO → go to next question

? Do you have a sore throat?

- YES → You may have a throat infection. Consult your physician.
  See • *Pharyngitis*
  • *Strep throat*
  • *Tonsillitis*
- NO

Continued on next page

Do you have one or more of the following symptoms?
- pain in the small or side of the back
- abnormally frequent urination
- pain when passing urine
- pink or cloudy urine

YES → **Consult your physician without delay!**
An acute infection of the kidney or bladder may be the cause of this.

See • *Cystitis*
• *Glomerulonephritis*
• *Pyelonephritis*

NO ↓

Have you recently returned from a stay in a hot country?

YES → **Consult your physician without delay!**
A tropical disease that is rare in this country is a possibility.

See • *Malaria*
• *Typhoid fever*

NO ↓

Have you spent most of the day in strong sunlight or in very hot conditions?

YES → Exposure to heat may have caused your temperature to rise. In most cases your temperature will return to normal after you have rested for an hour or so in a cool room. Drink plenty of fluids. Call your physician at once if the fever continues to rise.

NO ↓

Fever in children
A fever is usually caused by infection from a virus or bacterium. However, a child may also become feverish if allowed to become overheated. Do not give aspirin; use an aspirin substitute. A raised temperature causes a child's forehead to feel hot and causes increased sweating and a general feeling of being sick. Normal temperature may vary from 97 to 99°F (36 to 37.5°C). Minor fluctuations within this range are no cause for concern if your child seems otherwise well.

If your baby's temperature rises above 102°F (39°C), whatever the suspected cause, call your physician at once. High temperatures can lead to seizures in some babies.

Are you a woman?

YES → Have you had a baby within the past two weeks?

YES → **Call your physician without delay!**
Puerperal infection, although rare today, is a possible cause of fever after childbirth. It occurs when the uterus and/or vagina become infected after delivery. If, however, you also have pain or redness of the breast, you may have a breast infection.

See • *Breast-feeding*
• *Mastitis*
• *Puerperal sepsis*

NO ↓

Do you have pain in the lower abdomen AND/OR have you had an unusually heavy or unpleasant-smelling vaginal discharge?

YES → An infection of the uterus AND/OR fallopian tubes is a possible cause of such symptoms.
Consult your physician.

See • *Salpingitis*

NO ↓

If you are unable to make a diagnosis from this chart, consult your physician.

Fiber, dietary

The indigestible components of plants, some of which are fibrous. Dietary fiber includes certain types of polysaccharides, cellulose, hemicelluloses, gums, and pectins, and also lignin (see *Carbohydrates*).

STRUCTURE

Cellulose, hemicelluloses, and lignin form the main structural components of plant cell walls. Pectins and gums are viscous substances in plant sap. Together, these five substances provide the plant with a structure that is stable and partially rigid. Humans do not possess the necessary enzymes to digest these substances. They pass through the digestive system virtually unchanged and are unable to be used as a source of energy. Some of them are fermented by bacteria in the large intestine to produce acids and gas.

FUNCTION

Some components of dietary fiber have the capacity to bind water and add bulk to the feces, which then pass through the intestines more easily, aiding normal bowel function. For this reason, dietary fiber can be effective in treating *constipation* and such disorders as *diverticular disease*. It may also be valuable in the treatment of *irritable bowel syndrome*.

The easiest way to increase the amount of fiber in the diet is to increase the intake of unrefined carbohydrate foods such as whole-grain bread, cereals, and grains, root vegetables, and fruits. (See also *Nutrition*.)

GOOD SOURCES OF FIBER (per 100-gram portion)

Essential for the efficient working of the digestive system, fiber is usually eaten as fruit or grains. Among the best sources are bran, apricots, prunes, and whole-grain bread. Eating sufficient fiber in food can reduce constipation

Fiberoptics

The transmission of images through bundles of thin, flexible, glass or plastic threads that propagate light by total internal reflection. This means that all the light from a powerful external source travels the full length of the fiber without losing its intensity.

Fiberoptics has led to the development of *endoscopes*, instruments that enable structures deep within the body to be viewed directly. One bundle of fibers carries light to the far end of the instrument and another bundle transmits the image to the viewer's eye or to a still or video camera. The flexibility of the fibers allows them to be passed through the loops of the large intestine or down through the curve of the stomach and into the duodenum without distorting the image. (See also *Endoscopy*.)

Fibrillation

Localized, spontaneous, rapid contractions of individual muscle fibers. Unlike *fasciculation* (a similar muscular "quivering"), fibrillation cannot be seen under the skin. It is detected by tests such as an electromyogram (*EMG*) or electrocardiogram (*ECG*).

Fibrillation usually occurs after a nerve that supplies a muscle is destroyed, in which case the affected muscle becomes weak and wastes away. Fibrillation of the heart muscle is caused by disruption of the spread of nerve impulses through the muscle wall of a heart chamber. As a result, the chamber no longer contracts as a single unit; instead, it produces a rapid, irregular rhythm (see *Atrial fibrillation*; *Ventricular fibrillation*).

Fibrinolysis

The breakdown or dissolution of fibrin, the principal component of any blood clot. Fibrin is a stringy protein that is formed in blood from a precursor substance, fibrinogen, as the end product of coagulation. Along with platelets and red blood cells, fibrin forms the final clot that plugs and seals a damaged blood vessel (see *Blood clotting*).

In addition to the coagulation system, blood contains a fibrinolytic system, the end product of which is an enzyme called plasmin, formed from a precursor called plasminogen. Plasmin acts directly to break up fibrin filaments and thus dissolve clots.

The fibrinolytic system is activated in parallel with the coagulation system when a blood vessel is damaged. It helps restrain clot formation in blood vessels (thus helping to prevent clots from blocking blood vessels) and eventually dissolves a clot once a broken blood vessel wall has healed. *Thrombosis* (i.e., the formation of undesirable, persistent blood clots) occurs only if there is a disturbance in the balance between mechanisms that encourage clot formation, such as sluggish blood flow, and those, such as fibrinolysis, that restrain clot formation or dissolve clots.

Fibrinolytic drugs

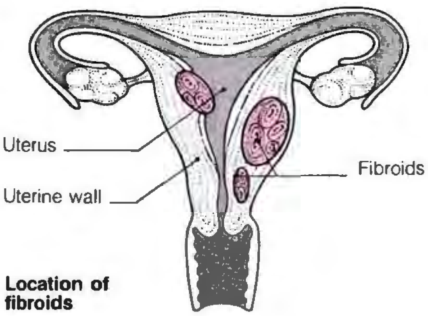
Drugs used to dissolve blood clots. (See *Thrombolytic drugs*.)

Fibroadenoma

A benign, fibrous tumor found commonly in the breast. Fibroadenomas of the breast are painless, firm, round lumps, usually 0.5 to 2 inches (1 to 5 cm) in diameter, and movable. Fibroadenomas occur most often in women under 30 and are more common in black women. Multiple fibroadenomas may develop in one or both breasts.

Removal is accomplished using either a local or a general anesthetic. After removal, the lump is examined by a pathologist to rule out the small chance of breast cancer.

Fibrocystic breast disease



See *Breast lump*.

Fibrocystic disease

A term that may refer either to the inherited disorder *cystic fibrosis*, characterized by the secretion of abnormal mucus by various glands and by recurrent respiratory infection, or to the presence of single or multiple benign tumors or cysts in the breast (see *Breast lump*; *Mastitis*).

Fibroid

A benign tumor of the uterus. Fibroids consist of smooth muscle bundles and connective tissue that grow slowly within the uterine wall. As the fibroid enlarges, it may grow within the muscle so that the uterine cavity is distorted, or it may protrude from the uterine wall into the uterine cavity but remain attached by a stalk. Fibroids vary from the size of a pea to that of a grapefruit, and several of them may develop simultaneously.

Location of fibroids

INCIDENCE AND CAUSE

Fibroids are one of the most common tumors, occurring in about 20 percent of women over 30. They appear most often in women aged 35 to 45 and seldom before age 20.

The cause of fibroids is unknown, but it is thought to be related to an abnormal response to estrogens. Pregnancy and estrogen hormone replacement therapy can cause fibroids to enlarge; decreased estrogen production after the menopause usually causes them to shrink.

SYMPTOMS

In many cases there are no symptoms, especially if the fibroid is small. If the fibroid grows and erodes the lining of the uterine cavity, it may cause heavy or prolonged menstrual periods; if severe, the bleeding can lead to iron-deficiency *anemia*. Large fibroids may exert pressure on the bladder, causing discomfort or urinary frequency, or on the bowel, causing backache or constipation. Occasionally, a fibroid attached to the uterine wall becomes twisted and causes a sudden pain in the lower abdomen. Fibroids that distort the uterine cavity may cause recurrent miscarriage or infertility.

DIAGNOSIS

Symptomless fibroids are often discovered during a routine pelvic examination. When fibroids are thought to be the cause of menstrual disturbances or responsible for other symptoms, *ultrasound scanning* can confirm the diagnosis.

TREATMENT

Small, symptomless fibroids usually require no treatment, but regular examinations may be necessary to determine if they are growing. Surgery is required for fibroids causing serious symptoms or complications. A *hysterectomy* (removal of the uterus) is sometimes considered if there are large numbers of fibroids. Myomectomy (shelling out the fibroid from its capsule) saves the uterus and is another alternative. Fibroids tend to shrink after the menopause.

Fibroma

A benign tumor of the cells that make up connective tissues (tissues that surround and support specialized structures). For example, a neurofibroma is a tumor of the cells that surround nerve fibers (see *Neurofibromatosis*). An ovarian fibroma is a tumor of the cells that surround the follicles from which ova (eggs) develop. If the tumor is not causing symptoms, treatment is not required.

Fibrosarcoma

A rare, malignant (cancerous) tumor of the cells that make up connective tissue (any tissue that surrounds and supports specialized structures). A fibrosarcoma may develop from a fibroma (a benign tumor) or it may be malignant from the start.

A fibrosarcoma is usually found in the tissues around the muscles in a limb but it can also affect a bone or the cells around nerve fibers. It can spread to damage nearby structures.

A fibrosarcoma causes a localized swelling, which may not be noticed at first, depending on its site and how deep it is. Occasionally, widened veins appear on the skin over the growth; the fibrosarcoma may feel warm or may pulsate.

Treatment is by surgical removal or *radiation therapy*; this may be only temporarily successful if cells from the tumor have spread via the blood to start growths elsewhere.

Fibrosis

An overgrowth of scar or connective tissue (any tissue that surrounds and supports specialized structures). Fibrous tissue may be formed as an exaggerated healing response to injury, infection, or inflammation. It can also result from a lack of oxygen in a tissue, usually due to inadequate blood flow through it—for example, in heart muscle damaged by myocardial infarction (heart attack).

As fibrous tissue replaces specialized structures (such as kidney cells or muscle cells) the function of the organ concerned is impaired and its structure modified.

An overgrowth of fibrous tissue can compress and thus block hollow structures. An example is *retroperitoneal fibrosis*, in which the tubes draining urine from the kidneys (ureters) into the bladder become blocked.

Fibrous tissue formed within a muscle after a tear shortens the muscle and disrupts the normal contraction of fibers. This increases the likelihood of further tears unless the muscle is stretched and exercised.

Fibrositis

Pain and stiffness in the muscles around joints and sometimes in the back. Fibrositis is not a medical term, and some physicians refuse to recognize the condition because investigation usually fails to reveal any inflammation of the muscles. In addition, there is no other detectable reason for the pain in most cases.

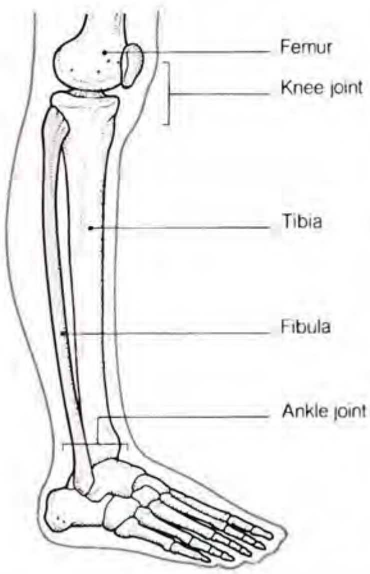
Tension and bad posture may cause the condition. It seems to occur more often in anxious people and in those who spend time sitting in a cramped position. Sometimes, an attack occurs after an infection or new exercise. Fibrositis is most common in middle-aged and elderly people.

SYMPTOMS

Pain and stiffness may be felt in the neck, shoulders, chest, buttocks, and knees, as well as in the back. There is usually no restriction of movement. Trigger zones may be felt in the affected muscles and are tender to the touch. In some cases, attacks (which are generally worse in cold, damp weather) are accompanied by exhaustion and disturbed sleep.

TREATMENT

Analgesics (painkillers), hot baths, massage, and relaxation exercises can usually relieve the pain and stiffness.



It is likely that exercises to improve posture, starting with a gradual program to tone the muscles, can help prevent attacks. (See also *Back pain*.)

Fibula

The outer and thinner of the two long bones of the lower leg. The fibula is much narrower than the other bone, the *tibia* (shin), to which it runs parallel and to which it is attached at both ends by ligaments. The top end of the fibula does not reach the knee, but the lower end extends below the tibia and forms part of the ankle.

LOCATION OF THE FIBULA

The fibula lies beside the tibia on the outside of each lower leg.

The main function of the fibula is to provide an attachment for muscles. It provides little supportive strength to the lower leg, which is why bone can safely be taken from it for grafting elsewhere in the body.

FRACTURE

The fibula is one of the most commonly broken bones. The usual site of fracture is just above the ankle as the result of a violent twisting movement, which can occur in a severe ankle sprain. Rarely, such a fracture of the fibula occurs with dislocation of the ankle, with or without fracture of the tibia (see *Pott's fracture*).

A suspected fracture of the fibula is X rayed; if the diagnosis is confirmed, the lower leg is immobilized in a plaster cast to allow the bone to heal, but, if the fracture occurs in the middle portion of the fibula, no immobilization is necessary for healing. With a severe fracture (especially accompanied by dislocation), surgery may be necessary to fasten together broken pieces of bone with metal pins.

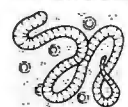
A fractured fibula may take up to six weeks to heal, depending on the severity of the break and the age of the person.

Fifth disease

An infectious childhood disease characterized by a widespread rash. It is also known as slapped cheeks' disease (because it often starts as a dramatic rash on the cheeks) or as erythema infectiosum. Fifth disease is the least well known of five common childhood infections, the other four being *measles*, *mumps*, *chickenpox*, and *rubella* (German measles).

Fifth disease affects young children, usually occurring in small outbreaks in the spring. The cause is a virus known as parvovirus.

SYMPTOMS AND TREATMENT



The rash starts on the cheeks as separate, rose-red, raised spots, which subsequently converge. Within a few days the rash spreads in a lacy pattern over the trunk, buttocks, and limbs. It is often accompanied by mild fever.

The only treatment required is bed rest, plenty of clear fluids, and acetaminophen to reduce any fever. The rash usually clears within 10 days.

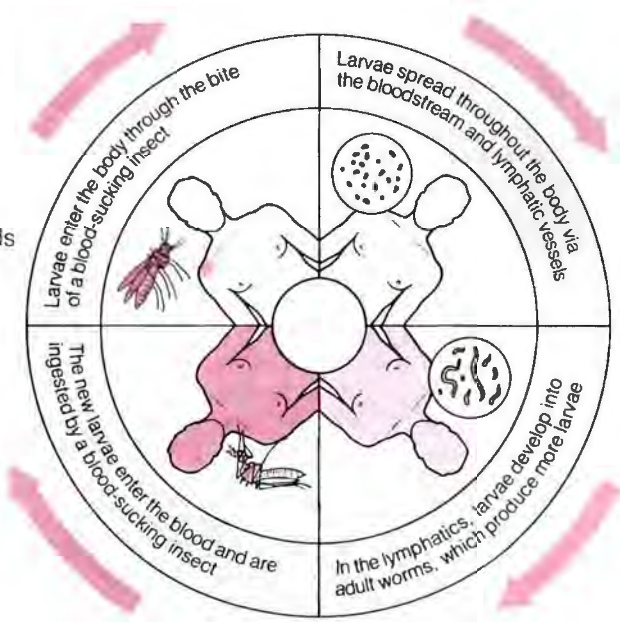
Fight or flight response

The physical response when the sympathetic division of the *autonomic nervous system* is aroused. The features are common to all animals, including man, and are a reaction to sensing a threat of any kind. Epinephrine, norepinephrine, and other hormones are released from the adrenal glands and the nervous system, leading to a raised heart rate, dilation of the pupils, the hair standing on end, and increased flow of blood to the muscles. All these responses make the body more efficient in either fleeing or fighting the apparent danger. These physiological changes occur in fear and also in *anxiety* and its disorders.

Filariasis

A group of tropical diseases caused by various parasitic worms or their larvae, which are transmitted to man by insect bites. Adult females, which vary in length from three quarters of an inch (2 cm) to 20 inches (50 cm), produce thousands of microfilariae (larvae) that are carried throughout the body in the bloodstream. Blood-sucking insects (primarily certain species of mosquito, fly, and midge) ingest the microfilariae while feeding on blood from infected people and transmit them by biting others.

Filariasis is prevalent in tropical Africa, Indonesia, the South Pacific, coastal Asia, southern Arabia, southern Mexico, and Guatemala.



TYPES AND SYMPTOMS

Some species of worm live in the lymphatic vessels, which they block. This results in localized *edema* (an accumulation of fluid in the tissues, causing swelling). Following repeated infections, the affected area—commonly a limb or the scrotum—becomes enormously enlarged and the skin becomes thick, coarse, and fissured, leading to a condition known as *elephantiasis*.

The larvae of another type of worm invade the eye, causing blindness (see *Onchocerciasis*). A third type, which may sometimes be seen and felt moving just beneath the skin, produces irritating, sometimes painful areas of edema called Calabar swellings.

THE CYCLE OF FILARIASIS

Filariasis is caused by parasitic worms and/or their larvae. There are several stages in the development of this infection as it spreads through the body.

DIAGNOSIS AND TREATMENT

The diagnosis of filariasis is confirmed by microscopic examination of blood or lymph fluid for the presence of microfilariae.

A three-week course of the drug diethylcarbamazine usually cures the infection, but may cause a reaction marked by fever, sickness, and muscle and joint pains.

PREVENTION

Where resources are available, filariasis can be controlled by all persons taking diethylcarbamazine preventively and by the use of insecticides, repellents, nets, and protective clothing to help avoid insect bites. (See also *Roundworms; Guinea worm disease; Insects and disease.*)

Filling, dental

The process of replacing a chipped or decayed area of a tooth with an inactive material. The term is also used to describe the restorative (filling) material itself. Amalgam, a hard-wearing mixture of silver, mercury, and other metals, is generally used for back teeth, where the filling will not show. Tooth-colored plastic material, porcelain, or acrylic is more likely to be used for front teeth. Other substances, such as gold, also are used.

WHY IT IS DONE

When enamel is damaged, bacteria can invade the dentin beneath and eventually attack the pulp (blood vessels and nerves), causing the tooth to die. It is therefore preferable to repair teeth at as early a stage as possible—ideally when only the enamel is affected. Filling also restores a tooth to its original shape, which is important not only for appearance but for maintaining a correct bite.

HOW IT IS DONE

If the filling required is large or in a sensitive area, the dentist will numb the surrounding gum with a local anesthetic. Any soft, decayed material is scooped out with sharp instruments. A high-speed drill is used to remove harder material and to shape a hole that will hold the filling securely. While the dentist works, a suction tube placed in the patient's mouth draws away saliva; the cavity is kept as dry as possible with occasional bursts of compressed air.

If the pulp is exposed, the bottom of the cavity is lined with a sedative paste to protect the sensitive pulp from pressure and temperature changes. If one or more of the walls of the tooth is missing because of extensive decay, a matrix (steel band) may be placed around the tooth to support the filling. The dentist then mixes the amalgam (or other filling material), which at first has a gummy consistency, and packs it into the cavity, contouring the surface so that it is smooth. The filling sets sufficiently to allow the matrix to be removed after a few minutes. The amalgam hardens completely over the next 24 hours.

If a front tooth is chipped, the dentist may use a *bonding* technique in which the surface of the tooth is etched with a mild acid solution and plastic or porcelain tooth-colored material is then attached to the roughened surface, shaped, polished, and finished.

OUTLOOK

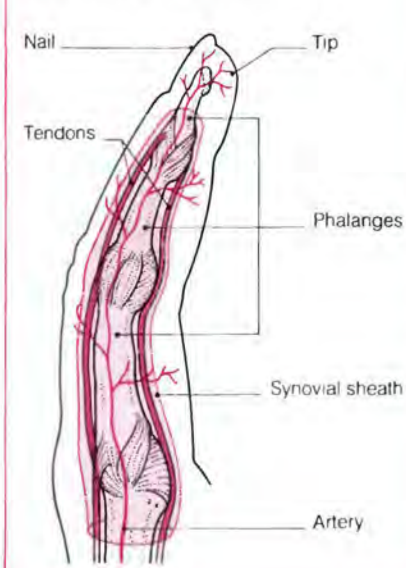
Amalgam fillings have a limited longevity and may need to be replaced after about 10 years. Occasionally, a filling needs to be replaced earlier—for example, if decay has continued to spread underneath the filling, either because of leakage at the filling margins or due to recurrent decay. Occasionally, fillings are dislodged, usually by chewing on sticky candy, or they fracture as a result of biting.

Film badge

A device that enables hospital staff members to monitor their exposure to radiation. Film badges are worn by those who perform X-ray procedures and radiation therapy to keep their exposure within safe levels.

The badge consists of a piece of photographic film in a holder that is worn on the clothing. The film has a fast (sensitive) emulsion on one side and a slow emulsion on the other. Small doses of radiation blacken the fast emulsion only; higher dosages start to blacken the slow emulsion and make the fast emulsion opaque.

Finger



One of the digits of the hand. Each finger has three phalanges (bones), except for the thumb, which has two. The phalanges join at hinge joints moved by muscle tendons that flex (bend) or extend (straighten) the finger. The tendons are covered by synovial sheaths that contain fluid, to enable the muscles to work without friction. A small artery, vein, and nerve run down each side of the finger. The entire structure is enclosed in skin with a nail at the tip.

DISORDERS

Congenital disorders include *polydactyly* (extra fingers), *syndactyly* (fused fingers), or missing fingers. Sometimes the skin membrane between the fingers is very long and deep, giving an appearance of *webbing*.

STRUCTURE OF A FINGER

The phalanges (bones) are joined at hinge joints and are moved by tendons.

Injuries to the finger are common, particularly *lacerations, fractures*, and tendon ruptures. *Baseball finger* occurs when the extensor tendon that runs along the back of the finger is pulled from its attachment following a blow to the fingertip.

Inflammation due to *rheumatoid arthritis* or *osteoarthritis* may affect the finger joints, causing stiffness, pain, swelling, and deformity. The flexor tendons, which run along the front of the fingers, may become inflamed and stuck in the tendon sheath, causing *trigger finger*.

Infections commonly occur in the finger pulp at the tip; *paronychia* (infection of the tissue around the nail) usually follows a minor cut.

Altered control of the muscles in the walls of the vessels and impaired blood supply to the hands and fingers may cause *Raynaud's disease*.

Dactylitis is a term for a spindle-shaped swelling of the fingers that occurs in *sickle cell anemia*. Dactylitis is also an uncommon feature of tuberculosis and syphilis.

Clubbing of the fingers may occur as a sign of chronic lung disease, lung cancer, and some forms of congenital heart disease, especially *tetralogy of Fallot*.

Tumors of the finger are rare but may be due to chondromas, which are benign cartilage tumors. (See also *Hand*; *Nail*.)

Finger joint replacement

A surgical procedure in which artificial joints made of metal, plastic, or silicone rubber are used to replace finger joints destroyed by disease.

WHY IT IS DONE

The main use of the operation is to relieve pain and restore some degree of movement to hands that have been crippled by *rheumatoid arthritis*, which destroys the cartilage, bone, and lining of finger (and other) joints, leaving them weak and unstable.

Less commonly, surgery is performed to relieve pain and improve mobility in joints in which *osteoarthritis* has destroyed the cartilage and created new bone.

HOW IT IS DONE

The operation is performed using an anesthetic. Several joints are usually treated simultaneously.

An incision is made to expose the joint; the ends of the two diseased bones in the joint are cut away, along with diseased cartilage. An artificial joint is then inserted into the bone ends. The tissue covering the joint and the overlying skin are sewn up and the finger is immobilized in a splint until the wound has healed.

RECOVERY PERIOD

The hand is bandaged and held high in a sling to prevent swelling. The stitches are removed after about 10 days, after which the patient is encouraged to move the fingers and return to normal activities. Exercises for the fingers may be required later to maintain function in them.

RESULTS

The procedure is usually successful in relieving pain and enabling the patient to use his or her hands again. However, it can rarely restore normal movement to the hand because joint diseases affect not only bones and cartilage in the joints, but also surrounding tissue that contributes to the flexibility of joints.

Fingerprint

An impression left on a surface by the pattern of fine curved ridges on the skin of the fingertips. The impression is made by minute amounts of sweat from pores in the skin or by ink or some other substance applied to the fingertips. The ridges occur in four main patterns—loops, arches, whorls, and compounds (combinations of the other three). It is on these ridges that fingerprint classification is based.

In law, fingerprints are accepted as a means of identification, since no two people—not even identical twins—have the same fingerprints.

First aid

The treatment of any injury or sudden illness given before professional medical care can be provided.

MINOR INJURIES

Most first aid consists of treating minor injuries, such as small *wounds*, *sprains*, foreign bodies in the eye (see *Eye, foreign body in*), minor *burns*, and *fractures*. Coping with these injuries requires proficiency with *bandages* and *splints*, and in applying *dressings*.

EMERGENCY FIRST AID

The aims of first-aid treatment in an emergency are to preserve life, to prevent the condition from worsening and protect the individual from further harm, to aid recovery, to provide reassurance to victim and family, and to make the ill or injured person as comfortable as possible.

The role of the person giving first aid is to assess the situation, to give immediate and appropriate treatment, and to arrange for the ill or injured person to be seen by a physician or taken to the hospital without delay. Additionally, the person administering first aid should find out as much as possible about the events surrounding the accident or injury from the victim or from bystanders.

If the person is unconscious or losing consciousness, the person giving first aid must first ensure that the airway is clear, that breathing is satisfactory (by checking respiratory rate), and that the circulation is good (by checking pulse and skin color). Airway, breathing, and circulation are easily remembered by the letters ABC.

The *recovery position* helps maintain an open airway in an unconscious person who is breathing. *Artificial respiration* is necessary if a patient is not breathing. *Cardiopulmonary resuscitation* is essential if the person is not breathing and has no heart beat. Any significant *bleeding* must be controlled by the rescuer applying pressure at the appropriate *pressure point*.

No severely injured or ill person should be moved without trained help

FIRST AID: FIRST-AID KIT

1 Adhesive bandages
2 Aspirin or aspirin substitute
3 Absorbent gauze bandages
4 Foil or "space" blanket
5 Triangular bandage
6 Calamine lotion
7 Roll of sterile cotton
8 Adhesive tape
9 Flashlight
10 Elastic bandages
11 Round-ended tweezers
12 Safety pins
13 Snub-nosed scissors
14 Antiseptic cream
15 Antiseptic wipes
16 Hydrogen peroxide (3% solution) or rubbing alcohol
17 Syrup of ipecac

unless life is in immediate danger. This especially applies to anyone with a suspected *spinal injury*. The person should be covered to keep him or her warm, and any tight or constricting clothing should be loosened.

If there are many people injured, the person giving first aid must establish an order of priority for their care. Highest priority is for those who have no pulse, are breathing with difficulty or not at all, are unconscious, or bleeding severely. Such people may die unless immediate treatment is given.

First-aid training is provided by various organizations, which award certificates to those who have attended courses and passed an examination. (See also *Childbirth* emergency box; *Choking*; *Drowning*; *Frostbite*; *Heat stroke*; *Hypothermia*; *Poisoning*. First-aid treatment for specific conditions appears under the appropriate heading—for example, *Epilepsy*; *Nosebleeds*.)

Fistula

An abnormal passage from an internal organ to the body surface or between two organs.

Fistulas may be congenital (present from birth) or may be acquired as a result of tissue damage. Congenital types include *tracheoesophageal fistulas*, branchial fistulas (see *Branchial disorders*), and thyroglossal fistulas (see *Thyroglossal disorders*). Acquired fistulas may result from injury, infection, or cancer. Some types of arteriovenous fistula (between an artery and a vein) are constructed artificially to provide ready access to the blood circulation, which may be necessary in *dialysis* patients.

Fistulas of the urinary tract, which open from the urethra or bladder to the perineum (the area between the anus and the genitals) usually occur as a complication of radiation therapy to the pelvis or damage caused by a difficult childbirth. Such fistulas may cause urinary *incontinence* or infection.

Fistulas between the intestine and the skin may occur in people with *Crohn's disease* and may also occur as complications of abdominal surgery. The intestinal contents may escape through an opening to the skin or through a surgical wound.

Some types of fistula close spontaneously, but most need to be cut and repaired surgically.

Fitness

Having the capacity for physical work so that normal daily activities can be performed without exhaustion. Fitness depends on strength (the ability to exert force for pushing, pulling, lifting, and other bodily functions), flexibility (the ability to bend, stretch, and twist through a full range of movements), and endurance (the ability to maintain a certain amount of effort for a certain period of time).

HOW FITNESS IS ACHIEVED

Because cardiovascular fitness is the precondition for all other forms of fitness, aerobic exercise, which increases the efficiency of the body's use of oxygen, is the basis for any fitness program. Exercises to develop flexibility and strength should be combined with aerobic exercise for a total fitness program. Although fitness training has cumulative effects that build up over many months (providing there is a sustained increase in activity levels), the effects are specific to the muscles used and the ways in which they are used. A variety of activities is necessary to achieve a general training effect.

BENEFITS OF FITNESS

A person who is fit has a better chance of avoiding *coronary heart disease* and preventing the effects of age and chronic disease. When the body is fit, the maximum work capacity is increased, endurance is increased, and a particular task utilizes a smaller proportion of the work capacity.

The strength, endurance, and efficiency of the heart is also increased by exercise. A fit heart pumps 25 percent more blood per minute when at rest and over 50 percent more blood per minute during physical exertion than an unfit heart. A fit person's heart normally beats 60 to 70 times a minute; an unfit person's heart beats 80 to 100 times per minute. The heart of a fit person works more efficiently than that of an unfit person and is therefore less subject to strain. (See also *Aerobics*; *Exercise*.)

Fitness testing

A series of exercises designed to determine an individual's level of fitness, primarily cardiovascular fitness and muscle performance.

WHY IT IS DONE

Fitness testing is usually performed to determine a person's level of fitness before starting an exercise program. It also determines whether or not a person will be at risk when starting to exercise, particularly following a heart attack. Fitness testing is also done periodically to assess and monitor progress during an exercise program.

HOW IT IS DONE

The tests are usually carried out by a physician in his or her office or in the outpatient department of a hospital. A physical examination is usually performed, including taking measurements of height, weight, and body fat. Blood and urine tests may be done, including an analysis of blood cholesterol and high-density and low-density lipoprotein content, since high cholesterol levels are related to *atherosclerosis*.

One test involves measuring the performance of the heart during physical work. The heart's efficiency at pumping blood is measured using the pulse rate (number of heart beats) per minute. The more efficient the heart, the slower it works during exercise and the quicker it returns to normal afterward. The pulse is taken at rest, and then the heart performance is measured during exercise at one or more intensities. This exercise may include step climbing, riding a stationary bicycle, or walking or running on a treadmill. After a specific period, the exercise is stopped and the pulse is taken to determine how hard the heart is working at its maximum level. The pulse is usually taken again after a minute to determine how long it takes for the heart beat to return to normal. The blood pressure response to exercise also provides useful information to the physician and patient.

Another type of exercise test involves measuring the overall performance in a standard exercise. This is most suitable for monitoring progress through an exercise program and for setting goals. The test may be based on measuring the distance covered in a fixed time or on the time needed to cover a fixed distance. (See also *Aerobics*; *Exercise*; *Fitness*.)

Fixation

A term used by Sigmund Freud to describe the attachment of a person's libido (sexual drive or interest) to real or imagined events during early childhood. Freud suggested that young children go through various stages related to certain parts of the body. In modern psychoanalysis, the stages are viewed within the context of the child's early relationships, starting with the mother. The major stages Freud called the oral, anal, and phallic, because putting things in the mouth, concern about feces, and playing with the penis or clitoris seemed to be prominent forms of behavior (because they are zones of pleasure).

EFFECTS

Fixations are unconscious and exist to some extent in all human beings; experiences from childhood are seen as permanently affecting the adult's thoughts and feelings. However, when the fixations are very powerful, resulting from especially traumatic relationships or series of events (experiences), they lead to the sort of repetitive behavior that would be expected from an immature child. Regression (going back) to one of these early stages is thus regarded by some analysts as the underlying cause of certain emotional disorders.

The type and severity depend on the stage regressed to. For example, fixation at the anal stage may be associated with concerns about control (*obsessive-compulsive behavior*), whereas fixation at the phallic stage may be associated with other deviations. Because these fixations are unconsciously repressed, the task of *psychoanalysis* is to uncover them so that patients become aware of the reason for their feelings and reactions.

Flail chest

A type of chest injury, usually resulting from a traffic accident or from violence. In flail chest, multiple rib fractures, usually at the front and side of the chest, produce an isolated portion of the chest wall. This portion moves in when the victim breathes in and moves out when he or she breathes out; this motion is opposite to the normal direction.

The injury may severely impair the efficiency of breathing and result in collapse due to *respiratory failure* and *shock*. It makes breathing and coughing very painful, which can predispose to chest infection and collapse of the lung (see *Atelectasis*).

Emergency treatment consists of turning the person onto the affected side or supporting the flail segment by firm strapping. In the most severe cases, the patient may need immediate admission to an intensive-care unit, where artificial *ventilation* will be performed. This treatment is continued for about 10 days until the ribs are sufficiently healed.

Flatfoot

Lack of an arch in the foot, resulting in the sole resting flat on the ground. The condition, known medically as pes planus, usually affects both feet.

CAUSES

Almost everyone is born with flatfeet. The arches, which then begin to develop from the formation of supportive ligaments and muscles in the soles of the feet, are not fully formed until the age of 6. In some people, however, the ligaments and muscles are weak and the feet remain flat (for unknown reasons). Less commonly, the arches do not form because of a hereditary defect in the structure of the small bones of the foot.

Flatfeet can also be acquired in adult life due to fallen arches, sometimes as a result of a rapid increase in weight. Flatfeet may also be caused by a weakening of the muscles and ligaments that support the arch, which sometimes occurs in a neurological or muscular disease such as *poliomyelitis*.

SYMPTOMS AND TREATMENT

Most flatfeet—due to ligaments and muscles never having developed fully—are usually painless and require no treatment. When the condition is caused by a defect in the foot bones or develops in adult life, the feet may ache when walking or standing. Affected children infrequently require an operation to correct the bones in the feet. In adults, treatment consists of wearing arch supports in the shoes and performing exercises to strengthen the weakened ligaments and muscles.

Flatulence

Expulsion of *flatus* (intestinal gas formed by swallowed air or fermentation) through the anus, sometimes accompanied by abdominal discomfort, which is relieved by the passage of flatus.

In an upright position, most swallowed air passes back up the esophagus to be expelled through the mouth. However, when in a prone position, the air may pass through the intestine and anus instead. Gas formed in the intestine is always passed through the anus.

Flatus

Gas or air in the intestines. Gas is formed in the large intestine as a result of the action of bacteria on carbohydrates and amino acids in digested food; the gas consists of hydrogen, carbon dioxide, and methane. Air in the stomach or intestine is swallowed usually while eating, but also (in anxious people) in times of stress.

Large amounts of flatus do not, as many believe, cause abdominal discomfort; such discomfort is usually due to intestinal sensitivity to normal amounts of flatus (see *Irritable bowel syndrome*; *Flatulence*).

Flatworm

Any species of worm that has a flattened shape—as opposed to a *roundworm* or nematode, which has a cylindrical shape. Flatworms are also sometimes called platyhelminths.

Two types of flatworm are parasites of humans—cestodes (tapeworms) and trematodes (flukes and schistosomes). (See also *Tapeworm infestation*; *Liver fluke*; *Schistosomiasis*.)

Flavoxate

ANTICHOLINERGIC
ANTISPASMODIC

Tablet

Prescription needed

Not available as generic

A drug used to treat the urinary symptoms of *cystitis*, *prostatitis*, and *urethritis*. The underlying disorder is treated with other drugs, usually *antibiotic drugs*.

HOW IT WORKS

Flavoxate works by suppressing muscular activity in the bladder by blocking the action of acetylcholine. As a result, the muscles that control urination relax and the volume of urine that can be held by the bladder increases. The drug also has an analgesic (painkilling) effect.

POSSIBLE ADVERSE EFFECTS

Adverse effects are rare, but may include dry mouth, blurred vision, and constipation.

Flea bites

See *Insect bites*.

Flies

See *Insects and disease*.

Floaters

Semitransparent bodies perceived to be floating in the field of vision. Floaters move rapidly with eye movement but drift slightly when the eyes are still. They do not affect vision.

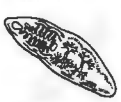
Most floaters are shadows cast on the retina by microscopic structures in the *vitreous humor*, a jellylike substance that lies behind the lens. In older people, the vitreous humor tends to shrink slightly and detach from the retina, often causing conspicuous floaters, which usually decrease with time.

The sudden appearance of a cloud of dark floaters, especially if accompanied by bright light flashes,

suggests *retinal detachment*. A large red floater that obscures vision is usually due to a *vitreous hemorrhage*.

Floppy infant syndrome
A condition in which a baby's muscles lack normal tension or tone. (See *Hypotonia in infants*.)

Floppy valve syndrome
See *Mitral valve prolapse*.



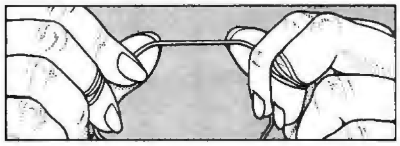
Floss, dental
Soft nylon or silk thread, waxed or unwaxed, used to remove plaque and food particles from between the teeth and around the gum line.

Flow cytometry
An automated test that reveals the arrangement and amount of deoxyribonucleic acid (DNA), or genetic material, within cells as a means of diagnosing malignancy. The pattern of DNA in cancer cells is different from that of normal cells.

The test is helpful in distinguishing benign from malignant cells, and also in monitoring the effects of *anticancer drug* treatment. (See also *Cytology*.)

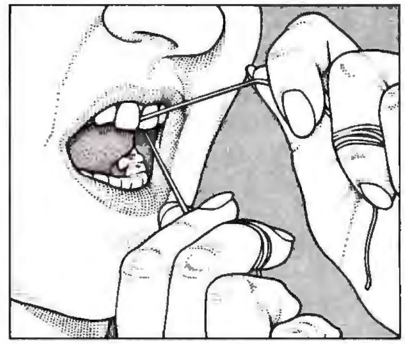
Flu
See *Influenza*.

Fluctuant
A medical term for the sensation of fluid moving within a swelling as it is palpated (examined by touch). It is a sign that the swelling contains liquid (such as pus in an abscess).



Fluke

A type of flattened worm, also called a trematode, that may infest humans or animals. The two main diseases caused by flukes are *liver fluke* infestation, which occurs worldwide, and *schistosomiasis*, a common and debilitating disease in the tropics.



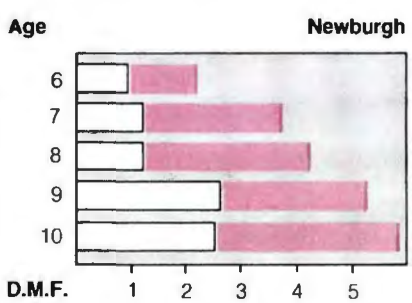
Fluocinolone
A *corticosteroid drug*. Fluocinolone is prescribed as an ointment to relieve symptoms of skin inflammation, such as itching and redness, caused by *eczema* or another skin disorder.

Fluorescein
A harmless orange-red dye used mostly in ophthalmology. Fluorescein drops are useful for showing up corneal ulcers, which stain bright green. The dye is also used in fluorescein *angiography*, a method of highlighting the details of blood circulation in the inside of the back of the eye. For this procedure, a sterile solution of fluorescein is injected into a vein. While the dye is passing through the eye in the bloodstream, photographs are taken of the retina (the innermost layer of the eye) using blue light and a green filter on the camera.

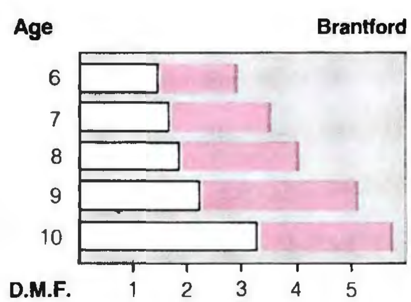
HOW TO USE DENTAL FLOSS
Floss should be used as an adjunct to toothbrushing to remove plaque and food particles from gaps between teeth and around gums. Care should be taken to avoid damaging the gum margins.

1 Break off a generous length of floss (about 18 inches) and wrap the ends around one finger of each hand. Do not use the same length of floss twice.

2 Holding the floss taut, guide it gently into the gap between the teeth until it reaches the gum line. Then rub the sides of each tooth with the floss using an up-and-down motion.

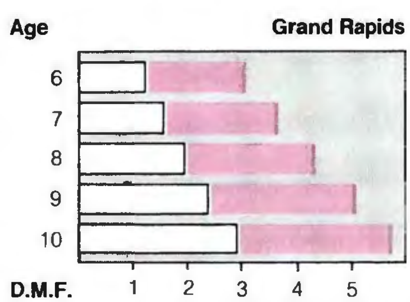


Fluoridation
The addition of fluoride to the water supply as a means of reducing the incidence of dental *caries* (tooth decay). Fluoridation began in the US in the 1940s; since then, water supplies serving 60 percent of the population have been fluoridated.



WHY IT IS DONE
Fluoride has been shown to be effective in helping to prevent dental caries, particularly if the fluoride is ingested while the teeth are forming. Children drinking fluoridated water from birth have up to 65 percent fewer

FLUORIDE AND DENTAL CARIES
Controlled water fluoridation is an effective means of reducing dental caries. Today, 60 percent of the US population drinks from a fluoridated water supply.



1944 (no fluoride)

1954 (after 10 years of fluoridation)

Controlled water fluoridation
Ten years after controlled water fluoridation had been introduced in three places (Newburgh, New York; Brantford, Ontario; and Grand Rapids, Michigan), it was found that the average number of decayed, missing, or filled (DMF) permanent teeth per child (between the ages of 6 and 10) had dropped significantly.

cavities and 90 percent fewer extractions during childhood than their counterparts who have drunk water with less than the recommended fluoride level.

Some areas have naturally high levels of fluoride in the drinking water; in other areas fluoride is added to bring levels up to the recommended standard of 0.7 to 1.2 parts per million, depending on the climate.

SAFETY

Although considerable controversy has surrounded fluoridation programs, there is no evidence that fluoridation at the recommended level has any harmful effects.

Fluoride

A mineral that is useful in helping prevent dental caries (tooth decay). Fluoride is thought to work by strengthening the mineral composition of the tooth enamel, making it more resistant to acid attacks; it may also affect plaque directly, reducing the acid-producing ability of the organisms plaque contains.

Fluoride is most effective when ingested during the formation of teeth, when it becomes incorporated into the tooth substance. It is most beneficial when taken from birth and has a lifelong effect. The water supply may naturally provide adequate amounts of fluoride (the recommended level is 0.7 to 1.2 parts per million) or provide fluoride as a result of *fluoridation*. If the level is inadequate, children can be given fluoride drops or tablets.

Fluoride is also beneficial to both children and adults when applied directly to the teeth. The dentist may treat children's teeth by painting on a fluoride solution or by holding a fitted tray filled with fluoride gel against the teeth for a few minutes. Fluoride mouthwashes and toothpastes are available for daily use at home.

Ingestion of excess fluoride during tooth formation may lead to *fluorosis*, mottling of the teeth that sometimes causes brown discoloration.

Sodium fluoride has been used without FDA approval to treat certain cases of osteoporosis.

Fluorosis

Mottling of the tooth enamel caused by ingestion of excess fluoride during tooth formation. In the most severe cases, mottling is so great that the enamel develops unsightly brown stains. Severe cases usually occur only in people living in areas where the natural level of fluoride in water is many times greater than the recommended level of 0.7 to 1.2 parts per million. Fluorosis can occur in other areas if excessive additional fluoride is consumed—for instance, via the unsupervised use of fluoride tablets.

Mild white mottling of the teeth may occur in a small percentage of children ingesting water at the recommended level, but this form of fluorosis does not cause discoloration or impair appearance.

Fluorouracil

ANTICANCER

Injection Cream

Prescription needed

Available as generic

An anticancer drug used in the treatment of cancers of the breast, bladder, ovary, stomach, and intestine.

Fluorouracil in cream form is used to treat some types of skin tumor, such as *keratosis* and *basal cell carcinoma*. It is used especially when several tumors occur together, making surgical removal difficult.

POSSIBLE ADVERSE EFFECTS

Fluorouracil may cause nausea, vomiting, diarrhea, hair loss, and impaired production of blood cells. Applied as a cream, it can cause inflammation of the skin.

Fluphenazine

One of the phenothiazine group of *antipsychotic drugs* used to relieve the symptoms of disorders such as *schizophrenia*, *mania*, and *dementia*. Fluphenazine (given as a tablet, liquid, or by injection) suppresses confused or abnormal behavior and has a tranquilizing effect.

Flurazepam

A *benzodiazepine drug* used in the treatment of *insomnia*.

Flush

See *Blushing*.

Foam, contraceptive

See *Spermicide*.

Folic acid

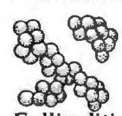
A vitamin essential to the production of red blood cells by the bone marrow. Folic acid is contained in a variety of foods, particularly liver and raw vegetables; adequate amounts are usually obtained from a well-balanced diet.

During pregnancy, folic acid plays an important part in fetal growth—in the development of the nervous system and in the formation of blood cells. During the last three months of pregnancy, folic acid tablets may be necessary to supplement the diet.

Folic acid deficiency is a cause of megaloblastic *anemia*, which causes symptoms such as fatigue, depression, and pallor.

Folk medicine

Any form of medical treatment based on the beliefs of a particular society. Examples include the charming of warts, the use of copper bracelets for the treatment of rheumatism, and the piercing of ears to improve the eyesight. What these remedies have in common is their support by belief within the culture and their lack of reliance on a practitioner. By contrast, the diagnostic and healing techniques used by a witch doctor are known as traditional medicine; those used by a chiropractor or a homeopathist are known as *alternative medicine*.



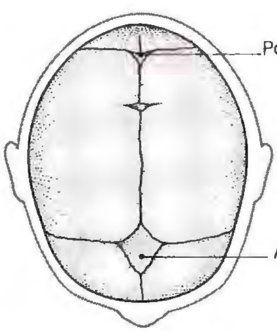
Follicle

A small cavity in the body. One example is a hair follicle, a pit on the surface of the skin from which a hair grows. Another is an ovarian follicle, one of the many fluid-filled cavities in the female ovary from which an ovum (egg) develops.

Follicle-stimulating hormone

A *gonadotropin hormone* (one that stimulates the gonads—the ovaries and testes) produced by the anterior part of the pituitary gland; also known by its initials, FSH.

Folliculitis



Inflammation of one or more hair follicles as a result of infection with *STAPHYLOCOCCUS* bacteria. Folliculitis may occur almost anywhere on the skin. It commonly is found on the neck, thighs, buttocks, or armpits, causing a boil, or it may affect the bearded area of the face, which leads to the development of pustules (see *Sycosis vulgaris*).

Treatment is with antibiotics. The infection often spreads from an infected person to the rest of the family. To prevent this or to control an outbreak, each person should shower frequently and use a separate washcloth and towel; clothes worn next to the skin should be washed daily in boiling water.

Fomites
Inanimate objects, such as clothing, books, bed linen, or a telephone receiver, that are not harmful in themselves, but which may be capable of harboring bacteria, viruses, parasites, or other harmful organisms and thus may convey an infection from one person to another.

Fomites mainly transmit respiratory infections, such as influenza.

Fontanelle
One of the two soft areas on a baby's scalp, a membrane-covered gap between the bones of the skull. At birth the skull bones are not yet fully fused and there are spaces between them. The only gaps of any size are the anterior (front) fontanelle, which is diamond-shaped, about 1 inch (2.5 cm) across, and usually closes up by the age of 18 months, and the posterior (rear) fontanelle, which is triangular, about 0.25 inch (0.6 cm) across, and closes within about two months of birth.

Location of the fontanelles
Two soft areas on the baby's skull—the anterior fontanelle is diamond-shaped, the posterior fontanelle is triangular.

DISORDERS
It is normal for the fontanelles to bulge and become tense when a baby cries. However, persistent tension at other times may indicate an abnormality, particularly *hydrocephalus* (an accumulation of fluid within the baby's skull). A sunken fontanelle may be a sign of *dehydration*. If a fontanelle is abnormally large or takes a long time to close, it may be due to *rickets* or a brain abnormality. Early closure of the fontanelles results in a deformity called *craniosynostosis*.

Occasionally, a third fontanelle is present between the other two; this occurs most commonly in *Down's syndrome*. Some babies have extra bones in the anterior fontanelle; this is normal. The extra bones fuse into the skull when the gap closes.

Food additives
Any substance that is added to food to perform a technological function. Contrary to popular belief, not all additives are artificial; sugar and salt are probably the most common.

Before any additive is accepted for use in food processing, the need for the additive must be proved and its safety assessed by the *Food and Drug Administration* (FDA).

TYPES AND USES
Additives fall into four main groups: those that preserve food and affect its "keeping" quality, those that affect texture, those that affect appearance and taste, and miscellaneous additives, such as rising and glazing agents, flour "improvers," and antifoaming agents.

Preservatives, such as sodium nitrate, are added to food to control the growth of bacteria, molds, and yeasts, especially those that might contaminate the food after it has left the manufacturer. Other additives, such as antioxidants, improve the keeping quality of the food by preventing undesirable changes (such as by stopping rancidity in foods containing fat).

Additives that improve food texture include emulsifiers, stabilizers, thickeners, and gelling agents. They alter the "mouth feel" and consistency of food. Lecithin, which occurs naturally in all animal and plant cells, is an emulsifier added to margarine to prevent separation.

Appearance and taste are often improved by the use of colorings, flavorings, sweeteners, and flavor enhancers. Colors and flavors are used mainly to compensate for losses during processing, to strengthen existing colors or flavors, and to ensure standardization in products. *Artificial sweeteners*, such as saccharin and aspartame, are used in place of sugar, especially in products designed for diabetics and weight control.

RISKS
All food additives are carefully monitored and regulated; there is no evidence that any additives in general use can harm the population as a whole. However, even though an additive may be harmless to most people, it may produce an allergic reaction in others. The best known flavor enhancer, *monosodium glutamate* (MSG), often causes *Chinese restaurant syndrome*, with reactions similar to a migraine. Tartrazine, a widely used yellow food coloring, produces an allergic reaction in a significant number of people.

Additives are often blamed for causing hyperactivity in children, but most physicians believe that, although this is true for a very small number of children, the majority of hyperactive children are not allergic to food additives. Foods containing nitrites and nitrates have been alleged to be involved with causing certain cancers (e.g., stomach cancer).

Food allergy
An inappropriate or exaggerated reaction of the *immune system* to a food. Sensitivity to cow's milk protein is a common food allergy in young children. Other foods most commonly implicated in food allergy include wheat, fish, shellfish, and eggs.

Food allergy is more common in people who suffer other forms of allergy or hypersensitivity, such as asthma, allergic rhinitis (hay fever), and dermatitis.

Immediate reactions, occurring within an hour or sometimes minutes of eating the trigger food, include lip swelling, tingling in the mouth or throat, vomiting, abdominal distention, *borborygmi* (audible bowel sounds), and diarrhea.

The only effective treatment of food allergy is to strictly avoid eating the offending food.

Food and Drug Administration
Part of the US Department of Health and Human Services, the Food and Drug Administration (FDA) monitors the safety of foods and cosmetics, and the radiation hazards of TV sets and microwave ovens. Most important, it determines, before general distribution, the safety and effectiveness of drugs and medical devices (such as insulin pumps).

Food-borne infection
Any infectious illness caused by eating food that has been contaminated with viruses, bacteria, worms, or other organisms.

CAUSES
There are two main mechanisms by which food can become infected.

First, many animals that are kept or caught for food may harbor disease organisms in their tissues or internal organs. If meat or milk from such an animal is eaten without being thoroughly cooked or pasteurized, the organisms may cause illness in their human host. In the US, the only common infection of this type is *food poisoning* from improperly cooked poultry, meat, fish, or shellfish.

Second, food may be contaminated with disease organisms spread from an infected person or animal—usually from their excrement (such as by flies moving from feces to food).

PREVENTION

In developed countries, food-borne infections are controlled or prevented by adequate sanitation and sewage treatment; by multiple laws and regulations that govern animal husbandry, the production of food in farms and factories, and its subsequent storage and distribution; and by generally high standards of personal hygiene with regard to handling and eating of food.

In some less affluent parts of the world, many of these controls do not exist and the chances of a food-borne infection are thus much higher. When visiting such countries, it is wise to avoid certain foods, particularly salads, any meat or fish that looks suspect or not thoroughly cooked, shellfish, milk, butter, cream, and ice cream. Raw fruits and vegetables are generally safe once the exterior peel or skin has been removed.

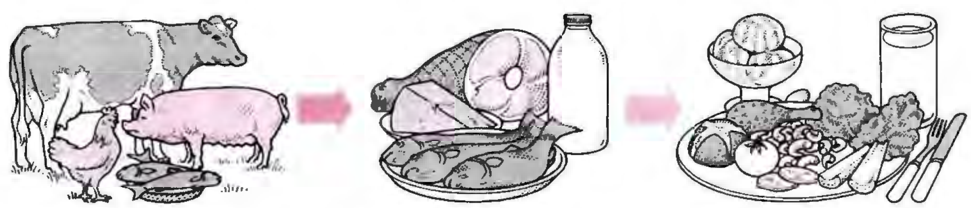
Immunization is available against certain food-borne and water-borne infections, such as typhoid and cholera, but it usually provides only partial protection and is no substitute for good food hygiene. (See also *Water-borne infection*.)

Food fad

A like or dislike of a particular food or foods that is carried to extremes. It may lead to an undue reliance on, or avoidance of, a particular foodstuff.

Fads are particularly common in toddlers and adolescents and in those under stress. For most people, food fads are not serious since they are either short-lived or restricted to a limited number of foods. However, when food fadism or food aversion has an obsessional quality about it, or is persistent, it may be indicative of a more serious eating disorder. (See also *Anorexia nervosa*; *Bulimia*.)

Food intolerance



A reproducible, adverse reaction to a food or food ingredient that is not caused either psychologically or by *food poisoning*.

CAUSES AND INCIDENCE

Food intolerance is mainly of unknown cause, but is sometimes due to various unknown irritants, toxins,

INFECTED ANIMAL PRODUCTS

Some animals harbor disease organisms (e.g., bacteria, worms, and parasites) in their tissues and these may cause infection if meat or milk is consumed raw or improperly cooked. Beef, pork, and fish tapeworm infestations, salmonella poisoning, and (rarely) brucellosis can be transmitted in this way.

1 Cows, pigs, poultry, fish, and particularly shellfish are sources of bacterial, viral, or worm infection or infestation.

2 Adequate milk pasteurization and inspection of meat and fish before sale prevents most infections and infestations of this type.

3 Thorough thawing, preparation, and cooking of meats, fish, shellfish, and poultry further reduces the risk of infection.

FOOD CONTAMINATION

Intestinal infections may be spread from person to person if organisms in feces contaminate food, directly or indirectly. This can occur if vegetable crops are sprayed with sewage, if flies settle on feces and then on food, or if food is handled by a person who has not washed his or her hands.

Contaminating organism

The photograph (left) taken through an electron microscope shows a typical SALMONELLA bacterium. The organism uses its many flagellae (whiplike structures) to move. SALMONELLA is a common contaminant of poultry, eggs, and egg products and causes severe food poisoning.

or *food additives*. It may be associated with an adverse reaction to foods such as green peppers, fried foods, or onions. Food intolerance can be caused by an inborn or acquired biochemical defect, such as *lactase deficiency* (an inability to digest milk sugar found more commonly in blacks, Asians, Indians, and people of Mediterranean origin).

Food poisoning

A term used for any illness of sudden onset, usually with stomach pain, vomiting, and diarrhea, suspected of being caused by food eaten within the previous 48 hours. Most cases are the result of contamination of food by bacteria or viruses.

Food poisoning is usually suspected when, for example, several members of a household (or customers at a restaurant) become ill after eating the same food.

TYPES AND CAUSES

Food poisoning can be classified, according to cause, into infective and noninfective types. Some foods can cause poisoning of either type. For example, shellfish such as mussels, clams, and oysters can become contaminated by viruses or bacteria, by toxins acquired from poisonous plankton (tiny marine animals and plants), or by chemical pollutants in the water.

BACTERIAL CAUSES The bacteria most commonly responsible for food poisoning belong to a group called salmonella, certain strains of which are able to multiply rapidly in the intestines to cause widespread inflammation. Some farm animals, especially poultry, commonly harbor such bacteria. If frozen poultry is not completely thawed before being cooked, it is liable to cause poisoning.

Salmonella bacteria may also be transferred to food from the excrement of infected animals or people, either by flies or by the handling of food by an infected person—especially if the hands have not been washed after using the toilet. If contaminated food is left for any time in warm conditions, a large colony of bacteria may develop without obvious food spoilage.

Other bacteria cause the formation of toxins that may be difficult to destroy even with thorough cooking. Toxin-forming strains of staphylococcal bacteria, for example, may spread to food from a septic abscess on a food-handler's skin. *Botulism* is a rare, life-threatening form of food poisoning caused by a bacterial toxin and associated with home preservation of food.

VIRAL CAUSES The viruses that most commonly cause food poisoning are Norwalk virus (a common contaminant of shellfish) and rotavirus. They cause food poisoning when raw or partly cooked foodstuffs have been in contact with water contaminated by human excrement.

NONINFECTIVE CAUSES include poisonous mushrooms and toadstools (see *Mushroom poisoning*), and fresh fruit and vegetables that have been accidentally contaminated with high doses of insecticide. Chemical poisoning can also occur if food has been stored in an unsuitable container—for example, if a container that has previously held a poison is used to store food, or if acidic fruit juice is kept in a metal container made partly of zinc.

Various exotic foods (for example, the puffer fish, considered a delicacy in Japan, or cassava, a staple food in many tropical countries) can also cause moderate to lethal poisoning if improperly prepared and cooked.

SYMPTOMS

The onset of symptoms varies according to the cause of poisoning. The symptoms usually develop within 30 minutes in the case of chemical poisoning, between one and 12 hours in the case of bacterial toxins, and between 12 and 48 hours with virus and salmonella infections. Symptoms vary considerably according to how heavily the food was contaminated, but usually include nausea, vomiting, diarrhea, stomach pain, and, in severe cases, *shock* and collapse.

The symptoms of botulism are markedly different, with nervous system symptoms such as difficulty speaking, visual disturbances, muscle paralysis, and vomiting.

DIAGNOSIS

The diagnosis of bacterial food poisoning can usually be made from a culture of a sample of the person's vomit or feces. Chemical food poisoning can often be diagnosed from a description of what the person has eaten within the previous few hours, and from analysis of a sample of the suspect food, if available.

FIRST AID AND TREATMENT

If severe vomiting and diarrhea suddenly develop (or if a person collapses), medical assistance should be sought. Samples of any food left from a recent meal should be kept; they may help pinpoint the cause and possibly prevent a widespread outbreak of food poisoning.

If poisoning by a chemical or bacterial toxin is suspected, gastric *lavage* (washing out the stomach) may be carried out. Otherwise, treatment in a hospital is directed primarily toward preventing dehydration by replacing fluids intravenously.

Milder cases can be treated at home. The affected person should eat no solid food but should drink plenty of fluids, which should include some salt and sugar to replace what is being lost (see *Rehydration therapy*).

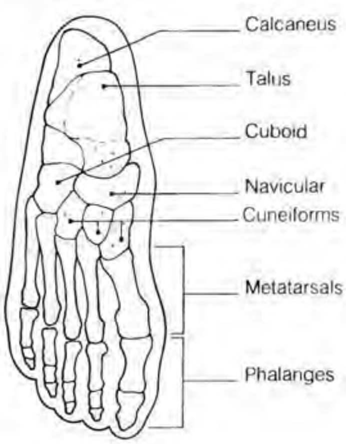
Except for botulism and some cases of mushroom poisoning, most food poisoning is not serious. Recovery generally occurs within three days.

PREVENTION

Some simple measures can virtually eliminate the chances of food poisoning. Hands should always be washed before handling food, and fresh vegetables and fruit rinsed in clean water. Cutting boards and implements used on raw meat should also be rinsed before they are used on other food. Frozen poultry should always be completely thawed before cooking and then should be well cooked.

Ask for advice on the preparation of any food unfamiliar to you at the point of sale. Suspect items—such as mussels that do not open when boiled, bulging tin cans, or any food that smells or looks obviously spoiled—should be rejected. Finally, people who preserve food at home should take care to sterilize food thoroughly by heating it in a pressure cooker at 250°F (120°C) for 30 minutes.

Foot



The foot has two vital functions—to support the weight of the body in standing or walking and to act as a lever to propel the body forward.

STRUCTURE

One of the bones of the foot is the calcaneus (heel bone); it is jointed with the talus, the second largest bone of the ankle. In front of the talus and calcaneus is a series of smaller bones—the navicular, cuboid, and cuneiform. These in turn are jointed with five long bones called the metatarsals. The phalanges are the bones of the toes; the big toe has two phalanges, all the other toes have three.

Tendons passing around the ankle connect the muscles that act on the various bones of the foot and toes. The main blood vessels and nerves pass in front of and behind the inside of the ankle joint to supply the foot. The undersurface of the normal foot forms a natural arch that is supported by

SKELETON OF THE FOOT
The calcaneus is attached to the talus above. In front are the navicular, cuboid, and cuneiform bones, which are attached to the metatarsals. Phalanges form the toes. An adult has 26 bones in each foot—one eighth of the total number in the entire skeleton.

ligaments and muscles. Fascia (fibrous tissue) and fat form the sole of the foot, which is covered by tough skin.

DISORDERS

Injuries to the foot commonly result in *fracture* of the metatarsals and phalanges. The calcaneus may fracture following a fall from a height onto a hard surface.

Deformities of the foot are fairly common and include *talipes* (clubfoot), *flatfoot*, and *clawfoot*. Another common deformity is a *bunion*, which is a *bursa* (fluid-filled pad) overlying the joint at the base of the big toe.

A number of disorders can affect the skin of the foot. *Corns*, small areas of thickened skin on a toe, are usually caused by tight-fitting shoes. *Plantar warts* appear on the skin on the sole, while *athlete's foot*, a fungal infection, mainly affects the skin between the toes, causing it to become itchy, sore, and cracked.

Gout, a fairly common type of arthritis, often affects the joint at the base of the big toe or one of the joints in the foot. *Ingrown toenail* commonly affects the nail of the big toe, causing inflammation of the surrounding tissue and *paronychia* (infection of these tissues). *Footdrop*, the inability to raise the foot properly, is due to damage to the muscles in the leg that perform this movement or the nerves that supply these muscles.

Footdrop

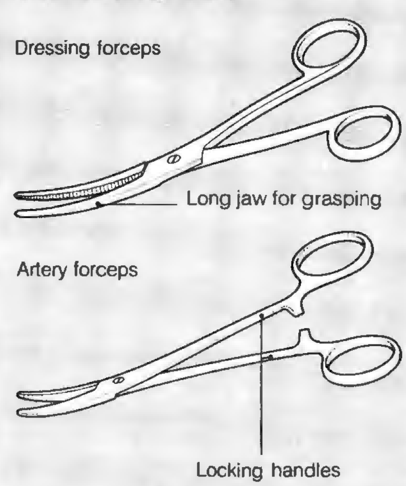
A condition in which the foot cannot be raised properly. It hangs limp from the ankle joint, causing it to catch on the ground when walking.

CAUSES

Neuritis (inflammation of a nerve) affecting the nerves that supply muscles that move the foot is a common cause of footdrop; it may be due to *diabetes mellitus*, *multiple sclerosis*, or certain neuropathies (see *Neuropathy*). Pressure on a nerve root as it leaves the spinal cord due to *disk prolapse* or, rarely, a tumor can also cause weakness in the foot muscles.

TREATMENT

The underlying cause is treated, but in many people the weakness persists. A footdrop splint (see *Brace, orthopedic*) can keep the foot fixed in position when walking.



Foramen

A natural hole or passage in a bone or other body structure, usually to allow the passage of nerves or blood vessels. The foramen magnum is the large opening in the base of the skull through which the spinal cord passes.

Forceps

A tweezerlike instrument used for handling tissues or equipment during surgical procedures. Various types of forceps are designed for specific purposes. For example, forceps used for holding or removing wound dressings have scissor handles to make manipulation easier. Tissue forceps have fine teeth at the tip of each blade so that tissues can be handled delicately during operations. (See also *Forceps delivery*; *Forceps, obstetric*.)

TYPES OF FORCEPS

Forceps delivery

The use of forceps (see *Forceps, obstetric*) by an obstetrician to ease out the baby's head during a difficult birth (see also *Childbirth*). *Vacuum extraction* may be used as an alternative.

WHY IT IS DONE

Forceps delivery is used if the mother is overtired or unable to push out her baby unaided, or if the baby is showing signs of *fetal distress*. (If fetal or maternal distress occurs before the second stage of labor begins, a *cesarean section* rather than a forceps delivery is necessary.)

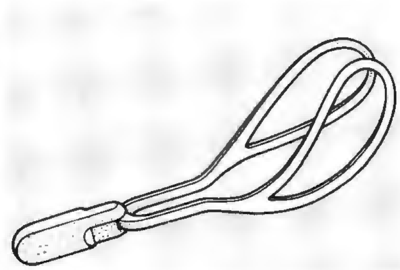
Forceps are used to control the head in *breech delivery* (with the baby's buttocks first) to prevent a too-rapid delivery. Forceps are also used if the baby's head is stuck in the middle of the mother's pelvis and needs to be rotated before delivery is possible. Called a midforceps delivery, this requires extreme skill on the part of the obstetrician; a cesarean section may be performed instead.

HOW IT IS DONE

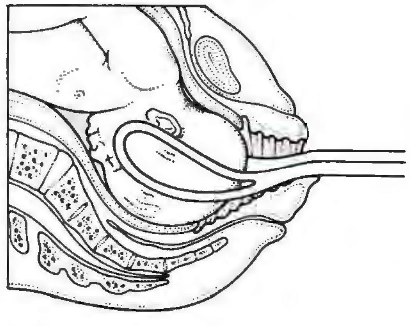
The mother is given an analgesic (painkiller) and either local or *epidural anesthesia*. She then lies on her back, with her legs raised in stirrups, and her bladder is emptied with a catheter. The obstetrician then examines the mother. Forceps can be applied only if the cervix (neck of the uterus) is fully dilated and the baby's head is engaged in the pelvis. An *episiotomy* (making of a small cut in the perineum) is usually performed before a forceps delivery.

The forceps blades are placed on either side of the infant's head, just in front of the ears. If the baby's chin points downward, gentle traction is applied to the forceps and the baby delivered. If the chin is pointing sideways or upward, rotation of the head is necessary before traction can be applied; in such cases, rotation forceps are used.

RECOVERY PERIOD



After a forceps delivery, care is similar to that following a spontaneous (unassisted) vaginal delivery. Sometimes there is greater bruising of the perineum, but this usually heals rapidly and can be eased by the application of ice packs. After a forceps delivery, the baby may have forceps marks on the face. They disappear after a few days. The length of stay in the hospital is usually the same as after a delivery without forceps.



Forceps, obstetric

Surgical instruments used to deliver the head of a baby in a difficult labor.

OBSTETRIC FORCEPS

The two wide, blunt blades are designed to fit around the baby's head. The handles lock together so that the blades are held apart.

Positioning
The forceps blades lie along the sides of the baby's head, just in front of the ears

The first obstetric forceps were invented about 300 years ago by the obstetrician Peter Chamberlen. They were kept as a family secret for use on private patients, and were not in common use until about 100 years later.

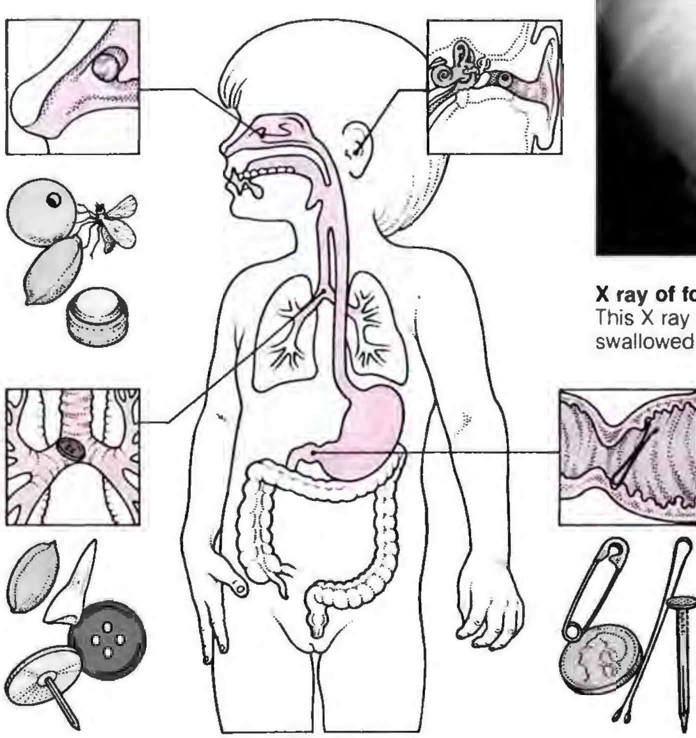
Obstetric forceps consist of two blades that cup the baby's head. Each blade is joined to a separate handle and the two handles are fitted together; when assembled, the blades are separated by a fixed distance (see illustrated box).

Foreign body

Any object in an organ, opening, or passage of the body that should not be there. It may enter accidentally (by inhalation or swallowing, for example) or it may be deliberately introduced. Common sites include the airways (see *Choking*), ear (see *Ear, foreign body in*), eye (see *Eye, foreign body in*), rectum, urethra, and vagina. A metallic, glass, or wood splinter that embeds in the subcutaneous tissue is also a foreign body.

Foreign medical graduate

Graduates of non-US medical schools, even if US citizens. Foreign medical graduates (FMGs) may qualify for training in US residency programs and for subsequent licensing after successfully passing a test of language and medical skills.



Forensic medicine

The branch of medicine concerned with the law, especially criminal law. The forensic pathologist is a physician who specializes in the examination of bodies when circumstances suggest death was unnatural (i.e., suicide, homicide, or an accident). The examination usually includes an assessment of the time of death (from data such as the temperature of the corpse and its state of decomposition), deduction of the likely nature of any weapon used (from study of the injuries), and matching of blood, hair,

COMMON FOREIGN BODIES IN CHILDREN

Children constantly experiment with objects in the environment. They frequently place small objects into their mouths, noses, or ears. As a result, a swallowed or stuck foreign body is a common occurrence. It is wise to keep all small objects well out of reach of children.

Ear and nose
Attempting to remove a foreign body from the ear can be dangerous because of the risk of pushing the object further in. The physician uses a syringe, suction, or forceps. A foreign body in the nose may be taken out with tweezers by the physician; an older child may be able to blow it out while the other nostril is blocked.

Lungs
Inhaled objects such as peanuts or teeth may become lodged in the bronchi and cause obstruction of air flow, resulting in pneumonia or lung collapse. Symptoms may include choking, coughing, and breathing difficulty. The child should *not* be inverted, slapped on the back, or made to vomit, but should be taken to the hospital immediately.

X ray of foreign body
This X ray shows that the child has swallowed a closed hair barrette.

Stomach
Foreign bodies in the stomach include coins, batteries, marbles, and buttons. Most small, smooth objects pass safely out of the body in feces, but an object that has failed to pass through the body after seven to ten days usually requires removal. Batteries should be removed surgically because they release acid that seriously damages the digestive tract.

and skin from the victim with those on any weapons, on the clothing of suspects, or on parts of an automobile.

Forensic pathologists may also be asked to examine victims of alleged sexual assault or child abuse. They also consult in cases of attempted poisoning and possible drug deaths.

Forensic scientists use laboratory methods to study body fluids (such as blood, semen, and saliva) found on or near the victim and compare the fluids with those from suspects. They are also trained in ballistics and the identification of fibers from clothing.

In addition, forensic scientists may advise on blood grouping (see *Blood groups*) in cases of disputed paternity.

F

Foreskin

The popular name for the prepuce, the loose fold of skin that covers the glans (head) of the penis when it is flaccid and which retracts during erection.

At birth, the foreskin is attached to the glans, but, after the age of 6 months, it gradually separates from the glans. In some boys, the foreskin remains tight until the age of 3 or 4, making retraction difficult or impossible. However, unless this causes recurrent infection (by preventing adequate cleaning of the glans) or prevents normal urination, there is no need to consult a physician and no attempt should be made to force the foreskin back.

In some societies, the foreskin is routinely removed from newborn boys, an operation called *circumcision*, usually for religious or hygienic reasons. Circumcision may be performed at any age as a treatment for disorders of the foreskin.

DISORDERS

In *phimosis*, the foreskin remains persistently tight after the age of 5, causing difficulty in urination and ballooning of the foreskin. There may be recurrent *balanitis* (infection and inflammation of the glans and foreskin). Erection is often painful, which is why the condition is frequently discovered only at puberty.

In the related disorder *paraphimosis*, the foreskin becomes stuck in the retracted position, causing painful swelling of the glans.

Forgetfulness

See *Memory*.

Formaldehyde

A colorless, pungent, irritant gas. In medicine, a solution of formaldehyde and a small amount of alcohol in water—a preparation known as formalin—is used to preserve tissue specimens or to harden them (a procedure called fixation) before they are stained and examined. Formalin is also used as a *disinfectant*.

Formication

An unpleasant sensation, as if ants were crawling over the skin. It is an uncommon symptom, most often resulting from abuse of cocaine or similar drugs. Formication should be distinguished from a paranoid *delusion* in which people falsely believe they are infested by ants or worms. In either case, a rash may result from excessive scratching and lead in rare cases to a misleading diagnosis of a skin disease.

Formula, chemical

A way of expressing the constituents of a chemical in symbols and numbers. Every known chemical substance has a formula. Water, for example, has the formula H_2O, indicating that it is composed of two hydrogen atoms (H_2) and one oxygen atom (O).

Fracture

A break in a bone, most commonly caused by a fall. A bone is usually broken directly across its width, but can also be fractured lengthwise, obliquely, or spirally.

TYPES OF FRACTURE

Fractures are divided into two main types: closed (or simple) and open (or compound). In a closed fracture the broken bone ends remain beneath the skin and little or no surrounding tissues are damaged; in an open fracture one or both bone ends project through the skin.

Fractures may also be classified according to the shape or pattern of the break (see box).

If the two bone ends have moved apart, the fracture is termed displaced; in an undisplaced fracture the ends remain in alignment and there is simply a crack in the bone.

CAUSES AND INCIDENCE

Most fractures are caused by a sudden injury that exerts more force on the bone than it can withstand. The force may be direct, as when a finger is hit by a hammer, or indirect, as when twisting the foot exerts severe stress on the tibia (shin).

Some diseases, such as *osteoporosis* and certain forms of cancer, weaken bone so much that it takes only a minor injury—or none at all—for the bone to break. This type of fracture is termed pathological.

Common sites of fracture include the hand, the wrist (see *Colles' fracture*), the *ankle joint*, the *clavicle* (collarbone), and the neck of the *femur* (thigh bone), usually as the result of a fall.

Elderly people are the most prone to fractures because they fall more and because their bones are fragile.

SYMPTOMS AND SIGNS

There is usually swelling and tenderness at the site of the fracture and, in some cases, deformity or projecting bone ends. The pain is often severe and is usually made worse by any movement of the area.

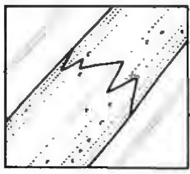
FIRST-AID TREATMENT

Anyone suffering a suspected or known fracture should be taken to the hospital; if the injured person cannot walk, medical help should be summoned. Do not try to force back a displaced bone yourself.

Treat severe bleeding (see *Bleeding, treatment of*), covering any open wounds with a clean dressing. Move the patient as little as possible. *Splinting* is usually necessary, especially if the injured person needs to be moved or if there is a long delay before help arrives. If an injured arm can be bent comfortably across the chest, splint it first and then apply a *sling*. If *spinal injury* is suspected, do not move the person at all unless his or her life is in immediate danger or he or she is choking on vomit.

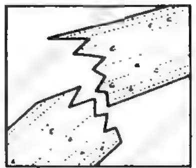
Do not give the injured person any food or liquid in case an operation requiring a general anesthetic must be carried out.

PROFESSIONAL TREATMENT



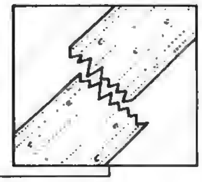
X rays are taken to confirm the diagnosis and to provide a clear picture of the type of fracture and the degree of displacement or malalignment.

Bone begins to heal immediately after it has broken. The first aim of treatment is therefore to ensure that the bone ends abut each other and are in alignment so that, when the fracture heals, the bone will retain its previous shape. Bone ends that have been displaced are maneuvered back into position—a procedure known as reduction. The bone may be manipulated through the skin (closed reduction) using a local or general anesthetic. Alternatively, the bone may be repositioned by means of an operation using anesthetic in which the site is opened (open reduction).

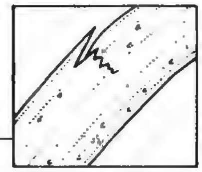


Once the fracture has been reduced, the bone is immobilized to allow the broken pieces to reunite firmly.

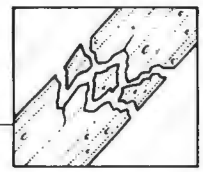
FRACTURES: TYPES AND TREATMENT



There are two main types of fractures: simple (closed) and compound (open). Within these two categories are several other types, three of which are illustrated here.



Simple fracture
The broken bone does not break the skin. Because organisms do not come into contact with the fracture, infection is rare.

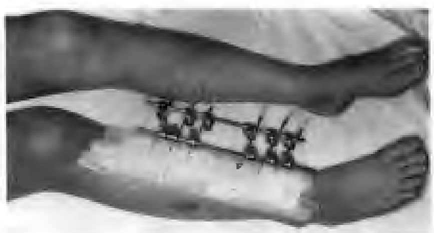


Compound fracture
A sharp piece of bone punctures the skin and is therefore exposed to organisms. There is a high risk of infection.

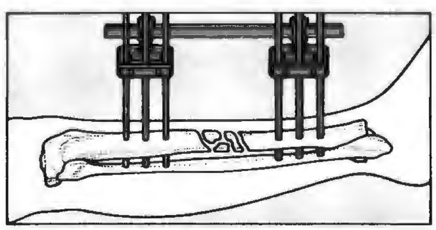
Transverse fracture
The result of a sharp, direct blow or a stress fracture caused, for example, by prolonged running.

Greenstick fracture
This type usually occurs in children. Sudden force causes only the outer side of the bent bone to break

Comminuted fracture
The bone shatters into more than two pieces. This fracture usually is caused by severe force, such as in a car accident.

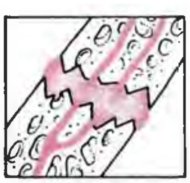


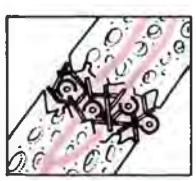
REPAIR OF FRACTURES



There are various ways of repairing fractures, depending on the particular bone, the severity of the fracture, and the age of the patient.

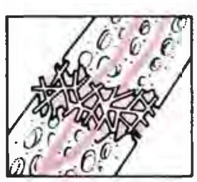
Internal fixation
The photograph at left shows immobilization of an unstable hip fracture by the insertion of metal screws across the bone ends.



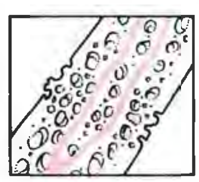


External fixation
Immobilization may be achieved by means of a plaster cast (above) or, in cases such as an unstable fracture of the tibia (left and above left), through the use of metal pins inserted into the bone on either side of the break and locked into position on an external metal frame.

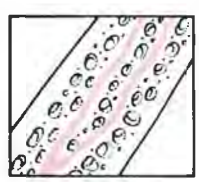
THE BONE HEALING PROCESS



After a fracture, the bone starts to heal immediately. Any displacement of the bone ends must therefore be corrected without delay to minimize deformity.



1 A blood clot forms between the bone ends, sealing off the ends of the damaged vessels.



2 Macrophages invade the fracture site to remove wound debris. Fibroblasts then create a mesh to form a base for new tissue.

3 New bone (callus) is laid down between the bone ends and over the fracture line.

4 Remodeling takes place, with more dense, stronger bone laid down.

5 Over a period of weeks, the bone returns to its former shape.

In some cases the ends of the fractured bone may be fixed together by metal pins inserted through the skin and into the bone and kept in position by attachment to an external frame (external fixation); once the fracture has healed, the pins and frame are removed. In other cases an operation is done to open up the injury site and fasten together the bone pieces with metal screws, nails, plates, rods, or wires (internal fixation).

RECOVERY PERIOD

The time taken for fractures to heal varies considerably and depends on many factors. Fractures mend much more easily in children than in adults, and in babies they can heal in as little as two weeks. In an adult a weight-bearing bone, such as the tibia, may take up to six months to knit together completely; bones that do not bear weight, such as the radius and clavicle (collarbone), generally take no longer than eight weeks.

COMPLICATIONS

Most fractures heal without problem. Healing is sometimes delayed because the blood supply to the affected bone is inadequate (as a result of damaged vessels) or because the bone ends are not close enough together. If the fracture fails to unite, internal fixation or a *bone graft* may be required.

Occasionally, bone ends reunite at the wrong angle. If this causes deformity, an operation may be necessary to refracture the bone, set it correctly, and fix it with nails. *Osteomyelitis* is a danger of open fractures and may be difficult to eradicate.

REHABILITATION

Complete immobility of a bone for a prolonged period can cause loss of muscle bulk, stiffness in nearby joints, and *edema* (accumulation of fluid in the tissues) with the risk, especially in the elderly, of permanent disability. For this reason the patient is encouraged to begin gradually using the affected part as soon as is safely possible and is given exercises to perform to restore flexibility to the joints and strength to the muscles (see *Physical therapy*).

Fracture, dental

A break in a tooth. Although tooth enamel is hard, it is also brittle and can easily be fractured by suddenly striking a hard surface, as may occur in a sports injury or a fall.

If the fracture is confined to the tooth's enamel or to the enamel and dentin, it can usually be repaired by bonding, in which the surface of the tooth is etched with a mild acid solution and a plastic resin material is attached to the roughened surface. If the pulp is affected, *root-canal treatment* may be necessary. Fractures of the root are most damaging if they occur in the lower two thirds of the tooth because the remaining fragment does not offer sufficient support for a replacement crown. A tooth fractured vertically usually cannot be saved.

Front teeth that project more than normal are vulnerable to accidental fracture. They should be repositioned by orthodontic treatment. (See also *Orthodontics*; *Bonding, dental*.)

Fragile X syndrome

An inherited defect of the X *chromosome* that causes mental retardation. Fragile X syndrome is the most common cause of mental retardation in males after *Down's syndrome*.

The disorder occurs within families according to an X-linked recessive pattern of inheritance (see *Genetic disorders*). Although males are mainly affected, women are able to carry the genetic defect responsible for the disorder and pass it on to some of their sons, who are affected, and some of their daughters, who in turn become carriers of the defect.

Approximately one in 1,500 men is affected by the condition; one in 1,000 women is a carrier. In addition to being mentally retarded, affected males are generally tall, physically strong, have a prominent nose and jaw, increased ear length, large testicles, and are prone to epileptic seizures. About one third of female carriers show some degree of intellectual impairment.

There is no treatment for the condition. If a woman has a history of the syndrome in her family, it is useful to seek *genetic counseling* regarding the risk of a child being affected.

Freckle

A tiny patch of pigmented skin, often round or oval in shape. Freckles occur on sun-exposed areas of skin and tend to become more numerous as a result of continued exposure. The tendency to freckling is inherited and most often occurs in fair and red-haired people.

Freckles are harmless, but people with highly freckled complexions should avoid excess sunlight and should use sunscreens.

Free-floating anxiety

Vague feelings of apprehension and tension associated with *generalized anxiety disorder*.

Frequency

See *Urination, frequent*.

Freudian slip

Also known as a slip of the tongue, a minor error in speech or action that turns out to be what the person really wanted to say or do. The term, also called a parapraxia, is derived from Sigmund Freud's book "The Psychopathology of Everyday Life." As the error tends to be laughed off, Freud saw the process as a compromise between the fulfillment of an unconscious wish and the conscious effort to repress it.

Freudian theory

A discipline of psychology developed by Sigmund Freud (1856-1939), a Viennese neurologist. The theory developed out of his treatment of neurotic patients using hypnosis and formed the basis of his technique of *psychoanalysis*. Freud believed that feelings, thoughts, and behavior were controlled by unconscious wishes and conflicts and that problems occurred when these desires were not fulfilled or the conflicts remained unresolved.

According to Freud, the conflicts originated in childhood and persisted into adulthood. The essence of his theory concerns early psychological development, particularly sexual development, which now is seen to encompass much more than just the "sexual" to include the early relationship with the parent. Freud defined a number of stages—oral, anal, and genital (representing the areas of the body on which an infant's attention becomes fixed at different ages)—and three components of personality—the id, ego, and superego (based on pleasure, reality, and moral and social constraints, respectively). The classic Freudian model sees all behavior as having its roots in unconscious instincts, but ultimately being determined by the interplay between the id, ego, and superego.

Psychoanalysis aims to treat mental disorders by encouraging the patient to allow thoughts to flow in any conscious direction without censorship. Freud believed that important information would emerge from the unconscious mind. (See also *Psychoanalytic theory*; *Psychotherapy*.)

Friedreich's ataxia

A very rare inherited disease in which degeneration of nerve fibers in the spinal cord causes *ataxia* (loss of coordinated movement and balance). The

disease is the result of a genetic defect, usually of the autosomal recessive type (see *Genetic disorders*). It affects about two people per 100,000.

SYMPTOMS

Symptoms first appear in late childhood or adolescence. The main symptoms are unsteadiness when walking, clumsy hand movements, slurred speech, and rapid, involuntary eye movements. In many cases there are also abnormalities of bone structure and alignment.

TREATMENT AND OUTLOOK

There is as yet no cure for the disease. Once it has developed, it becomes progressively more severe, and, within 10 years of onset, more than half the sufferers are confined to wheelchairs. If *cardiomyopathy* (heart muscle disease) develops, it may contribute to an early death. People who have blood relatives with Friedreich's ataxia should seek *genetic counseling* before starting a family.

Frigidity

A term used to describe the inability to want or enjoy sexual intercourse (see *Sexual desire, inhibited*). The term has been used almost exclusively with reference to women and is now being discouraged because of its negative connotations—blaming a woman for something that may exist only in the mind of her partner.

In the past, the term frigid was also used to describe a woman who does not achieve orgasm. This condition is now called inhibited sexual excitement; the terms anorgasmia, and fore-orgasmy are also sometimes used (see *Orgasm, lack of*).

Frostbite

Damage to tissues caused by extremely cold temperatures—below 32°F (0°C). Frostbite can affect any part of the body that is not properly covered, but the nose, ears, fingers, and toes are most susceptible. If only the skin and underlying tissues are damaged, recovery may be complete. If blood vessels are affected, the damage is permanent and *gangrene* can follow, which may necessitate amputation of the affected part.

The lower the temperature, the shorter the time required to cause damage; wind and blizzard conditions also cause damage more quickly.

The first symptoms are a pins and needles sensation, followed by complete numbness. The skin appears white, cold, and hard, and then becomes red and swollen. After the tissue has thawed, blisters form and some areas of skin are black, indicating that the tissue is dead.

FIRST AID: FROSTBITE

DO NOT
- rub the affected parts
- attempt to burst blisters
- warm the affected area with direct heat
- allow the victim to walk on a frostbitten foot

WARNING
Frostbite is often accompanied by hypothermia, which must be treated first. Proper medical attention should be sought promptly, but first aid should be given immediately.

1 Shelter the victim from the cold and remove clothing from the affected part. Remove anything that constricts, such as rings or a watch.

2 Rewarm the affected area by covering it with warm hands or clothing. Frostbitten hands can be warmed in the victim's armpits; feet can be warmed in the rescuer's armpits.

3 If warm water (no hotter than 110°F) is available, immerse the affected part. The area should then be covered with a sterile dressing.

Frostbite must be treated promptly. The person should be sheltered from the cold and the affected parts warmed as quickly as possible by immersing them in lukewarm water at 110°F (44°C). Movement of the affected parts should be avoided; massage is not helpful.

Frottage

The act of rubbing against another person to achieve sexual arousal. Also called frotteurism, it is usually carried out in a densely packed crowd where a man rubs his (clothed) genitals against a woman's buttocks or thigh. Such men commonly indulge in other sexual deviations, may have a fetishist interest in buttocks, and are unable to form successful sexual relationships.

Frozen section

A rapid technique for preparing *biopsy* specimens (small pieces of tissue) for microscopic examination.

WHY IT IS DONE

Frozen section is carried out during surgical procedures to determine whether tissue is malignant, so that the surgeon knows whether to remove more tissue before completing the operation. It is primarily used in diagnosing a breast lump as benign or malignant, but can also be useful in excluding malignancy as a diagnosis in growths of the thyroid or intestine or in diagnosing a lymphoma.

In many instances, diagnosis is made before surgery, obviating the need for frozen section. Diagnosis may be by percutaneous (through the skin) needle biopsy.

HOW IT IS DONE

A small piece of tissue is removed by the surgeon and sent to the histology laboratory. After being frozen quickly in liquid nitrogen, the specimen is cut into very thin sections, placed on a glass slide, and stained so that the cells can be examined under the microscope. The entire process takes about 20 minutes.

Frozen shoulder

Stiffness and pain in the shoulder, making normal movement of the joint impossible. In severe cases, the shoulder may be completely rigid and pain may be extremely intense.

Frozen shoulder is caused by inflammation and thickening of the lining of the capsule in which the joint is contained. The problem usually develops for no known reason, but in some cases it follows a minor injury to the shoulder, a *stroke*, chronic *bronchitis*, or *angina pectoris*.

The condition mainly affects middle-aged people, and there is a higher-than-average incidence among people with *diabetes mellitus*.

TREATMENT

Moderate symptoms can be eased by taking analgesics (painkillers) and anti-inflammatory drugs, and by applying ice packs to the shoulder or using a heat lamp on it. A severe case may require injections of *corticosteroid drugs* into the joint to relieve pain and exercises to restore movement. Manipulation of the joint using a general anesthetic can also restore mobility, but carries the risk of initially increasing pain in the joint.

Whatever the severity and treatment of the condition, recovery is usually slow and may be prolonged.

Frustration

A deep feeling of discontent and tension because of unresolved problems, unfulfilled needs, or because the path to a goal is blocked. In a person who is mentally healthy, frustration can be dealt with in a socially acceptable way. In less well-adapted people, it may lead to *regression* (going back to childlike behavior) and, in particular, *aggression* or *depression*.

There has been much research into the relationship between frustration and violent and criminal behavior. Some people believe that all aggressive acts are related to exposure to violence while growing up or are an indication of prior frustration.

FSH

Abbreviation for *follicle-stimulating hormone*, a *gonadotropin hormone* (one that stimulates the gonads—the ovaries and testes) produced by the anterior part of the pituitary gland.

Fugue

An episode of altered consciousness that causes the sufferer to wander (e.g., from home or work). It may last hours or days and the subject does not remember it afterward.

In a fugue of long duration, behavior may appear normal but certain symptoms (e.g., hallucinations, feeling unreal, or an unstable mood) may accompany it. In a fugue that lasts only for a matter of hours, the patient may be confused and agitated. A fugue is not common, but causes great alarm among relatives and friends because of its sudden onset and strange quality.

Causes include *dissociative disorders*, the *automatism* of certain types of *epilepsy* (especially temporal lobe or psychomotor epilepsy), *depression*, *head injury*, and *dementia*.

Fulminant

A medical term used to describe a disorder that develops and progresses suddenly and with great severity. The term is usually applied to an infection that has spread rapidly through the bloodstream to affect several organs and cause a high fever.

The term may also be applied to types of arthritis in which many joints are painful and stiff and deformities appear soon after the onset of symptoms, or to a cancer that has spread rapidly to cause dramatic weight loss and debility.

Fumes

See *Pollution*.

Functional disorders

A term for illnesses in which there is no evidence of organic disturbance even though performance is impaired.

Fungal infections

Diseases of the skin or other organs caused by the multiplication and spread of fungal organisms. Infections range from mild and unnoticed to severe and sometimes fatal. Fungal infections are also called mycoses. Fungi can also cause *asthma* and allergic *alveolitis* but these are allergic disorders not infections.

CAUSES

Some fungi are harmlessly present all the time in areas of the body such as the mouth, skin, intestines, and vagina, but are prevented from multiplying through competition from bacteria. Other fungi are dealt with by the body's *immune system* (defenses against infection).

Fungal infections are more common and serious in people who are taking long-term antibiotics (which destroy the bacterial competition) and in those who are taking *corticosteroid drugs* or *immunosuppressant drugs* (used to suppress the immune system). These infections more commonly involve people with an immune deficiency disorder, such as *AIDS*. Fungal infections are described as opportunistic because they take advantage of the victim's lowered defenses.

Some fungal infections are also more common in people with *diabetes mellitus*. A warm, moist atmosphere encourages the development of fungal skin infections.

TYPES

Fungal infections can be broadly classified into superficial infections (those that affect the skin, hair, nails, genital organs, and the inside of the mouth); subcutaneous infections (those beneath the skin); and "deep" infections (those affecting internal organs, such as the lungs or, more rarely, the liver, bones, lymph nodes, brain, heart, or urinary tract).

SUPERFICIAL INFECTIONS The main superficial fungal infections are *candidiasis* (thrush) and *tinea* (including ringworm and athlete's foot), both of which are very common. Candidiasis is caused by the yeast *CANDIDA ALBICANS* and usually affects the genitals or inside of the mouth. Tinea affects external areas of the body.

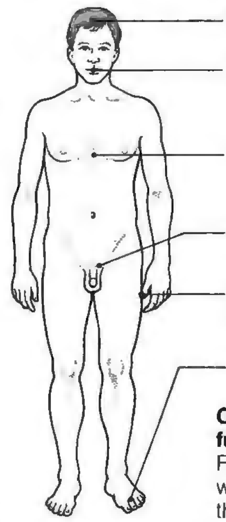
SUBCUTANEOUS INFECTIONS These are rare. The most common is called *sporotrichosis* and may follow contamination of a scratch. Most other conditions of this type occur mainly in tropical countries. The most important example of this type is *mycetoma*, or Madura foot.

DEEP INFECTIONS These are rare or uncommon (although becoming more common), but can be a serious threat to people who have an immune deficiency disorder or are taking immunosuppressive drugs. In the US, fungal infections of this sort include *aspergillosis*, *histoplasmosis*, *cryptococcosis*, and *blastomycosis*, all caused by different fungi. The fungal spores enter the body by inhalation into the lungs. Candidiasis can also spread from its usual sites to infect the esophagus, urinary tract, and numerous other internal sites.

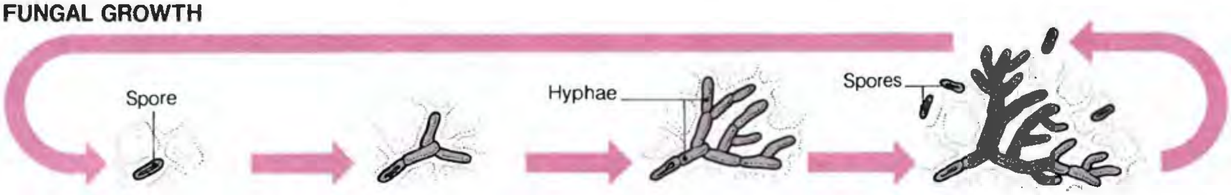
Fungi

Simple parasitic life-forms including molds, mildews, yeasts, mushrooms, and toadstools. There are more than 100,000 different species of fungi worldwide. Of these, most are either harmless or positively beneficial to human health, including various yeasts used in baking and brewing, some molds that are the source of certain *antibiotic drugs*, and various edible mushrooms and truffles that are considered gastronomic delicacies in many parts of the world. There are,

FUNGAL DISEASES



The skin, scalp, genitals, and nails are the most common sites of fungal infection. Examples of types include *tinea* (ringworm) and *candidiasis* (thrush). Fungi also (rarely) infect the lungs and other internal organs to cause a more serious disease. They may also cause allergic lung disease, such as farmers' lung.



Fungal nail infection
This condition most often affects people whose hands are frequently immersed in water. It is liable to last for years. Antifungal medications benefit some people.

Colony of fungal cells
The microscope photograph at left shows a colony of yeast cells in a skin fragment.

Common sites of fungal infection
Fungi grow best in warm, moist areas of the body.

FUNGAL GROWTH

1 Many fungal colonies originate from spores that have been carried in the air and have settled at a suitable site for growth.

2 If nutrients are available and other conditions (such as temperature) are favorable, a spore starts to divide.

3 The cells of many fungi divide to form a network consisting of branched chains of tubular filaments called hyphae

4 Eventually a colony may start forming its own spores. They may be carried to new sites to set up new growths.

however, also a number of types of fungi that can cause illness and sometimes fatal disease in humans. The study of fungi and fungal diseases is known as *mycology*.

Some fungi, notably the yeasts, occur as colonies of individual cells. In others, the cells divide to form chains of tubular filaments called hyphae, which are organized into a complex network called a mycelium. With some soil-living fungi, parts of the mycelium form into large fruiting bodies, seen as mushrooms or toadstools. Many fungi form minute bodies called spores, which are like seeds. These spores can be carried in the air and, if they settle in a suitable location with nutrients available, they divide to form a new mycelium; the molds that eventually form on exposed food are a type of mycelium. Fungal spores are ever-present in the air and soil.

FUNGI AND DISEASE

Fungi can cause illness and disease in a variety of ways.

First, the fruiting bodies of some soil-living fungi contain toxins that can produce direct poisoning if eaten (see *Mushroom poisoning*).

Second, certain fungi that infect food crops produce dangerous toxins that can cause a type of food poisoning if contaminated food is eaten. The best known of these are a fungus that infects rye and other cereals and produces a toxin called *ergot*, and another that grows on groundnuts and produces the poison *aflatoxin*. Ergot poisoning is rare today, but chronic aflatoxin poisoning from eating moldy groundnuts is a suspected cause of liver cancer in some regions of Asia and Africa.

Third, the inhaled spores of some fungi can cause a persistent allergic reaction in the lungs, known as allergic *alveolitis*. Farmers' lung, caused by spores from moldy hay, is an example of such a reaction. Fungal spores are also sometimes responsible for other allergic disorders such as *asthma* and allergic *rhinitis* (hay fever).

Fourth, some fungi are able to invade and form colonies or mycelia within the lungs, in the skin, beneath the skin, or sometimes in various tissues throughout the body, leading to conditions ranging from mild skin irritation to severe, or even fatal, widespread infection and illness (see *Fungal infections*).

Fungicidal

See *Antifungal drugs*.

Funny bone

Popular term for the small area at the back of the *elbow* where the ulnar nerve passes over a prominence of the humerus (upper arm bone). A blow to the nerve causes acute pain and sometimes numbness of the forearm.

Furosemide

A *diuretic drug* commonly used to treat *edema* (fluid retention) and *hypertension* (high blood pressure). When given by injection, furosemide has a rapid effect. It is therefore often used in emergencies to treat pulmonary *edema* (fluid in the lungs).

Furuncle

Another name for a *boil* that usually involves a hair follicle.

G

G6PD deficiency

An inherited disorder that affects the chemistry of red blood cells, making them prone to damage during an infectious illness or from certain drugs or foods.

CAUSES AND INCIDENCE

G6PD deficiency is caused by the production within red blood cells of abnormal molecules of an enzyme (a type of protein) called glucose-6-phosphate dehydrogenase. Because the molecules of this substance are defective, they cannot carry out their normal function, which is to help in a chemical process that protects the cells from damage.

The disorder is the result of an abnormality in the affected person's genetic material and is inherited in an X-linked recessive pattern (see *Genetic disorders*). This means that most of those affected are male, but women may carry the defective gene in a hidden form and pass it on to some of their sons.

The disorder is much more common among blacks than whites, affecting about 15 percent of black males in the US. A variant of the disorder, called *favism*, affects a small number of whites of Mediterranean origin.

The particular drugs that can precipitate hemolysis (red cell destruction) in affected people are shown below. Individuals with favism are, in addition, extremely sensitive to a chemical in broad beans, which they must avoid eating.

SYMPTOMS

A few days after taking an incriminated drug or food, or during the course of an infectious illness, symptoms of hemolytic *anemia* (such as jaundice, fatigue, headaches, shortness of breath on exertion, and sometimes darkening of the urine due to the destruction of red blood cells) may develop in affected people.

DIAGNOSIS AND TREATMENT

The presence of G6PD deficiency can be established by a blood screening test. The deficiency cannot be treated but any episode of hemolytic anemia caused by a drug can be halted by stopping use of the drug. Full recovery then takes place within a few days.

Anyone with a history of G6PD deficiency in the family should ask for a screening test before taking any of the incriminated drugs. If the test result is positive, these drugs should be avoided. Anyone known to have the condition should also seek prompt treatment for any infectious illness to prevent a hemolytic crisis.

DRUGS TO BE AVOIDED BY PEOPLE WITH G6PD DEFICIENCY

Class	Drugs to avoid
Antimalarial drugs	Primaquine, chloroquine, quinine, dapsone
Antibacterial and antibiotic drugs	Nitrofurantoin, sulfonamides (such as sulfisoxazole and sulfacetamide), chloramphenicol,* nalidixic acid
Analgesics (painkillers)	Aspirin*
Miscellaneous	Vitamin K (water-soluble form), probenecid, quinidine*

*These drugs do not usually cause problems in the type of G6PD deficiency that affects blacks in the US

GABA

Common abbreviation for gamma-aminobutyric acid, a *neurotransmitter* (chemical released from nerve endings). GABA controls the flow of nerve impulses by blocking the release of other neurotransmitters (e.g., *norepinephrine* and dopamine) that stimulate nerve activity. The activity of GABA is increased by *benzodiazepine drugs* and by *anticonvulsant drugs*.

It has been suggested that people with *Huntington's chorea* (a hereditary disease characterized by mental retardation and involuntary movement) have insufficient GABA-producing nerve cells in the brain centers that coordinate movement.

Gait

The style or manner of *walking*. Some neuromuscular disorders are evaluated on the basis of altered gait.

Galactorrhea

Spontaneous, persistent production of milk by a woman who is not pregnant or lactating (producing milk after childbirth), or, very rarely, production of milk by a man.

CAUSES

Lactation is initiated by a rise in the level of prolactin (a hormone produced by the pituitary gland). Galactorrhea is caused by an excessive amount of prolactin being secreted as a result of a *pituitary tumor*, or due to other endocrine diseases, such as *hypothyroidism*. Certain *antipsychotic drugs* (such as chlorpromazine) and some brain diseases (for example, *meningitis*) may be associated with increased prolactin production. However, in about 50 percent of cases, no cause can be found.

SYMPTOMS AND SIGNS

The breast secretion is obviously milklike. If it is of any other color or bloodstained, another cause (such as a breast tumor) should be suspected. Excessive levels of prolactin may also adversely affect the ovaries, causing *amenorrhea* (absence of menstrual periods) or *infertility*. If the underlying cause is a pituitary tumor, the symptoms may include headache and visual disturbances.

TREATMENT

Surgery or *radiation therapy* may be required if there is a pituitary tumor, but the symptoms are often controlled and the size of the tumor is decreased by treatment with *bromocriptine*.

In addition to treating the underlying cause, hormone or drug therapy may be used to suppress prolactin and prevent milk production. Bromocriptine, which suppresses prolactin production, can successfully treat galactorrhea when the cause is unknown, and also may regulate periods and fertility.

Galactosemia

An extremely rare inability of the body's biochemical system to break down galactose (a sugar derived from the milk sugar lactose) into glucose because of the absence of an enzyme in the liver. Galactosemia is caused by an autosomal recessive genetic defect (see *Genetic disorders*).

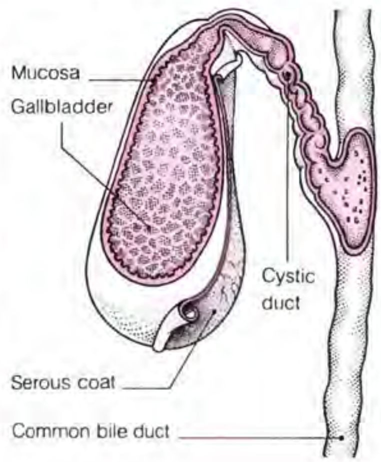
SYMPTOMS

Galactosemia causes no symptoms at birth, but jaundice, diarrhea, and vomiting soon develop and the baby fails to gain weight. If untreated, the condition results in liver disease, *cataract* (opacity in the lens of the eye), and *mental retardation*.

DIAGNOSIS AND TREATMENT

The diagnosis is confirmed from urine and blood tests. Feeding with a special lactose-free milk leads to dramatic improvement; normal milk must be avoided throughout life.

Gallbladder



A small, pear-shaped sac situated underneath the liver, to which it is attached by fibrous tissue. Bile produced by the liver passes to the gallbladder by means of a small tube, the cystic duct. This duct branches off from the bile duct, which carries bile from the liver to the duodenum.

Within the gallbladder, bile is stored and concentrated (by absorption of its water content through the gallbladder walls). When food passes from the stomach to the duodenum, secretin and cholecystokinin (gastrointestinal hormones) cause the gallbladder to contract and expel its content of bile into the duodenum, where the bile emulsifies fats contained in the food. (See also *Biliary system*.)

ANATOMY OF THE GALLBLADDER

A small, muscular sac that lies under the liver. The gallbladder expels bile via the common bile duct into the duodenum.

Gallbladder cancer

A rare cancer of unknown cause, occurring mainly in old age. It usually occurs in gallbladders with *gallstones*, but affects only a minute number of gallstone sufferers. The incidence of this cancer is less than three new cases per 100,000 population per year.

The cancer may cause *jaundice* and tenderness in the upper right abdomen but is sometimes symptomless. It is diagnosed by *ultrasound scanning*; occasionally, the cancer is discovered during surgery on the gallbladder.

Cancer of the gallbladder is treated by removal of as much of the tumor as possible. The cancer often has invaded the liver by the time it is detected, making the outlook poor.

Gallium

A metallic element whose radioactive form is used in *radionuclide scanning* (a technique for obtaining images of internal organs). Gallium is injected into the bloodstream and, about 72 hours later, scanning is performed.

DISORDERS OF THE GALLBLADDER

The gallbladder rarely causes problems in childhood or early adulthood but, from middle age onward, the increasing occurrence of gallstones can sometimes give rise to symptoms.

Because the digestive system can function normally without a gallbladder, its removal has little known long-term effect.

CONGENITAL AND GENETIC DEFECTS

Abnormalities present from birth may include no gallbladder, an oversized gallbladder, or two gallbladders; these defects rarely cause problems.

METABOLIC DISORDERS

The principal disorder of the gallbladder, with which most other problems are associated, is the formation of *gallstones*. Gallstones are common, but only about 20 percent of people with gallstones have symptoms requiring *cholecystectomy* (surgical removal of the gallbladder). Attempts by the gallbladder to expel the stone or stones can cause severe *biliary colic* (abdominal pain). There are three main types of gallstones: cholesterol gallstones, pigment gallstones, and mixed gallstones. The great majority are cholesterol or mixed gallstones, and women are affected four times as often as men. Every year about 1 million Americans develop gallstones. Many people carry "silent" gallstones, which produce no symptoms.

INFECTION AND INFLAMMATION

If a gallstone becomes stuck in the outlet from the gallbladder, the trapped bile may irritate and inflame the gallbladder walls and the bile itself may become infected. This is called acute *cholecystitis*. The first symptom may be biliary colic, which is followed by fever and abdominal tenderness.

Repeated attacks of biliary colic and acute cholecystitis can lead to chronic cholecystitis, in which the gallbladder becomes shrunken and thick-walled and ceases to function. Rarely, the gallbladder may become inflamed without the presence of gallstones—a condition that is called acalculous cholecystitis.

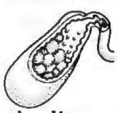
Occasionally, cholecystitis proceeds to a condition in which the gallbladder fills with pus, called *empyema* of the gallbladder. This can cause a high fever and severe abdominal pain.

TUMORS

Gallbladders harboring *gallbladder cancer* usually contain gallstones. However, this cancer is extremely uncommon compared to the high prevalence of gallstones.

OTHER DISORDERS

In rare cases where a gallbladder is empty when a stone obstructs its outlet, it may fill with mucus secreted by the gallbladder walls, resulting in a distended, mucus-filled gallbladder known as a *mucocele*.



INVESTIGATION

Gallbladder problems are investigated by physical examination and techniques such as *ultrasound scanning*, *radionuclide scanning*, or *cholecystography* (X rays of the gallbladder after it has been filled with a contrast medium). Blood tests may also be carried out.

Gallium tends to accumulate in tumors and pus cells; its main uses in scanning are to detect malignant diseases, such as *Hodgkin's disease*, and abscesses or areas of *osteomyelitis*.

Gallstones

Round or oval, smooth or faceted lumps of solid matter found in the gallbladder (the sac under the liver where bile is stored and concentrated). Gallstones are sometimes found in the bile ducts (which connect the gallbladder and liver to the duodenum). In these cases, the symptoms can be severe. There may be between one and 10, or sometimes more, stones varying in size from about 0.05 inch to 1 inch (1 to 25 mm) across. Gallstones composed principally of cholesterol are the most common type, but some contain a high content of bile pigments and other substances, such as chalk.

CAUSES AND INCIDENCE

Gallstones develop when an upset occurs in the chemical composition of bile. When the liver makes bile, it can put too much cholesterol into it (which occurs in obesity) or it may fail to put in enough of the detergent substances that normally keep cholesterol, a fatty substance, in solution.

Once the bile is overloaded with cholesterol, a tiny particle can form that gradually grows as more material solidifies around it, eventually forming a stone. Something else in the bile (its nature is unknown) actually triggers this process. Fasting for long periods may help gallstones develop by causing bile to stagnate in the gallbladder.

Gallstones are rare in childhood and become progressively more common with age. Two to three times more women than men are affected (autopsies show that 20 percent of all women have gallstones when they die).

Risk groups include overweight people and women who have had many children. Use of the birth-control pill may cause gallstones to form earlier than they would otherwise.

PREVENTION

People should avoid becoming overweight and should eat as little sugar and fat as possible. Some experts believe a high intake of fiber helps and that drinking one alcoholic drink a day has a protective value.

SYMPTOMS

Only about 20 percent of gallstones cause symptoms or complications. Symptoms commonly begin only when a gallstone gets stuck in the duct leading from the gallbladder. This causes *biliary colic* (intense pain in the upper right side of the abdomen or between the shoulder blades) and may make the sufferer feel sick and possibly vomit. Indigestion made worse by fatty foods often seems to be associated with gallstones. Other potential complications include *cholecystitis* (inflammation of the gallbladder) and *bile duct obstruction* leading to jaundice.

DIAGNOSIS AND TREATMENT

Ultrasound scanning can detect 95 percent of gallstones and is therefore the first test to be performed. An older and slightly less sensitive method is X-ray *cholecystography*, which utilizes an iodinated dye that is taken either by mouth or injected into a vein. Blood tests may also be performed. If the physician suspects the stones have escaped into the bile ducts, *cholangiography* may be carried out.

Stones that do not cause symptoms can safely be left alone, as they are unlikely to cause trouble. When symptoms are severe, *cholecystectomy* (surgical removal of the gallbladder) is carried out; this cures the problem in 95 percent of cases.

In some cases drug treatment may be used, especially if the stones are small and noncalcified. Tablets containing chenodiol or ursodeoxycholic acid can dissolve stones over several months. X rays or ultrasound scans of the gallbladder are done to check progress. Stones recur in about half the cases when the drug is stopped, so ultrasound scans are carried out over the following few years.

OUTLOOK

New treatments are being developed. Extracorporeal shock-wave *lithotripsy* uses shock waves to shatter the stones. In another technique a tube is inserted into the gallbladder and a strong solution that dissolves cholesterol is flushed through. The safety and long-term value of these treatments is still being investigated.

Gambling, pathological

Chronic inability to resist impulses to gamble, resulting in personal or social problems. Most gamblers can stop at a given point; pathological or "compulsive" gamblers seem unable to control the amount they spend and are unable to stop even when they continue to lose. The urge to gamble is so great that tension can be relieved only by more gambling. Family problems, bankruptcy, and crime may follow.

Gamma globulin

A substance prepared from human blood that contains *antibodies* against most common infections. (See *Immune serum globulin*.)

Ganglion

A cystic swelling associated with the sheath of a tendon. It is a common condition and usually occurs on the wrist, although a finger or foot may sometimes be affected. The cyst, which contains thick fluid derived from the synovial fluid that lubricates tendons and joints, can vary from the size of a small pea to, rarely, the size of a golf ball.

A ganglion may disappear spontaneously; if it does not, treatment is usually necessary only if it is painful or unsightly. The fluid may be sucked out with a needle and syringe. The cyst commonly recurs after such treatments, however. The best approach is to remove the cyst surgically, after which recurrence is rare.

Gangrene

Death of tissue, usually as a result of loss of blood supply. It may affect a small area of skin, a finger, or a substantial portion of a limb.

SYMPTOMS

Pain is felt in the dying tissues, but once they are dead they become numb. The affected skin and underlying tissue turn black. Bacterial infection may develop, causing the gangrene to spread and give off an unpleasant smell. There may be redness, swelling, and oozing pus around the blackened area.

There are two types of gangrene (dry and wet). In dry gangrene there is usually no bacterial infection; the deprived area dies because its blood supply is blocked. This type of gangrene does not spread to other tissues. It may be caused by *arteriosclerosis*, *diabetes mellitus*, *thrombosis*, an *embolism*, or *frostbite*.

Gangrene of the foot
This photograph shows a foot with an extensive area of dead tissue, with blackening of the overlying skin

Wet gangrene develops when dry gangrene or a wound becomes infected by bacteria. A particularly virulent type—known as gas gangrene—is caused by a dangerous strain of bacteria that destroys muscles and produces a foul-smelling gas. Gas gangrene has caused millions of deaths in war.

TREATMENT

Treatment of dry gangrene consists of improving circulation to the affected body part before it is too late. If the tissue becomes infected, the patient is given antibiotics to prevent wet gangrene from setting in.

If wet gangrene is diagnosed, *amputation* of the affected part is unavoidable. Usually, some of the adjacent living tissue must be removed as well.

Ganser's syndrome

A rare, *factitious disorder* in which a person seeks, consciously or unconsciously, to mislead others regarding his or her mental state. Ganser's syndrome occurs most often in prisoners. A characteristic of the disorder is the giving of "approximate answers" (for example, 2x2=5); the choice of an answer near the correct one suggests that the person knows the real response. The sufferer also displays symptoms that simulate *psychosis*, such as episodes of intense agitation or stupor.

Gardnerella vaginalis

A bacterium found in increasing numbers in the vaginal discharge of women with *vaginitis* (inflammation of the vagina).

Gargle

A liquid preparation to wash and freshen the mouth and throat, usually not meant to be swallowed. Gargles may contain mouth fresheners, flavorings, *antiseptics*, or local anesthetics (see *Anesthesia, local*). Those containing antiseptics and local anesthetics relieve the irritation associated with sore throats, but do not cure the underlying cause. The home remedy of gargling with salt water is equally effective in most circumstances.

Gastrectomy

Removal of the whole stomach (total gastrectomy) or, more commonly, a part of the stomach (partial gastrectomy). Gastrectomy is a major operation requiring hospitalization and extensive postoperative care.

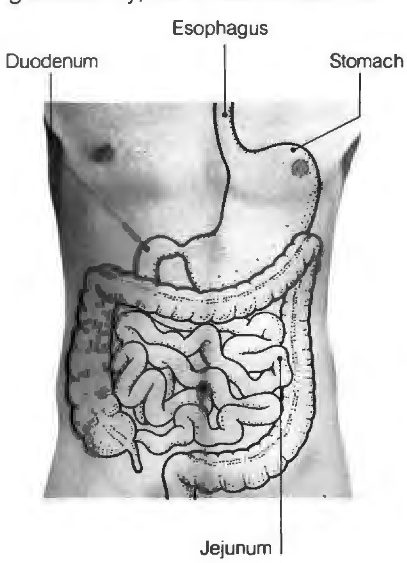
WHY IT IS DONE

Total gastrectomy is a rare operation used to treat some stomach cancers. Partial gastrectomy is fairly common; it is usually performed to deal with a *peptic ulcer* (gastric ulcer or duodenal ulcer), ulcers that have failed to heal after changes in diet or drug treatment, ulcers that bleed very badly or perforate (break through the stomach or duodenal wall), and some cancers located closer to the stomach's outlet. In treating duodenal ulcers, removal of part of the stomach may be combined with *vagotomy* (cutting of the nerves to the acid-secreting part of the stomach) to prevent more ulcers.

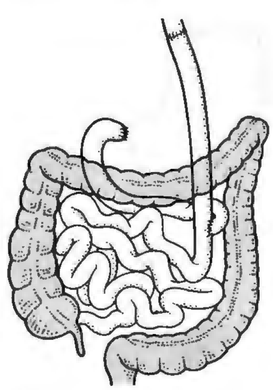
HOW IT IS DONE

A general anesthetic is given and the stomach emptied by means of a *nasogastric tube* (a tube passed through the nose down the esophagus into the stomach). The entire stomach is removed in a total gastrectomy; the risk of complications or death from this procedure is high. Smaller portions of stomach are removed with less danger.

RECOVERY PERIOD

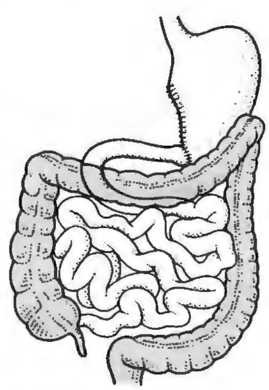


After the operation, the nasogastric tube is left in position to allow digestive system secretions to drain. When the volume of these secretions diminishes and normal *peristalsis* (the rhythmic contractions that force food through the digestive system) returns, the patient is given small amounts of water. If these do not cause abdominal pain or nausea, the nasogastric tube is removed. Intake of fluids is gradually increased and, within a few days, a light diet can be started.



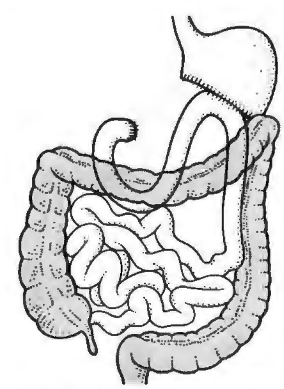
COMPLICATIONS

Because removal of the stomach disturbs normal digestion, postgastrectomy syndromes (side effects after gastric surgery) can develop



TYPES OF GASTRECTOMY

There are several different types of gastrectomy operations. In total gastrectomy, the whole stomach is removed; in partial gastrectomy, between one half and two thirds of the stomach is removed. There are two common types of partial gastrectomy operation—the Billroth I and the Billroth II.



Total gastrectomy
The whole stomach is removed and the esophagus is joined directly to the jejunum (the middle section of the small intestine).

Billroth I gastrectomy
The remaining part of the stomach is joined to the duodenum (the first part of the small intestine).

Billroth II gastrectomy
The surgeon performs a *gastrojejunostomy* (a procedure in which the stomach is joined to the jejunum) and seals the end of the duodenum to form a blind loop.

in some patients. The most troublesome are fullness and discomfort after meals; formation of an ulcer at the new junction between stomach and small intestine; regurgitation of bile, which may lead to *gastritis* (inflammation of the stomach), *esophagitis* (inflammation of the esophagus), and vomiting of bile; diarrhea; and the *dumping syndrome* (sweating, nausea, dizziness, and weakness felt soon after eating a meal because food leaves the stomach too quickly). These side effects usually disappear in time, but diet and drug treatment or another operation may be necessary.

Other complications include *malabsorption* (a reduced ability to absorb food, minerals, and vitamins), which may lead to *anemia* or *osteoporosis* (thinned bones). After total gastrectomy, patients cannot absorb vitamin B_{12} and are therefore given monthly injections for the rest of their lives.

G

OUTLOOK

Only about 10 percent of patients suffer complications requiring further treatment. Ulcer recurrence is infrequent, but there is a small risk of cancer of the stomach developing after partial gastrectomy.

Gastric bubble

A balloon, about 2 inches (5 cm) in diameter and 3.5 inches (9 cm) long, that is inserted through the mouth and into the stomach as a means of weight control in people who are dangerously obese.

The gastric bubble was approved in 1985 by the US Food and Drug Administration (FDA) only for people who are 100 percent overweight. The procedure is not without risk. In addition, no studies have been performed to evaluate whether or not weight is regained after removal of the balloon.

Gastric erosion

A break in the innermost layer (mucosa) of the membrane that lines the stomach. If a break extends deeper than this layer, it is called a gastric ulcer (see *Peptic ulcer*). Gastric erosion occurs in some cases of *gastritis* (inflammation of the stomach lining).

The causes of gastric erosions are not clear, but many cases are the result of the ingestion of alcohol, iron tablets, aspirin, or other nonsteroidal anti-inflammatory drugs (NSAIDs), such as phenylbutazone or indomethacin. The stress of serious illness, such as septicemia (blood poisoning), burns, or renal failure, may also bring on a gastric erosion.

Often there are no symptoms, although erosions may bleed, resulting in hematemesis (see *Vomiting blood*) or *melena* (black feces containing blood). The blood loss, on the other hand, may be small but persistent, eventually causing *anemia*. The condition is diagnosed by *gastroscopy* (direct examination of the stomach through a flexible viewing tube), which reveals the small bleeding points in the stomach lining.

Gastric erosions usually heal completely in a few days when treated with *antacid drugs* and *ulcer-healing drugs*, such as cimetidine, ranitidine, or famotidine.

Gastric ulcer

A raw area in the wall of the stomach caused by a breach of its inner surface lining. (See *Peptic ulcer*.)

Gastritis

Inflammation of the mucous membrane that lines the stomach. The illness may be acute, occurring as a sudden attack, or chronic, developing gradually over a long period.

CAUSES

Gastritis may be caused by irritation of the stomach lining by a drug, most commonly aspirin or alcohol; by infection of the stomach by *CAMPYLOBACTER* bacteria; or, in some people, by extreme physical stress such as head injury, severe burns, or the development of liver failure.

Chronic gastritis may be caused by prolonged irritation of the stomach by alcohol, tobacco smoke, or bile; damage of the lining by an *autoimmune disorder*, as in pernicious anemia (see *Anemia, megaloblastic*); or degeneration of the lining with age.

Acute gastritis may cause erosions in the lining that bleed easily. In the chronic form, blood may ooze continually from the lining.

SYMPTOMS

Gastritis produces many of the same symptoms as a gastric ulcer, with which it may be confused. Symptoms include discomfort in the upper abdomen (often aggravated by eating), nausea, and vomiting. In acute erosive gastritis, the feces may be black with blood lost from the stomach; in the chronic condition, slow blood loss may cause anemia (see *Anemia, iron-deficiency*), resulting in pallor, tiredness, and breathlessness.

DIAGNOSIS

The diagnosis is made by examining the stomach lining through a gastroscope, a viewing tube passed down the esophagus to the stomach (see *Gastroscopy*). A *biopsy* (removal of a tiny sample of tissue for analysis) may be performed at the same time, using an attachment at the end of the gastroscope. Microscopic examination of the sample indicates the type of inflammation. The correlation between the microscopic findings and the symptoms is not always clear.

TREATMENT

A person with gastritis should take acetaminophen rather than aspirin for pain relief, avoid alcohol, and not smoke. *Ulcer-healing drugs* may help heal the inflamed lining.

Gastroenteritis

Inflammation of the stomach and intestines, often causing sudden and sometimes violent upsets. The illness does not usually last for more than two or three days and the sufferer tends to recover without any specific treatment other than replacement of lost fluid and salt. *Dysentery*, *typhoid fever*, *cholera*, *food poisoning*, and travelers' diarrhea—as well as many milder stomach upsets—are all forms of gastroenteritis.

CAUSES AND INCIDENCE

Gastroenteritis is an extremely common cause of mild illness in developed countries and a major cause of death in some developing ones.

The illness may be caused by any of a variety of viruses, bacteria, and other small organisms that have contaminated food or water supplies. There are also a number of noninfectious causes of gastroenteritis—for example, *food intolerance*, very spicy foods, certain drugs, toxic substances, and excessive intake of alcohol. In many people, *antibiotic drugs* cause symptoms similar to those of gastroenteritis because the drugs can upset the balance of bacteria that occur naturally in the intestines.

SYMPTOMS

The onset and severity of symptoms depends on the type and concentrations of the microorganisms, food, or toxic substance causing the illness. Appetite loss, nausea, vomiting, cramps, and diarrhea are the symptoms; these may come on gradually, but more often appear suddenly. The combination of symptoms may be so mild that they cause little disruption to daily routine, or the attack may be so severe and persistent that it is disabling, causing dehydration, *shock*, and collapse. In babies and the very old, this may warrant intravenous fluid treatment.

DIAGNOSIS
In mild attacks, the symptoms alone are sufficient to make a diagnosis, but in more serious cases the physician may ask about contact with infected people, food that has been eaten recently, and recent travel abroad.

TREATMENT AND OUTLOOK
Mild cases are treated at home. The affected person should rest, preferably in bed, and take plenty of fluids, which should include salt and sugar if much fluid is being lost by vomiting and diarrhea—4 level teaspoons of sugar and a quarter of a teaspoon of salt for each pint of liquid (see *Rehydration therapy*). No solid food should be eaten until symptoms subside.

In severe cases where shock and collapse occur, the person will be taken to the hospital. Patients are given intravenous fluids to replace the vital body salts lost by vomiting and diarrhea. After the acute phase, water and then other clear fluids are given; if these fluids do not cause further upset, a bland diet is introduced. Antibiotic treatment is reserved for specific bacterial infections such as typhoid.

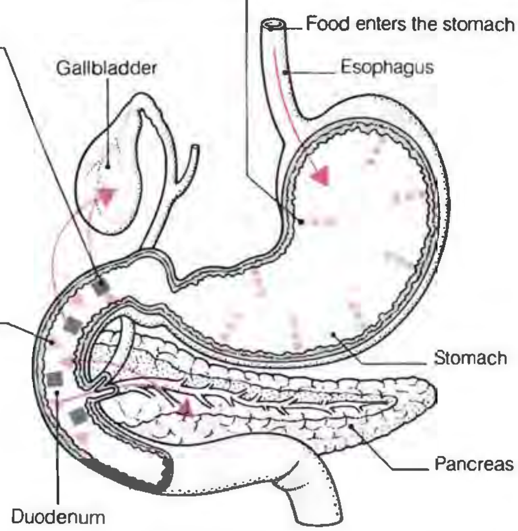
In most cases the illness subsides gradually without any special measures; recovery is usually complete with no complications.

PREVENTION
Care taken in food preparation and hygiene can substantially reduce the chances of gastroenteritis (see *Food poisoning*; *Food-borne infection*). Some protection against typhoid and cholera can be acquired by vaccination before traveling to countries where these diseases are still common. Avoidance of substances known to cause upset helps minimize noninfectious attacks of gastroenteritis.

Those caring for a person with the symptoms of gastroenteritis should be scrupulous about personal hygiene to prevent the illness from spreading.

Gastroenterologist
A physician specially trained in the management of disorders of the digestive system. His or her work is concerned with the treatment of *peptic ulcers* of the stomach and duodenum, conditions affecting the gastrointestinal tract from mouth to anus, and diseases of the liver and gallbladder.

The work of the gastroenterologist has been revolutionized in recent years by the development of fiberoptic *endoscopes*. Much of the gastrointestinal tract can now be visualized directly by these instruments and samples can be taken for laboratory examination.



The gastroenterologist, whenever possible, treats patients by advising on diet and life-style and/or by prescribing medication; if necessary, the gastroenterologist refers patients for surgical treatment.

HORMONES IN THE DIGESTIVE TRACT
Hormones released from endocrine cells in the stomach, pancreas, and intestine aid digestion by stimulating the release of bile from the gallbladder and enzymes from the pancreas into the duodenum.

Gastrin
Secreted mainly by cells in the stomach in response to eating food (especially protein). It causes the stomach to produce more acid and stimulates contraction of muscle in the wall of part of the stomach, ileum, and colon. This contraction propels food through the digestive tract.

Cholecystokinin
Released by the duodenum in response to fats and acid. It causes the gallbladder to squeeze bile into the duodenum and stimulates the production of pancreatic enzymes, which pass into the duodenum through the pancreatic duct.

Secretin
Secreted by the lining of the duodenum in response to acid entering from the stomach. It acts on the pancreas to increase the output of bicarbonate, which neutralizes acid from the stomach. It also increases the release of enzymes from the pancreas.

Gastroenterology
The study of the digestive system and the diseases and disorders affecting it. The major organs involved include the mouth, esophagus, stomach, duodenum, small intestine, colon, and rectum. Diseases of the liver, gallbladder, and pancreas are also included in this specialty.

Gastrointestinal hormones
A group of hormones released from specialized endocrine cells in the stomach, pancreas, and intestine that controls various functions of the digestive organs. Gastrin, secretin, and cholecystokinin are probably the best documented of these hormones. (See illustrated box, above.)

Various other gastrointestinal hormones released by the intestine include motilin, neurotensin, and enteroglucagon; their precise functions are still being studied.

DISORDERS
Disorders that are produced by gastrointestinal hormones are relatively rare. The most notable example is a tumor of gastrin-secreting cells in the pancreas or the wall of the intestine, a condition called *Zollinger-Ellison syndrome*.

Gastrointestinal tract
The part of the *digestive system* that consists of the *mouth*, *esophagus*, *stomach*, and *intestine*; it excludes the liver, gallbladder, and pancreas.

Gastrojejunostomy
A surgically created connection between the stomach and the jejunum (the middle two thirds of the small intestine). It is sometimes combined with partial *gastrectomy* (removal of the lower part of the stomach).

WHY IT IS DONE
The operation is performed as part of the treatment of a duodenal ulcer (see *Peptic ulcer*). The purpose of the procedure is to allow food to pass directly from the stomach to the small intestine, thereby avoiding the faulty emptying encountered when *vagotomy* alone is performed, and permitting a bypass around a scarred, obstructed duodenum.

HOW IT IS DONE
The preparation of the patient is the same as for gastrectomy. If the gastrojejunostomy is to be combined with partial gastrectomy, some of the lower part of the stomach is removed. The

surgeon then pulls up the first part of the jejunum and stitches it to the lower part or remnant of the stomach; a new opening is made through which food will pass.

RECOVERY PERIOD AND OUTLOOK

Complications, recovery, and outlook are the same as for gastrectomy.

Gastroscopy

Examination of the lining of the esophagus, stomach, and duodenum (first part of the small intestine) by means of a long, flexible viewing tube, called an esophagogastroduodeno-scope, inserted through the mouth (see *Endoscope*).

WHY IT IS DONE

Gastroscopy is used to investigate symptoms (such as severe pain or bleeding in the upper abdomen) and to look for disorders of the esophagus, stomach, and duodenum. The procedure may also be used to assess how these disorders are responding to treatment. Gastroscopy is used to identify the source of bleeding and sometimes to treat bleeding sites in the stomach and duodenum.

Attachments at the end of the instrument enable the physician to remove *biopsy* samples (small amounts of tissue for inspection).

Other procedures may be carried out using a gastroscope, such as injecting *esophageal varices* (abnormally enlarged veins in the esophagus) or dilatation (opening up) of an *esophageal stricture*. The gastroscope is also used to facilitate passage of a gastric feeding tube through the skin (percutaneous gastrostomy).

HOW IT IS DONE

The stomach should be empty for gastroscopy, so patients are asked to fast for at least six hours beforehand.

The procedure is usually performed using a local anesthetic sprayed onto the back of the throat and a sedative to relax the patient. A general anesthetic is used if elaborate investigations or treatments are required or if the patient is particularly anxious.

A diagnostic examination usually lasts for between five and 20 minutes. Some discomfort may be felt as the tube passes down the throat; there may be a sore throat afterward.

Complications from gastroscopy are rare. Most are caused by inhalation of vomit or reactions to the sedatives.

Gastrostomy

A surgically produced opening in the stomach, usually connecting the stomach to the outside so that a feeding tube can be placed into the stomach or passed into the small intestine. (*Gastroscopy* utilizes a flexible viewing tube to examine the lining of the stomach and other organs.)

People who are starving because of cancer of the esophagus (see *Esophagus, cancer of*) or who are unable to chew and swallow due to stroke or other neurologic disease may be candidates for gastrostomy. (See also *Feeding, artificial*.)

Gauze

An absorbent, open-weave fabric, usually made of cotton. For medical purposes it is usually sterilized and sealed in a package.

Gauze is often used as a *dressing* for wounds. It can be applied dry or can be immersed in an antiseptic fluid or cream; a bandage is used to hold it in place. The gauze absorbs blood and other fluids oozing from the wound. Gauze is usually not used to dress skin ulcers because it tends to stick to moist surfaces and, when removed, dislodges new tissue.

Surgeons sometimes insert pieces of gauze into wounds during surgery to keep the operative site relatively free of blood, which otherwise might obscure structures.

Gavage

The process of feeding liquids through a *nasogastric tube* (one passed into the stomach through the nose). See *Feeding, artificial*.

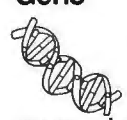
Gavage also refers to hyperalimentation (treatment of a patient by excessive feeding beyond the requirements of appetite).

Gay bowel syndrome

A group of conditions affecting the anus, rectum, and colon that occurs most frequently, but not exclusively, in male homosexuals.

Most of the conditions in gay bowel syndrome result from various forms of sexual contact, including penile-anal contact, oral-anal contact, and fisting (insertion of the fist into the rectum). If carried out regularly, these activities are likely to cause structural abnormalities (such as *hemorrhoids*, *anal fistulas*, and rectal ulcers) or inflammatory anal-rectal conditions (such as *proctitis*). They may also cause the spread of *AIDS*, *hepatitis*, and intestinal infections (such as *shigellosis* and *amebiasis*) or other infections (such as genital *warts*, *gonorrhea*, *syphilis*, and *lymphogranuloma venereum*) that can also be spread by vaginal intercourse.

Gemfibrozil



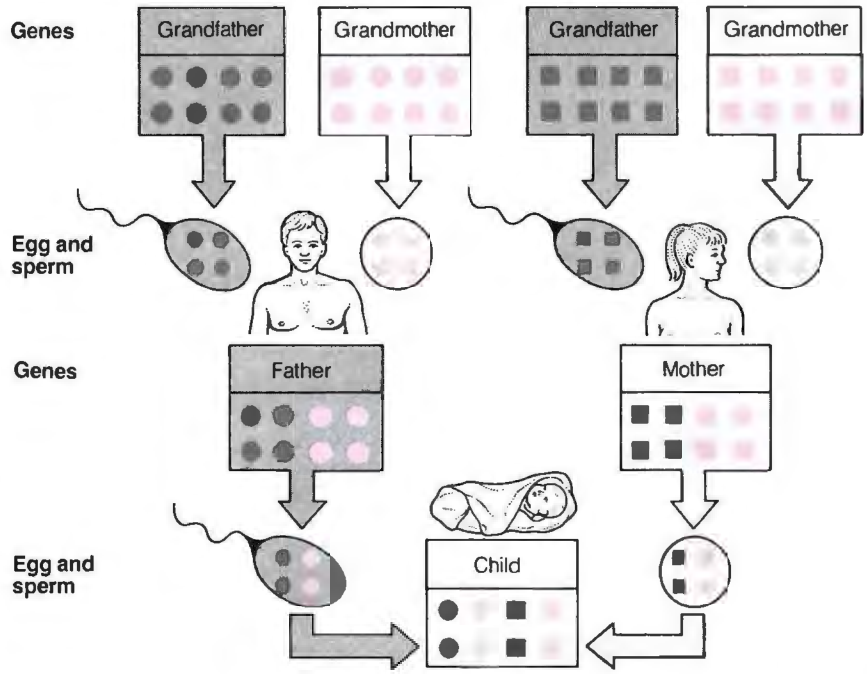
A *lipid-lowering drug* used in the treatment of certain types of *hyperlipidemia* (raised levels of fats such as cholesterol in the blood). Gemfibrozil works mainly by reducing the production of lipoproteins (fats combined with protein) in the liver.

Gender identity

The inner feeling of maleness or femaleness. Gender identity is not necessarily the same as biological sex. Gender identity is fixed within the first two to three years of life and is reinforced during puberty; once established, it usually cannot be changed. Gender role is the public declaration of gender identity—that is, the image people present outwardly that confirms their inner feelings about their gender.

Gender identity problems occur when a person has persistent feelings of discomfort about his or her sexual identity. *Transsexualism* is the most common example of this problem.

Gene



A unit of the material of heredity. In physical terms, a gene consists of a short section of the substance deoxyribonucleic acid (DNA) contained within the nucleus of a cell (see *Nucleic acids*). In functional terms, a particular gene has a specific influence on the workings of a cell; the activities of the same gene in many different cells specifies a particular physical or biochemical feature of the whole body (for example, hair color or a chemical step in the digestion of food).

Every human cell holds, within its nucleus, more than 50,000 different genes. Through the sum of their effects, genes influence and direct the development and functioning of all organs and systems within the entire body. In short, they provide an instruction manual or program for growth, survival, reproduction, and possibly also for aging and death.

Each of a person's cells (with the exception of egg and sperm cells) contains an identical set of genes. This is because all the cells are derived, by a process of division, from a single fertilized egg, and with each division the genes are copied to each offspring cell. Within any cell, however, some genes are active and others are idle, according to the specialized nature of the cell (e.g., different sets of genes are active within liver cells and nerve cells).

WHERE DO YOUR GENES COME FROM?

A person's genes are inherited from his or her parents. Half come from the mother and half from the father via the egg and sperm cells. Each parent provides a different selection, or "mix," of his or her genes to each child; this accounts for the marked differences in appearance, health, and personality among most brothers and sisters. Everyone holds a copy of his or her genes within each body cell.

Gene transmission
In this diagram, only eight genes are shown—in reality, each cell in the body contains about 50,000 genes. Half of them come from the mother and half from the father—thus a quarter of the genes originate from each of the four grandparents.

If the genes from any two people (other than identical twins) are compared, they always show a number of differences. These differences account for all or much of the variation among people in such aspects as gender, height, skin, hair and eye color, and body shape, and in susceptibility to certain diseases and disorders (see *Inheritance*; *Genetic disorders*). Genes also influence intelligence, personality, physical and mental talents, and behavior, although the extent of their contribution here is less clear-cut because environment and learning also play an important role.

GENE STRUCTURE AND FUNCTION

The physical material of inheritance, DNA, is an extremely long, chainlike structure. Along with some protein, it is what makes up the 23 pairs of *chromosomes* in the nuclei of all cells. A gene corresponds to a small section of DNA within a chromosome.

All genes fulfill their function, or exert an influence in cells or in the body at large, by directing the manufacture of particular proteins. (See illustrated box, next page.)

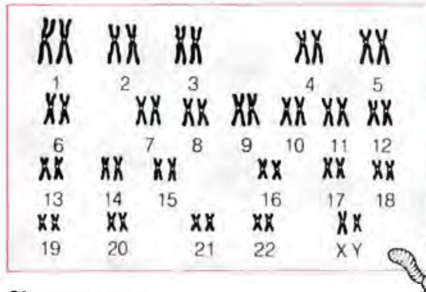
Although many proteins have a particular structural or catalytic role in the body, others are synthesized solely for the purpose of influencing the activity of other genes, which they are able to switch "on" or "off." The genes responsible for making these proteins are termed "control" genes. The whole process of development and growth can be thought of as being programmed by the sequential switching "on" or "off" of particular genes; this control program is exceedingly complex.

The activities of control genes help differentiate, for example, between nerve and liver cells, where quite different sets of genes are active or idle. If the control genes are disrupted, cells may lose their specialist abilities and begin to multiply out of control; this is the probable mechanism by which cancers and other tumors are started (see *Carcinogenesis*; *Oncogenes*).

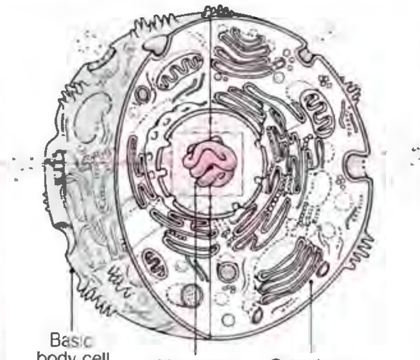
MUTANT GENES

Whenever a cell divides, copies of all of its genetic material are made for the two daughter cells by the process of DNA replication (see *Nucleic acids*) and chromosomal division. However, the copying process is not perfect, and very occasionally a fault occurs, leading to a small change (mutation) in the nucleic acid sequence; this, in turn, alters the structure of the DNA in one of the daughter cells—and thus leads to a change in one of its genes. This mutant gene is then passed on each time the cell subsequently divides. If a gene mutation occurs during the formation of an egg or sperm cell that later takes part in fertilization, the person who develops from the fertilized egg will have the mutant gene in each of his or her cells.

Carrying a mutant gene can have various effects. In some cases, it affects the structure of the protein whose manufacture the gene directs. Depending on the importance of the protein and the change in its structure, this usually has a disadvantageous effect, ranging from mild to lethal. Moreover, the mutant gene may be passed on to some of the person's own children. Diseases or disorders that result from such mutant genes are known as *genetic disorders*. Very rarely, genetic mutations occur that have a positively beneficial effect (see *Mutation*).



ALLELES, DOMINANCE, AND RECESSIVENESS

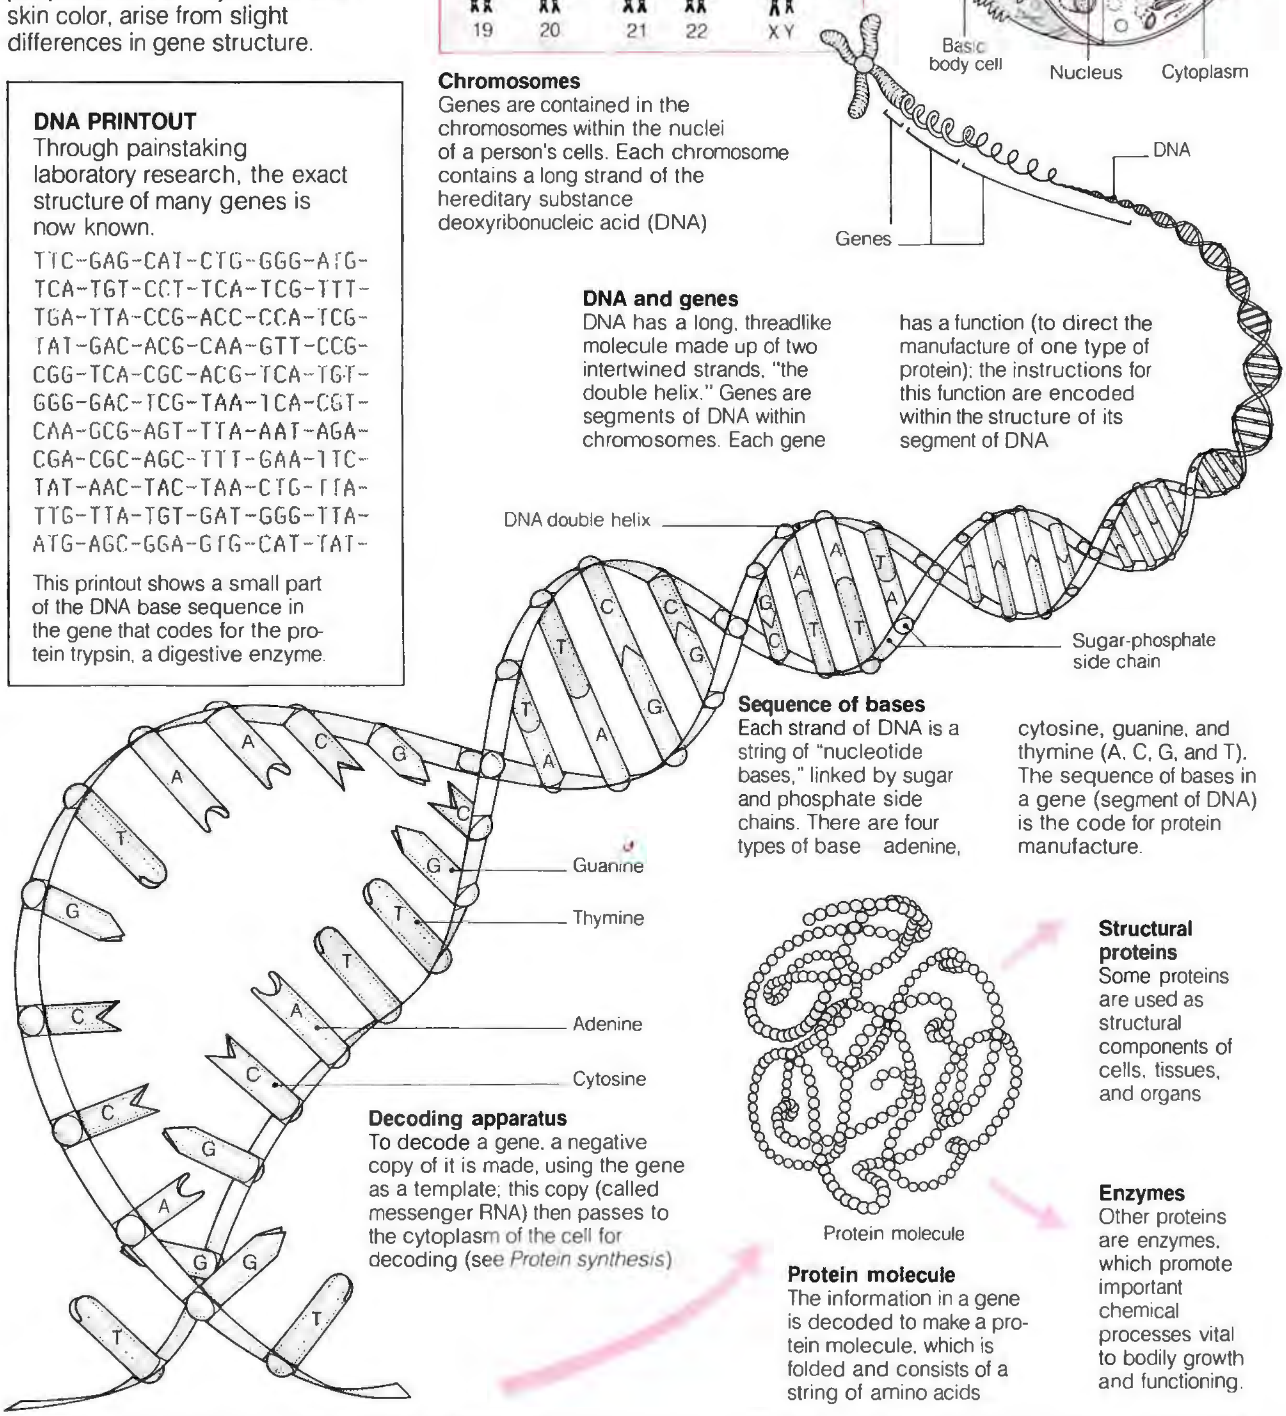


The consequences of inheriting a mutant gene are influenced by further factors. For every protein in the body, there are normally two genes capable of directing the manufacture of that protein—one inherited from the mother and one from the father. These may or may not be identical. The two genes are carried at the same location on each of a pair of chromosomes. If one of the genes mutates, leading to production of an altered protein, it can often be "masked" by the presence of a normal gene on the other chromosome of the pair.

In fact, the gene at any particular location on a chromosome can exist in any of various forms, called alleles, consisting usually of a normal form and one or more mutant forms, which

WHAT GENES ARE AND WHAT THEY DO

Genes are units of hereditary material contained in a person's cells. They hold information for all aspects of bodily growth and development, exerting their effects by directing the manufacture of proteins. All of a person's genes come from his or her parents. The physical differences between people, such as in eye, hair, and skin color, arise from slight differences in gene structure.



Chromosomes
Genes are contained in the chromosomes within the nuclei of a person's cells. Each chromosome contains a long strand of the hereditary substance deoxyribonucleic acid (DNA)

DNA PRINTOUT

Through painstaking laboratory research, the exact structure of many genes is now known.

This printout shows a small part of the DNA base sequence in the gene that codes for the protein trypsin, a digestive enzyme.

DNA and genes
DNA has a long, threadlike molecule made up of two intertwined strands, "the double helix." Genes are segments of DNA within chromosomes. Each gene has a function (to direct the manufacture of one type of protein); the instructions for this function are encoded within the structure of its segment of DNA

Sequence of bases
Each strand of DNA is a string of "nucleotide bases," linked by sugar and phosphate side chains. There are four types of base adenine, cytosine, guanine, and thymine (A, C, G, and T). The sequence of bases in a gene (segment of DNA) is the code for protein manufacture.

Decoding apparatus
To decode a gene, a negative copy of it is made, using the gene as a template; this copy (called messenger RNA) then passes to the cytoplasm of the cell for decoding (see *Protein synthesis*)

Protein molecule

Protein molecule
The information in a gene is decoded to make a protein molecule, which is folded and consists of a string of amino acids

Structural proteins
Some proteins are used as structural components of cells, tissues, and organs

Enzymes
Other proteins are enzymes, which promote important chemical processes vital to bodily growth and functioning.

cause the production of altered proteins. If the effects of a particular allele mask or override those of the allele carried at the same location on its partner chromosome, it is said to be dominant. The masked allele is said to be recessive.

Dominant genetic traits, such as brown eyes and blood group A, are those in which the allele producing the trait needs to be present only in a single dose for it to have an outwardly apparent effect. Recessive traits, such as blue eyes and blood group O, are those in which an allele for the trait must usually be present in a double dose for it to have an outward effect.

The patterns by which various traits and disorders are passed on from parents to children, including the further complication of sex-linked and multifactorial inheritance and disorders, are discussed under *Inheritance* and *Genetic disorders*. Medical advice on genetic matters—for example, to parents on the chances of an intended child being affected by a particular genetic disorder—is the province of *genetic counseling*.

Generalized anxiety disorder

A neurotic illness in which the main symptoms are chronic and persistent apprehension and tension about nothing in particular ("free-floating anxiety"). There may also be many unspecific physical reactions such as trembling, jitteriness, sweating, lightheadedness, and irritability.

Symptoms may be so severe that they interfere with everyday living and require medical attention. *Psychotherapy* and drugs are the treatment, although sedatives and tranquilizers are kept to a minimum because dependence can result.

General paralysis of the insane

The common term for the mental and physical deterioration that occurs in the late stage of untreated *syphilis* when it affects the brain substance.

Generic drug

A medicinal drug marketed under its official, chemical name (its generic name) rather than under a patented brand name. Generic names are chosen by appointed drug experts and approved by governmental agencies.

Genetic code

The inherited instructions, contained in chemical form within the nuclei of cells, that specify the activities of cells and thus the development and functioning of the whole body. The term "genetic code" is also used more widely to include the system by which the instructions are copied from a cell to its offspring, the chemical basis by which the instructions are encoded, and the "key" by which the coded instructions are translated.

The basis of the genetic code is contained within molecules of the long, chainlike substance deoxyribonucleic acid (DNA). DNA, along with some protein, makes up the *chromosomes* present in the nuclei of cells. A particular *gene*, or unit of inheritance, corresponds to a section of DNA within a chromosome. Each gene contains the coded instructions for a cell to manufacture a particular protein, which may be an *enzyme* with a vital role in the cell's activities or may have some other function or structural use in the body. Most activity in the body stems from the manufacture of proteins under the guidance of genes.

Little was known about how bits of DNA could specify the manufacture of proteins until the chemical structure of DNA was worked out in 1953. It was found that DNA consists of two long intertwined strands (the "double helix"), each consisting of a sequence of simple chemicals called nucleotide bases. Four different types of base, labeled A, C, G, and T, occur in DNA. The sequence of these bases along particular sections of one of the strands provides the instructions for protein manufacture.

The bases A, C, G, and T can be thought of as the letters of the code. Their sequence along a section of DNA (for example, CGGATCCTAGT-TGATCATGAC) would be completely meaningless without the key to the code, employed by the cell's decoding apparatus. This decoder reads the bases three at a time, and each triplet of bases codes for a particular amino acid, the chemical unit from which proteins are made. For example, the base sequence ACG in a section of DNA codes for the amino acid cysteine and the sequence TGA codes for threonine. As triplets of nucleotide bases are read in turn, the corresponding amino acids are brought together and linked, and, as a complete sequence of bases is read, a chain of amino acids (a polypeptide chain) is formed. This may be a protein molecule itself or may form part of a larger protein structure. Certain base triplets, found at the end of gene sequences, code for termination of protein synthesis.

A complication of the system is that the decoding apparatus does not read directly from DNA but from an intermediary substance, messenger ribonucleic acid (RNA). The DNA acts as a template for RNA manufacture (see *Protein synthesis*). See *Nucleic acids* for the process by which DNA is copied and passed on from each cell to its offspring (and via egg and sperm cells to a new individual).

Genetic counseling

Guidance given to a person or persons (usually by a physician who has experience in genetics) who are considering having a child but are concerned because there is a blood relative (including perhaps a previous child) with an inheritable disorder, or because they are at risk for some other reason of bearing a child with such a disorder.

In most cases, genetic counseling entails predicting the chances of recurrence of a condition that has already affected one or more members of a family. Such counseling depends first on a precise diagnosis of the disorder; the counselor must be able to explain why the disorder occurred and how it is inherited.

Genetic counseling may also include discussion of the prognosis (outlook) for an affected child, advising couples about contraception if, after counseling, they decide not to have children or more children, and sometimes discussing the alternative routes to parenthood.

WHO IS COUNSELED?

Counseling is important for parents of a child with a *genetic disorder*, such as cystic fibrosis or hemophilia, or a *chromosomal abnormality*, such as Down's or Turner's syndrome. It may be useful if a child is born with *birth defects*, such as a cleft lip or congenital heart disease, and may be helpful in many other conditions, such as epilepsy, mental retardation, or abnormal sexual development. It may also be useful for prospective parents if there is a history of any of these conditions in a blood relative.

Genetic counseling may also help in relation to first-cousin marriages and advanced maternal age.

HOW IT IS DONE

Genetic counseling may be provided by a clinical geneticist, by a pediatrician, or by the family practitioner.

The counselor makes a pedigree (family tree) of the family. This includes details of any diseases in the family, any blood relationship

G

between partners, or any history of miscarriages. Information from death certificates or postmortem reports of relatives may also be needed.

When a couple has already had a child with abnormalities, the counselor will ask if there was any exposure to radiation or drugs during pregnancy, or if there was any injury to the child at birth, as these can cause abnormalities in otherwise healthy families. The counselor also examines the affected child (and his or her parents) and arranges for any necessary tests, such as *chromosome analysis*, to be done. The parents' chromosomes may sometimes need to be studied as well, because certain conditions, such as Down's syndrome, sometimes result from abnormalities in the parents' chromosomes.

For many genetic disorders, it is now possible to establish with some certainty whether or not the parents of an affected child are "carriers" of a defective gene, which can significantly affect the chances of recurrence. Although the actual genes are not identified, DNA markers (fragments of genetic material known to be close to the defective gene on a chromosome) have been identified, and these can be looked for on the parents' chromosomes by advanced laboratory techniques (see *Genetic probe*). Such techniques are becoming more readily available.

Virtually every case investigated by a genetic counselor is unique. Several factors may influence the chances of a disorder recurring and, in some cases, complex mathematical calculations must be carried out to estimate the risk for a couple.

WHAT IT CAN OFFER

When a couple has had a child with abnormalities, an important aspect of counseling is the explanation of how it occurred and how the child will fare, including the chances of the child having children and whether they, too, will be affected.

Otherwise, advice consists mainly of an estimate of the risk of occurrence or recurrence of the disorder in question. The couple's decision to have children or more children of their own depends partly on the risk estimate, but also on other factors, such as the severity of the disorder, the burden an affected child would place on the family, and the availability of alternative routes to parenthood.

The decision on the best course of action is left to the parents after they have had detailed discussions with the counselor and feel satisfied that they understand the condition in question and its implications.

When there is a significant risk of producing an abnormal child, the parents may choose to try for a healthy child (but may allow the pregnancy to continue to term only if no abnormality is found during prenatal testing). This applies only to certain conditions, such as spina bifida, Down's syndrome, hemophilia, and muscular dystrophy, in which prenatal diagnosis by *amniocentesis* or *chorionic villus sampling* is able to reveal (with reasonable accuracy) an abnormality early in pregnancy. In such cases, an elective abortion may be chosen if an abnormality is found.

If a couple decides against having children, options for parenthood include adoption and *artificial insemination* by donor (the mother's egg is fertilized by a donor sperm). The latter is worth considering if both parents are carriers of a rare inherited condition or if the father has a dominant or X-linked genetic disorder.

Test-tube fertilizaton of a donor egg by the father's sperm, in cases where the mother carries an abnormal gene, is not yet widely available but is a possibility for the future.

Genetic disorders

Any disorder caused, wholly or in part, by a fault or faults in the inherited, genetic material within a person's cells—that is, in the *genes* formed from the substance deoxyribonucleic acid (DNA), which make up the *chromosomes* in a person's cells. A large number of diseases have, wholly or in part, a genetic cause.

Many genetic disorders are apparent at birth and are thus also *congenital*. However, the terms genetic and congenital are not synonymous; many genetic defects do not become apparent until many years after birth, and many congenital abnormalities are not genetic in origin.

Most people with a genetic disorder have one or more relatives affected by the same disorder—that is, the disorder is also *familial*. However, there are also occasions when a child is born unexpectedly with a genetic disorder (that is, with no previous family history). There are a number of mechanisms by which this can occur.

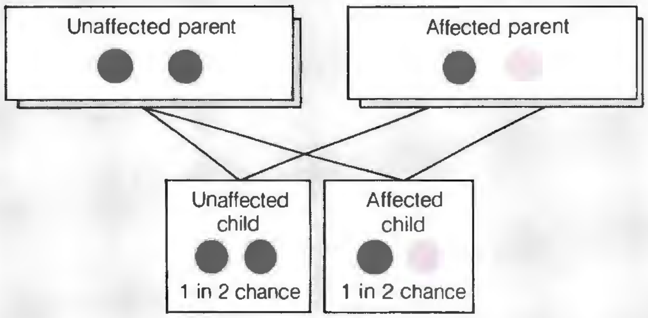
CAUSES AND TYPES

The reason abnormal genetic material can lead to disorders or disease is that genes control the manufacture in cells of *enzymes* and other proteins that play roles of varying importance in cells and in the body as a whole. If the genetic material is defective, abnormal proteins (or abnormal amounts of proteins) may be produced, causing disturbances in body chemistry that lead to disease.

For a person to exhibit a genetic disorder, the abnormality in the genetic material must usually be present in each of his or her cells, which means that it must also have been present in either the egg or the sperm cell (or both) from which the individual was derived. There are two ways in which this can happen. The first is that one or both parents carried a defect in their own genetic material; the second is that a *mutation* (a change in the genetic material) occurred during the formation of egg or sperm cell. Mutations are one of the mechanisms by which a child affected by a genetic disorder can be born into a family that has never had a known history of genetic disorders. With some of the more common genetic disorders, such as hemophilia, about one third of cases are due to new mutations.

Genetic disorders fall into three broad classes: chromosome abnormalities, unifactorial defects, and multifactorial defects. In the first, a child is born with an abnormal number of whole chromosomes, or extra or missing bits of chromosomes, in the cells. Since chromosomes contain many genes, this can lead to multiple disturbances and disorders. (See *Chromosomal abnormalities*.)

Unifactorial disorders are caused by a single defective gene or pair of genes; these disorders are distributed among the members of an affected family according to relatively simple laws of inheritance. Multifactorial disorders are caused by the additive effects of several genes, along with environmental factors; the pattern of inheritance is less straightforward.

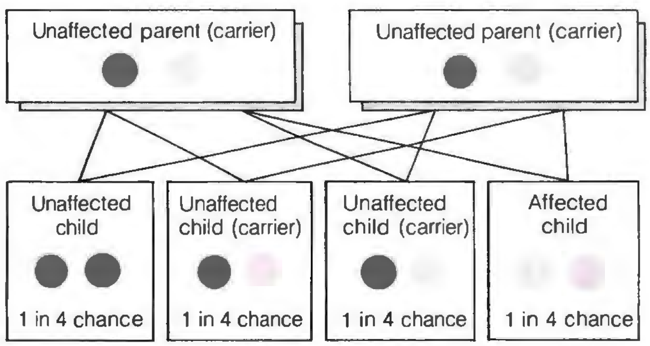


UNIFACTORIAL DISORDERS

These disorders are rare, but there are many, and in total they cause a considerable amount of disability.

All unifactorial genetic disorders are the result of defects in a gene, or in a pair of genes, controlling the production of a particular protein. They can be divided into two groups—called sex-linked and autosomal disorders—according to whether the affected gene or genes are located on the sex chromosomes (nearly always the X chromosome) or on any of the other 22 pairs of chromosomes, which are called autosomes (see *Chromosomes*).

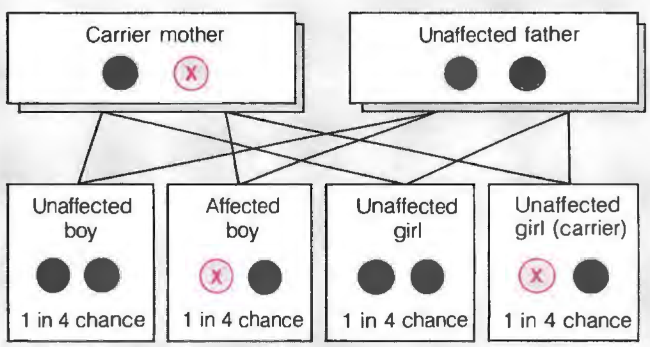
UNIFACTORIAL GENETIC DISORDERS



Autosomal dominant
In these disorders, the defective gene must be present in only a single dose to cause outward abnormality. Each child of an affected person usually has a 1 in 2 chance of inheriting the defective gene and of being affected and a 1 in 2 chance of being unaffected.

Examples
Achondroplasia
Hereditary spherocytosis
Huntington's chorea
Marfan's syndrome
Neurofibromatosis
Polycystic kidney (adult type)
Polyposis coli
Tuberous sclerosis

Key
Defective gene
Normal gene



Autosomal recessive
Here, a defective gene must be inherited in a double dose to cause abnormality. Usually both parents of an affected person are unaffected carriers of the defective gene. Each of their children has a 1 in 4 chance of being affected and a 2 in 4 chance of being a carrier.

Examples
Albinism (oculocutaneous)
Cystic fibrosis
Friedreich's ataxia
Galactosemia
Hurler's syndrome
Phenylketonuria
Sickle cell anemia
Tay-Sachs disease

Key
Defective gene
Normal gene

X-linked recessive
These conditions are caused by defects on the X chromosome usually leading to outward abnormality in males only, where the defect cannot be masked by a second, normal, X chromosome. Women can be carriers of the defect and half their sons may be affected.

Examples
Christmas disease
Color blindness (most types)
Fragile X syndrome
G6PD deficiency
Hemophilia
Muscular dystrophy (Duchenne)

Key
Defective X chromosome
Normal X chromosome
Y chromosome

Autosomal disorders generally affect both sexes equally and are further divided into two groups, called autosomal dominant and autosomal recessive, according to whether the defective gene need be present in a single or double dose to cause an outward abnormality.

The sex-linked disorders show a bias in their incidence among the sexes. Most are of one type—called X-linked recessive disorders—and primarily males are affected.

Some examples of these three varieties of unifactorial disorder are shown in the table.

AUTOSOMAL DOMINANT DISORDERS With these disorders, a person need carry the defective gene in only a single dose for it to have an outwardly apparent effect. Such individuals are termed *heterozygotes* with respect to the gene, which means they carry one normal copy and one defective copy of the gene. Because the defective gene is dominant—that is, it overrides the normal gene—its presence usually leads to an outward abnormality (but not always a severe one).

Some affected people have inherited the defective gene from one of their parents. In other cases there is no family history of the condition; the defect has usually arisen as a result of a mutation.

If an affected individual has children, each one has a 50 percent chance of inheriting the defective gene and thus also the chance of being affected. Often these disorders appear in each of several generations, finally disappearing only when the affected individuals in a generation have no affected children or no children at all.

AUTOSOMAL RECESSIVE DISORDERS People who manifest these disorders have always acquired the particular gene defect in a double dose—they are said to be *homozygotes* with respect to the defective gene. In most cases, both parents of an affected person are heterozygotes—they carry the defective gene in a single dose along with a normal gene. But, because the defective gene is recessive and "masked" by the normal gene, they display no outward abnormality.

With all autosomal recessive defects, the number of such carriers in the population always outnumbers those who are actually affected. For example, with *cystic fibrosis* (the most common disorder of this type), one in 22 of the population is a carrier of the defective gene, but only one person in 2,000 is born with the condition. The majority of carriers are unaware of the fact and have no family history of the condition—the defective gene has been passed on to them silently over many generations. When two carriers have children and one is born with an autosomal recessive condition, the manifestation of the defect thus usually comes as a complete surprise.

If both parents are carriers, any subsequent child will have a one in four chance of also being affected.

X-LINKED RECESSIVE DISORDERS In these conditions, the defective gene is on the X chromosome. Women have two X chromosomes in their cells; men have only one, which they inherit from their mothers and pass on to their daughters.

When a woman inherits the defective gene in a single dose, because it is recessive, it is masked by the normal gene on her other X chromosome, so she displays no outward abnormality. She is a heterozygote carrier of the defective gene. However, when a male inherits the defective gene, there is no normal gene on a second X chromosome to mask it, and he will display the abnormality.

The familial pattern of these disorders is as follows. Affected males far outnumber affected females and in all cases have inherited the genetic defect from their mother (who is a carrier). They pass the defective gene to none of their sons but to all of their daughters, who become carriers in turn. Carrier females transmit the defective gene on average to half their sons, who are affected, and to half their daughters, who become carriers in turn. Thus, the pattern is for some of the males in an affected family to have the disorder, while the females in the family are either known or possible carriers.

MULTIFACTORIAL DISORDERS

A large number of disorders fall into this category—including *asthma*, insulin-dependent *diabetes mellitus*, *schizophrenia*, and a number of conditions present at birth, such as clubfoot and *cleft lip and palate*.

In each case, susceptibility to the disorder is thought to be determined by a number of different genes that, along with environmental influences, have an additive effect. The degree to which susceptibility to each of these various disorders is determined by genes has been estimated and is termed its *heritability*.

AFFECTED FAMILIES

The underlying cause of genetic disorders (defects in genes) cannot be treated. However, there are a number of methods by which the chances of a child being born with a genetically based disorder can be reduced.

If a couple is considering having children and any parents or close blood relatives (or they themselves) have a genetically based disorder, they would be wise to obtain *genetic counseling*. This is especially important if the couple has had a child with a genetically based condition.

Once a pregnancy is established, study of the genetic material in fetal cells obtained by techniques such as *chorionic villus sampling* and *amniocentesis* can establish whether or not certain genetic disorders are present. In cases where a serious disorder is found, a termination of the pregnancy may be chosen.

Genetic engineering

A branch of *genetics* concerned, in its broadest sense, with the alteration of the inherited, genetic material carried by a living organism to produce some desired change in the characteristics of the organism.

In practice, the main application of genetic engineering to date has been to mass-produce a variety of substances—all proteins of various sorts—that have uses in medical treatment and diagnosis. The function of any *gene* is to control the production of a particular protein in a living cell. If the gene responsible for synthesizing a useful protein can be identified, and if such a gene can be inserted into another cell that can be made to reproduce rapidly, then a colony of cells containing the gene can be grown. The colony will then produce the protein in large amounts.

WHY IT IS DONE

Genetic engineering has been used for producing some human hormones (notably *insulin* and *growth hormone*), some proteins for use in vaccines (against hepatitis, for example), and *interferon*, a substance with potential for treating viral infections. Other valuable aids to treatment are genetically engineered *factor VIII* (a protein used for the treatment of hemophilia), TPA (*tissue plasminogen activator*), a substance that dissolves blood clots, and many other medically useful substances.

HOW IT IS DONE

The main technique for mass-producing useful proteins by genetic engineering is called recombinant deoxyribonucleic acid (DNA) technology. DNA is the substance in cells that consists of strings of genes, which control the manufacture of different proteins.

The first step is to identify the gene in the DNA of a cell that controls the manufacture of a particularly useful protein. This involves a number of highly sophisticated laboratory techniques. The next step is either to extract the gene from the cell or, if the exact chemical structure of the gene can be worked out, to synthesize it.

The final step is to introduce the gene into the DNA of a suitable recipient cell. By the use of *enzymes* that can split a molecule of the recipent cell's DNA at certain sites, a gap can be produced into which the additional gene can be spliced (hence the term recombinant DNA).

The types of cells or organisms suitable for such genetic alteration are those that can subsequently be made to reproduce rapidly and indefinitely. The most popular organisms to date have been the common intestinal bacterium *ESCHERICHIA COLI* and various yeasts, but cells of other organisms, including human cancer cells, have also been used with success.

OUTLOOK

In view of the ease with which some of the bacteria and other organisms used for genetic engineering can reproduce, and the possibility of accidentally creating and liberating highly dangerous microorganisms, doubts have frequently been expressed about the dangers of "tampering with nature" in this way. These dangers are real but are well recognized by researchers in the field, who have produced stringent codes of practice and regulations to ensure safety.

In the future, it may be possible to extend genetic engineering to the manipulation of human genetic material for purposes of treating *genetic disorders*.

Genetic probe

A specific fragment of deoxyribonucleic acid (*DNA*) used to determine whether particular defects or genetic "markers" are present in a person's or a fetus's genetic material—that is, in the DNA that, along with some pro-

tein, makes up the *chromosomes* in his or her cells.

Genetic probes are used primarily in the prenatal diagnosis of certain genetic disorders and to determine whether or not certain people are "carriers" of gene defects. Often, there is no technique for detecting the defective gene itself. However, for certain gene defects (e.g., the one responsible for *cystic fibrosis*) markers (sections of DNA with a specific base sequence) have been identified that very commonly occur on particular chromosomes in association with the defect. Hence, if the marker can be found, it provides strong evidence that the gene defect is also present. This has particular implications for *genetic counseling*.

In one technique, the chromosome under test (obtained from a cell of the person or the fetus under investigation) is first broken up using *enzymes* (the probe) in a test tube; the fragments are then fixed onto a filter. A radioactively labeled sequence of DNA that will bind to the "marker" sequence of DNA in the chromosome (if present) is then added, and sophisticated techniques are performed to see whether such binding has occurred.

Genetics

The study of *inheritance*—that is, how the characteristics of living organisms are passed from one generation to another, the chemical basis by which such characteristics are determined, and the causes of the similarities and differences among individuals of one species (for example, the human species) or among different species. More particularly, genetics includes the study of deoxyribonucleic acid (*DNA*), the substance in cells that determines the characteristics of an organism, and of *genes*, which are units of inheritance corresponding to specific bits of DNA.

Particular branches of human genetics include population genetics, which studies the relative frequency of various genes in different human races; molecular genetics, which is concerned with the structure, function, and copying of DNA from one cell to another, and also how *mutations* (changes) occur in DNA; and medical or clinical genetics, which is concerned with the study and prevention of *genetic disorders*.

Genital herpes

See *Herpes, genital*.

Genitalia

The reproductive organs, especially the external ones. The male genitalia include the *penis*, *testes* (within the *scrotum*), *prostate gland*, seminal vesicles, and associated ducts, such as the *epididymis* and *vas deferens*. The female genitalia include the *ovaries*, *fallopian tubes*, *uterus*, *vagina*, *clitoris*, *vulva*, and *Bartholin's glands*.

Genital ulceration

An eroded area of skin on the *genitalia*. In men the ulcer may be on the skin of the penis or scrotum; in women it may be on the vulva or within the vagina.

CAUSES

The most common cause of genital ulceration is a *sexually transmitted disease*. The early stages of *syphilis* are characterized by a hard *chancre*, a painless ulcer where the bacteria penetrated the skin. This may be followed by shallow, elongated ulcers once the chancre has healed. The *herpes simplex* virus causes painful, fluid-filled blisters to develop on the genitalia; if these blisters become infected by bacteria they may ulcerate. Both *chancroid* and *granuloma inguinale* are bacterial infections that cause genital ulcers; they are common in tropical countries. In the former the ulcers are painful, in the latter they are painless. *Lymphogranuloma venereum* is a viral infection in which the resulting blisters occasionally ulcerate.

Other causes of genital ulceration include *herpes zoster*, *tuberculosis*, or a tumor of the testis, which can erode the scrotum to cause an ulcer.

Genital ulceration may also be a side effect of drugs. It can be caused by solutions applied to genital warts in high concentrations. It can also be a reaction to a drug taken by mouth; sulfonamide antibacterial drugs, for example, can cause mouth and genital ulcers (see *Stevens-Johnson syndrome*).

Behçet's syndrome is a rare condition that causes tender, recurrent ulcers in the mouth and on the genitals. Cancer of the penis or vulva may cause a single, painless ulcer with raised, rolled edges that turn outward.

DIAGNOSIS

The diagnosis of the underlying cause is made from the appearance of the ulcer and the presence of other signs, such as enlarged lymph glands or a skin rash. Swabs from the ulcer are taken and the material examined and cultured to look for a specific bacterium or virus. Blood tests to detect antibodies to a specific type of infection may be performed.

Genital warts

See *Warts, genital*.

Gentamicin

ANTIBIOTIC

Injection Ointment Cream Eye drops

Prescription needed

Available as generic

A drug given by injection, sometimes in combination with another antibiotic, to treat serious infections. For example, gentamicin is used to treat *meningitis*, *septicemia* (blood poisoning), and *endocarditis* (inflammation of the heart lining). Gentamicin cannot be given by mouth because it is inactivated during digestion.

During treatment, blood tests are taken to determine gentamicin levels to monitor dosage and thus reduce the risk of toxic damage to the kidneys or inner ear.

The drug is used in eye drops to treat *conjunctivitis* caused by infection.

Gentian violet

A purple dye used mainly by biologists to make bacteria visible under the microscope. Gentian violet also has antiseptic properties and can be applied to the skin to treat burns, boils, carbuncles, and fungal infections. It is occasionally used to relieve soreness in the mouth caused by *candidiasis* (thrush).

Genu valgum

The medical term for *knock-knee*.

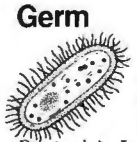
Genu varum

The medical term for *bowleg*.

Geriatrician

A physician who specializes in treating elderly patients and the special conditions related to aging.

Geriatric medicine



The medical specialty concerned with care of the elderly. Many diseases and disorders that affect the elderly may occur in patients of all ages, but older people tend to respond differently to sickness and treatment. For example, *aging* is associated with a progressive decline in the functioning of major organs—the heart, lungs, kidneys, liver, and brain. Consequently, an infection in one of these organs or elsewhere in the body that would cause only minor illness in a young adult might be life-threatening in an

G

older person. Any illness in an elderly person may cause a temporary but marked slowing of thought processes, and may even lead to confusion and other features that may be mistaken for dementia. This is due to the added stress placed on the brain during the illness. Furthermore, many medicinal drugs are eliminated from the body by the liver or kidneys and, if these organs are affected by aging, dosages of drugs used in treatment may need to be modified to avoid dangerous side effects.

A physician who specializes in geriatrics is expert at assessing the health of patients and in assessing the complex features of their disease. He or she takes particular care not to give excessive doses of drugs and tries also to avoid moving the patient away from familiar surroundings unless hospital admission is essential. Geriatricians are also skilled at rehabilitation; they usually make the contacts (with social services and voluntary agencies) that are necessary to arrange a comprehensive rehabilitation program.

Germ

The popular term for any microorganism that causes disease. Examples include a *virus* or bacterium (see *Bacteria*). In medicine, the term is used to describe simple, undifferentiated cells that are capable of developing into specialized tissues, such as the cells of the early embryo.

German measles

Another name for *rubella*.

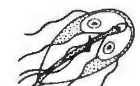
Germ cell tumor

A localized proliferation of cells that are the immature forms of either sperm in the male testis or ova (eggs) in the female ovary. (See *Seminoma*.)

Gerontology

The study of *aging* in all its aspects (developmental, biological, medical, sociological, and psychological). The specialty that treats the medical problems of the elderly is called geriatrics (see *Geriatric medicine*).

Gestalt theory



Ideas based on the notion that the whole is more than the sum of its parts; a school of psychology based on the idea that a sense of wholeness is more important than the individual bits and pieces of perception and behavior. It was founded in Germany early this century by a group that adopted the name gestalt, meaning "form," "pattern," or "configuration." In studying emotional states and social issues, Gestalt theory emphasizes viewing things as a whole rather than breaking them down into collections of stimuli and responses. Gestalt therapy became popular as a means of coping with personal problems and is still practiced today by some therapists; this type of therapy aims to increase self-awareness by looking at all aspects of an individual within his or her environment.

Gestation

The period from conception to birth, during which the developing fetus is carried in the uterus.

Gestation normally lasts around 270 days, about nine months. Because of the difficulty in determining the precise date of conception, physicians time pregnancies from the first day of the last normal menstrual period, giving a gestation period of 284 days.

Giardiasis

An infection of the small intestine, caused by the protozoan (single-celled) parasite *GIARDIA LAMBLIA*. Giardiasis is most common in tropical areas and in travelers to the tropics. Recently it has become more common in developed countries, affecting especially homosexual men, people living in institutions, and preschool children. The infection is particularly common where large numbers of young children gather together—for example, in day-care centers and preschools. The disease is spread by contaminated food or water or by direct personal contact (e.g., by hand-to-mouth contact).

SYMPTOMS

About two thirds of those infected have no symptoms. When symptoms do occur they begin one to three days after the parasite has entered the body. The person has violent attacks of diarrhea accompanied by flatus (gas); the feces are foul-smelling, may be greasy, and tend to float in the toilet bowl. Abdominal discomfort, cramps, or swelling, loss of appetite, and nausea may also occur. In some cases, the infection becomes chronic.

DIAGNOSIS AND TREATMENT

The infection is diagnosed from microscopic examination of a sample of feces for the presence of the parasites. If there is any doubt, a jejunal *biopsy* (removal of a small sample of tissue for microscopic analysis) may be carried out.

Acute giardiasis usually clears up without treatment. However, treatment incorporating the antibiotic metronidazole or quinacrine relieves symptoms quickly and prevents the spread of infection.

PREVENTION

Infection can be prevented by thorough hand washing before handling food and by avoiding eating food or drinking water that could possibly be contaminated.

HOW GIARDIASIS IS SPREAD

Giardiasis is spread by contaminated water or food, or by personal contact. This parasitic infection is most common in the tropics, but recently it has become a more frequent occurrence in developed countries, especially among groups of preschool children.

Giddiness
See *Dizziness*.

Gigantism
Excessive growth (especially height) resulting from overproduction, during childhood or adolescence, of growth hormone by a tumor of the pituitary gland. Untreated, the tumor eventually destroys the pituitary gland and results in death during early adult life. If the tumor develops after growth has stopped, the result is *acromegaly* rather than gigantism.

Oversecretion of growth hormone from early life can result in an individual attaining an immense height. The tallest documented giant in medical history, Robert Wadlow, reached a height of 8 feet 11 inches and a weight of 475 pounds before he died at age 22. Such instances are rare, however. By far the most common reason for a child being tall is that his or her parents are tall. Other rare causes of excessive height in childhood are *Marfan's syndrome* and *thyrotoxicosis*.

DIAGNOSIS AND TREATMENT

The diagnosis of gigantism is made when *brain imaging* and blood tests confirm the presence of a pituitary tumor and excessive growth hormone. The condition may be treated with bromocriptine, a drug that blocks the release of growth hormone, or by surgery or radiation therapy to destroy or remove the tumor.

Gilbert's disease
An inherited disorder that affects the way bilirubin is processed by the liver and that may cause mild jaundice. Sufferers are otherwise healthy.

Gilbert's disease is common, affecting about 2 percent of the population. Usually there are no symptoms. When there are symptoms, they may include malaise, anorexia, upper abdominal pain, and mild jaundice.

Usually no treatment is necessary, but the drug phenobarbital can relieve jaundice and other symptoms.

Gilles de la Tourette's syndrome
A rare disorder of movement, named for the French neurologist who first described it in 1885. It starts in childhood with repetitive grimaces and tics, usually of the head and neck, sometimes of the arms, legs, and trunk. Involuntary barks, grunts, or other noises may appear as the disease progresses. In about half the cases, the sufferer has episodes of coprolalia (using foul language).

The syndrome is more common in males, partially inherited, and is probably underdiagnosed because of its strange symptoms. It is usually of lifelong duration but *antipsychotic drugs*, such as haloperidol, can often provide effective relief.

Gingiva
The Latin name for the *gum* that surrounds the base of the teeth.

Gingivectomy
Surgical removal of part of the gum margin. Gingivectomy may be used to treat severe cases of gingival *hyperplasia* (thickening of the gums), a condition usually caused by anticonvulsant treatment with phenytoin. Gingivectomy also is used to remove pockets of infected gums formed during advanced stages of gum disease (*periodontitis*).

Gingivectomy is performed in the dentist's office using local anesthetic. After surgery, the newly exposed area around the base of the teeth may initially be sensitive; the exposure also gives the teeth a longer appearance. There are no complications as long as scrupulous *oral hygiene* is maintained after surgery.

Gingivitis
Inflammation of the gingiva (gums), often due to infection. Gingivitis is a reversible stage of gum disease.

CAUSES

Gingivitis is usually caused by the buildup of plaque (a sticky deposit of bacteria, mucus, food particles, and other irritants) around the base of the teeth. It is thought that toxins produced by bacteria within the plaque irritate the gums, causing the gums to become infected, tender, and swollen. Gingivitis can result from injury to the gums, usually from overvigorous toothbrushing or careless flossing.

INCIDENCE

Mild gingivitis is very common in young adults. Pregnant women and diabetics are susceptible because of changes in their hormone levels.

SYMPTOMS

Healthy gums are pink or brown and firm; in people with gingivitis, they become red-purple, soft, shiny, and swollen. The gums bleed easily, especially during toothbrushing, and are often tender.

PREVENTION AND TREATMENT

Good *oral hygiene* is the main means of preventing and treating gingivitis. Teeth should be thoroughly brushed with a fluoride dentifrice (toothpaste) at least once a day and after meals, if possible; dental floss should be used at least once a day. It is also important to visit your dentist at least once a year (or more often if he or she recommends) so that teeth can be cleaned to remove calculus (mineralized plaque) and accumulated plaque through a procedure known as scaling. The dentist may prescribe an antibacterial mouthwash for use at home.

Example of gingivitis
The gums around the bases of the upper teeth are puffy, shiny, and tender. They overhang the teeth margins. Affected gums often bleed when brushed.

COMPLICATIONS

Untreated gingivitis may damage gum tissue around the base of the teeth, leading to the formation of pockets in which plaque and calculus can collect. Bacteria within the plaque may cause inflammation to spread, eventually leading to *periodontitis*, an advanced stage of gum disease in which the supporting tissues of the teeth and the surrounding bone become eroded, loosening the teeth.

Acute necrotizing ulcerative gingivitis may develop due to invasion of tissue by *anaerobic* bacteria in people with chronic gingivitis, especially those with lowered resistance to infection. Also called trench mouth or Vincent's disease, acute necrotizing ulcerative gingivitis is a serious condition resulting in destruction of gum tissue; it requires a course of antibiotic treatment.

Gland
A group of specialized cells that manufactures and releases chemical substances, such as hormones and *enzymes*, for use in the body.

There are two main types of glands: endocrine and exocrine. *Endocrine glands* do not have ducts and thus release their secretions directly into the bloodstream; examples include the pituitary, thyroid, and adrenal glands. Target organs may be quite distant from the endocrine glands.

G

Exocrine glands have ducts and release their secretions either onto the surface of the skin or into a hollow structure such as the mouth or digestive tract; examples include the sebaceous glands, which secrete sebum onto the skin, and the salivary glands.

Collections of cells in the *lymphatic system*, the lymph nodes, are sometimes referred to as glands. Strictly speaking, this is incorrect usage because they do not secrete chemical substances. However, they do release white blood cells, which play an important role in fighting infections and allergic reactions.

Glanders

An infection of horses and donkeys that is rarely transmitted to humans. It occurs in Asia, Africa, and South America and is caused by the bacterium PSEUDOMONAS MALLEI, which enters the body through a cut or abrasion or by being breathed in.

Initially, symptoms (mild fever, headache, general aches and pains, and possibly some generalized swelling of the lymph nodes) are vague. If bacterial entry was through a wound, ulcers or abscesses may then appear at the site; if entry was through the lungs, *pneumonia* may develop. In severe cases, *septicemia* (blood poisoning) may then follow.

DIAGNOSIS AND TREATMENT

The disease is diagnosed by identifying the bacteria in a sample of pus or sputum (phlegm) or by detecting antibodies to the bacteria in a blood sample. Early treatment with an appropriate antibiotic usually clears the infection.

Glands, swollen

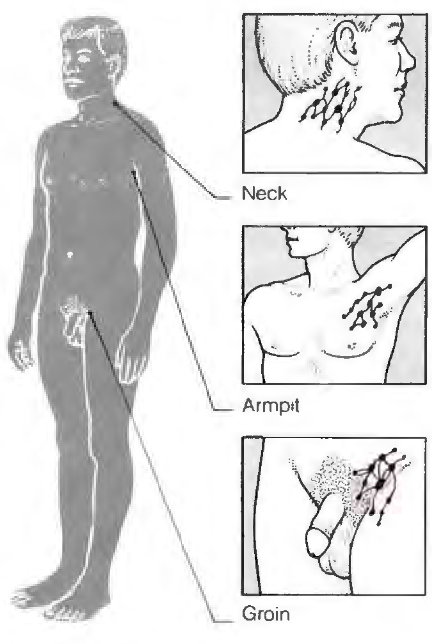
Known medically as lymphadenopathy, enlargement of the lymph nodes (glands) as a result of inflammation and/or proliferation of white blood cells within them.

CAUSES

Swollen glands are a very common symptom and are usually due to an infection or allergic reaction (see *Allergy*). Children are especially prone to swollen glands as a result of infection, partly because the lymphatic system plays a more important part in combating infections in childhood than in adult life.

Rarer causes of swollen glands include *lymphoma, Hodgkin's disease, leukemia* (cancer of the white blood cells), or a *metastasis* (secondary cancer that has spread from elsewhere in the body).

When the underlying cause is localized, swollen glands also tend to be confined to a limited area; for example, a throat infection may result in swelling only of the lymph glands in the neck.



Swollen glands near the surface of the skin—in the groin or neck, for example—are usually felt as tender, slightly warm lumps. However, swelling of deeper glands, such as those in the lungs or abdomen, is almost invariably unnoticeable.

INVESTIGATION AND TREATMENT

In many cases, the cause of swollen glands is obvious from the presence of a localized infection or a bee sting that has caused an allergic reaction. In other cases, the accompanying symptoms usually indicate the cause; for example, swollen glands with a sore throat, fever, and tiredness suggest infectious *mononucleosis* (glandular fever).

If swollen glands persist or there is no obvious cause, tests may be necessary. These may include a blood count, chest X rays to look for swollen glands in the lungs, or a *biopsy* (removal of tissue for microscopic analysis) of an affected gland.

Treatment depends on the underlying cause. Antibiotics may be given for a bacterial infection, antihistamines for an allergy, or *radiation therapy* or *chemotherapy* (or both) may be used to treat a tumor.

Common sites of swollen glands
The three most common sites where swollen glands can be felt are in the neck, armpit, and groin

Glandular fever

See *Mononucleosis, infectious.*

Glasses

Simple optical devices used to correct focusing errors in the eyes so that clear vision is achieved. The lenses are made of glass or plastic and the shape and thickness are chosen during an eye test (see *Vision tests*).

TYPES OF LENSES

Lenses may be convex (outwardly curved), concave (inwardly curved), or cylindrical. Most are single-vision lenses, but bifocal or trifocal lenses, with smaller areas differing in power from the main lens, are common. Varifocal lenses, with power increasing gradually from the center to one edge, are becoming popular. Lenses may have a permanent tint or may incorporate chemicals that produce darkening on exposure to light.

Glass eye

See *Eye, artificial.*

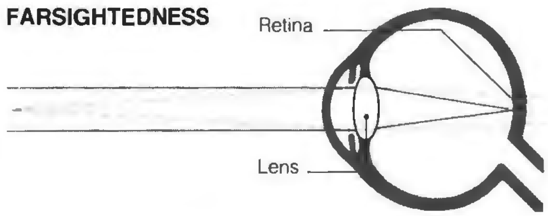
Glaucoma

A condition in which the pressure of the fluid in the eye is so abnormally high that it causes damage. A minimal pressure is required to maintain the shape of the eyeball, but excessive pressure may result in the compression and obstruction of the small internal blood vessels and/or the fibers of the optic nerve. The result is nerve fiber destruction and partial or complete loss of vision.

TYPES AND CAUSES

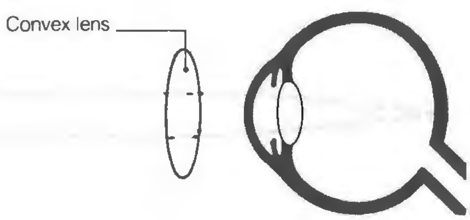
The most common form is chronic open-angle glaucoma, which rarely occurs before the age of 40 and often causes no symptoms until blindness is advanced. It is due to a gradual blockage of the outflow of aqueous humor (fluid in the front compartment of the eye) over a period of years, causing a slow rise in pressure. This type tends to run in families.

In acute closed-angle glaucoma, there is a sudden obstruction to the outflow of aqueous humor from the eye and the pressure rises suddenly. Subacute angle-closure glaucoma is similar to acute glaucoma, but develops more slowly or occurs intermittently.



Congenital glaucoma is due to a structural abnormality in the drainage angles of the eyes.

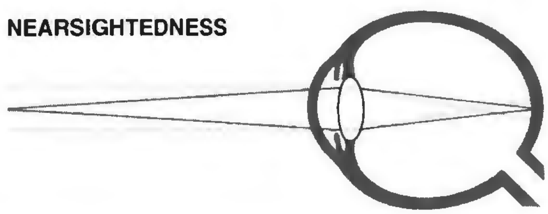
Glaucoma can also be caused by injury to the eye, or by a serious eye disease such as *uveitis*, dislocation of the lens, or adhesions between the iris and the cornea.



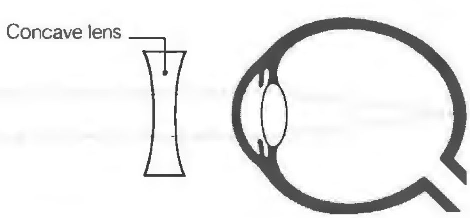
WHY GLASSES ARE USED

For *hyperopia* (farsightedness), convex (or plus) lenses are needed. Sufferers of *presbyopia* also need plus (magnifying) lenses. Myopia (nearsightedness) requires concave (or minus) lenses.

FARSIGHTEDNESS

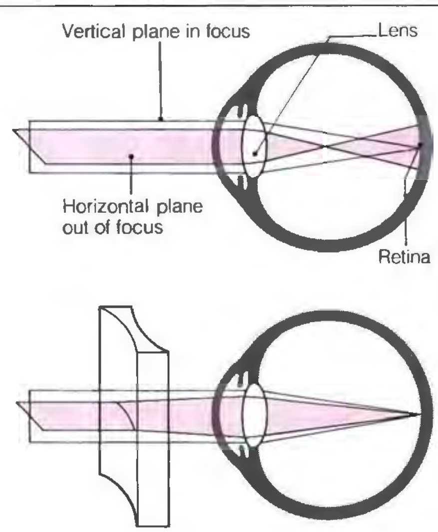


Before correction
Farsightedness is caused when focusing power is inadequate. Light from a distant object is focused on the retina, but light from a close object is focused behind it.



After correction
Convex magnifying (or plus) lenses cause the light from the close object to focus on the retina.

NEARSIGHTEDNESS

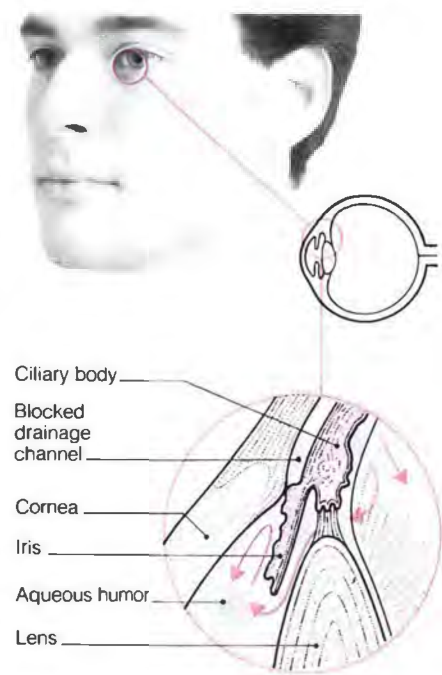


Before correction
Distant objects are blurred, because the focusing power of the eye is too great. Light from the distant object is focused in front of the retina.

After correction
Concave weakening (or minus) lenses are used to cause the light from the distant object to focus onto the retina.

ASTIGMATISM

The surrounding surfaces of the cornea are steeper in one direction than in the other. The correcting lenses are designed with additional curvature in one meridian. The lenses are then set accurately in the frame of the glasses so that the steepest curves correspond to the flattest meridian of the cornea. Both concave lenses for myopia and convex lenses for hyperopia and presbyopia can be designed in this way to correct astigmatism.



INCIDENCE

Glaucoma is one of the most common major eye disorders in people over 60; it is responsible for 15 percent of blindness in adults in the US. Nearly 2 percent of people over the age of 40 have chronic glaucoma. The incidence rises with age and about 10 percent of people over 70 have abnormally raised pressure within the eye.

SYMPTOMS AND SIGNS

Chronic glaucoma often causes no symptoms because the gradual loss of peripheral vision is not apparent to the affected person. Only late in the disease, when there is severe, irreversible damage, may the person be aware of some visual loss.

Acute closed-angle glaucoma
This type of glaucoma is caused by an unduly narrow angle between the iris and the back of the peripheral cornea. Dilation of the pupil may therefore lead to a sudden complete blockage of the outflow, causing a rapid increase in pressure in the eyeball.

The symptoms of acute glaucoma include a dull, severe, aching pain in and above the eye, some fogginess of vision, and the perception of rainbow rings around lights at night (halos). Nausea and vomiting can occur and the eye can become red and have a partly dilated pupil and a hazy cornea. Subacute glaucoma can cause similar mild, brief episodes.

DIAGNOSIS

Chronic glaucoma often causes no symptoms and is usually detected only by regular, routine eye examina-

tions. Applanation tonometry (by which eye pressure is measured) is an essential check for glaucoma (see *Eye, examination of*), especially if there is a family history of the disorder. Use of an *ophthalmoscope* to examine the back of the eye may show an abnormal optic nerve. Visual field testing and gonioscopy (examination of the drainage angle) can also be important.

TREATMENT

Chronic open-angle glaucoma can usually be controlled with eye drops, which reduce the pressure in the eye. Repeated tonometry and visual field testing may be carried out to ensure that the pressure is being controlled; if necessary, other eye drops will be given. If drops fail to control the pressure, tablets or long-acting capsules may also be prescribed. The medications for treatment of chronic glaucoma usually are prescribed for life since, if stopped, the pressure generally rises. If medications fail to reduce the pressure in chronic glaucoma, and if there is a continuing loss of visual field or vision, laser surgery or cutting surgery may be necessary to open up the drainage channel or to create an artificial channel for the aqueous humor.

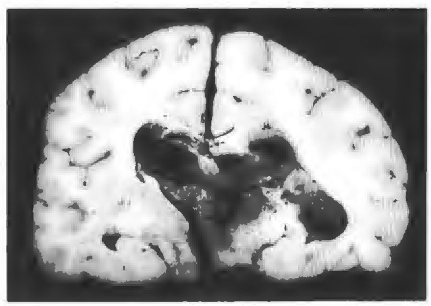
Acute closed-angle glaucoma is a medical emergency calling for urgent treatment. Various treatments (i.e., eye drops, pills, liquids, and/or intravenous fluids) are given to try to reduce the very high eye pressure. Usually, after the pressure is controlled, laser surgery or cutting surgery is necessary for the treatment of acute glaucoma and subacute glaucoma to try to prevent a recurrent attack. Usually a peripheral *iridectomy* is done. A small opening is made in the periphery of the iris so that aqueous humor can drain more easily. The iridectomy is often curative but, if the drainage angle was damaged by the attack, medications may be needed to control the pressure after surgery. If the iris is scarred at the drainage angle, other types of surgery, such as creating an artificial drainage channel, may be necessary.

OUTLOOK

The pressure rise of glaucoma can be prevented by treatment, but early diagnosis and treatment are needed to prevent any impairment of vision. Regular eye examinations are important for early detection.

Glioblastoma multiforme

A fast-growing and highly malignant type of *brain tumor*. Glioblastoma multiforme is a type of *glioma*, a tumor arising from glial (supporting) cells within the brain. Most glioblastomas develop within the cerebrum (the main mass of the brain).



There are about five to 10 new cases of glioblastoma multiforme per million population per year in the US. The cause is unknown.

Symptoms, diagnosis, and treatment are as for other types of brain tumor. Despite treatment, the outlook is poor, with few patients surviving beyond two years.

Glioma

A type of *brain tumor* arising from the supporting glial cells within the brain.

Gliomas make up about 60 percent of all primary brain tumors (growths originating from the brain itself rather than spread from elsewhere). There are about two to four new cases of glioma per 100,000 people annually in the US.

Cross section of a brain
This photograph (taken from an autopsy specimen) shows a large area of brain infiltrated by a glioma (dark color)

Types of glioma include *astrocytoma*, *glioblastoma multiforme* (a highly malignant variety of astrocytoma), *ependymoma* and *medulloblastoma* (more common in children), and *oligodendroglioma*. Symptoms, diagnosis, and treatment are as for other types of brain tumor.

Glipizide

An oral *hypoglycemic drug* used in the treatment of non-insulin-dependent *diabetes mellitus*. Glipizide stimulates the pancreas to produce *insulin*, which promotes glucose uptake into muscle and fat, thereby lowering the blood glucose level.

Globulin

Any of a group of proteins characterized by being insoluble in water but soluble in dilute salt solutions; *antibodies* (also known as *immunoglobulins*) are an example.

TYPES

Globulins can be divided into three main groups, known as alpha-, beta-, and gamma-globulins.

Alpha-globulins include alpha$_1$-antitrypsin and haptoglobin. The former is an enzyme produced by the lungs and liver; deficiency is associated with *hepatitis* in children and *emphysema* (a lung disorder) in young adults. Haptoglobin is found in the blood, where it binds together *hemoglobin* (the oxygen-carrying protein in red blood cells) and prevents it from being excreted in the urine by the kidneys. Various other alpha-globulins are produced as a result of inflammation, tissue damage, *autoimmune disorders* (when the immune system attacks the body's own tissues), or certain cancers.

Beta-globulins consist mainly of low-density lipoproteins (LDLs), substances involved in the transport of fats in the blood circulation, and transferrin, which carries iron in the blood. The amount of beta-globulins is increased in certain types of *hyperlipidemia* (abnormally high levels of fats in the blood).

All of the gamma-globulins are antibodies, proteins produced by the immune system in response to infection, during allergic reactions, and after organ transplants. Gamma-globulins may also be produced in any disorder that causes persistent inflammation of an organ, such as *rheumatoid arthritis* or *cirrhosis* of the liver. In addition, certain conditions, such as *multiple myeloma*, result in the production of large amounts of a specific gamma-globulin.

Globus hystericus

A form of hysteria in which there is an uncomfortable feeling of a "lump in the throat." This lump is felt to interfere with swallowing and breathing, sometimes so much so that the sufferer is convinced that he or she cannot breathe. Respiration comes in sighs or gasps, anxiety increases, and *hyperventilation* (rapid breathing) and symptoms of a *panic attack* often ensue. Some patients insist that their Adam's apple has become larger or displaced in some way.

There is no true physical basis for these attacks, which occur in anxious or depressed people. The condition is not life-threatening. Breathing in and out of a small paper bag fitted tightly around the nose and mouth will alleviate the symptoms brought on by hyperventilation. Treatment is by

reassurance, breath-control training, and, in some instances, psychotherapy. Use of *antianxiety drugs* or *antidepressant drugs* to treat the condition is rarely helpful.

Glomerulonephritis

Inflammation of the glomeruli (filtering units of the kidney). Both kidneys are affected, although not all the glomeruli are affected simultaneously. Damage to the glomeruli hampers the removal of waste products, salt, and water from the bloodstream, which may cause serious complications.

CAUSES AND INCIDENCE

The incidence of glomerulonephritis varies markedly among different parts of the world, mainly because some common tropical diseases (such as malaria and schistosomiasis) are important causes. Although these diseases rarely are responsible for glomerulonephritis in developed countries, glomerulonephritis is still the most common cause of chronic *renal failure* (loss of kidney function) in the US and Europe.

Some types of the disease are caused by the patient's *immune system* making antibodies to eliminate microorganisms—usually the bacteria responsible for a minor infection, such as streptococcal sore throat infections. Particles called immune complexes, formed from antibodies and bacterial antigens, circulate in the bloodstream and become trapped in the glomeruli; this triggers an inflammatory process that may damage the glomeruli and prevent them from working normally. Glomerulonephritis also occurs in some *autoimmune disorders*, systemic *lupus erythematosus* (a chronic disease of connective tissues), and the immunoglobulin A (IgA) glomerulonephritis known as Berger's disease.

SYMPTOMS

Mild forms of glomerulonephritis may produce no symptoms and the disease may be noted only when a urine sample is tested for some other reason. Sometimes a mild puffiness of the soft tissues surrounding the eyeballs (periorbital edema) may be apparent. Other times it comes to light only when renal failure has reached an advanced stage and symptoms arise because of the accumulation of waste products and fluid that are usually eliminated in the urine.

High blood pressure may develop and some sufferers experience a dull ache in the loins. Damaged glomeruli may allow the escape of red blood cells into the urine, which can become blood-stained. When protein is continually lost in the urine, the result is *edema* (swelling of parts of the body; see illustration). The combination of proteinuria (large amounts of protein in the urine), low albumin (protein) in the blood, and edema is called the *nephrotic syndrome*.

In some cases, glomerulonephritis is severe and sudden, so that kidney failure develops over a few days; patients often notice that they are passing very small quantities of urine.

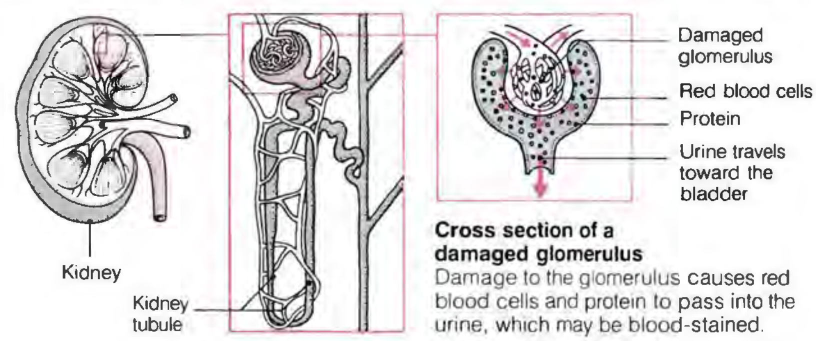
DIAGNOSIS

There are numerous types of glomerulonephritis; one cause may produce a different type in different individuals. Urinalysis and examination of the urine sediment (after centrifugation) is helpful in diagnosis. Kidney *biopsy* (removal of a small amount of tissue for laboratory analysis) is also important for diagnosis. Other tests that may be performed are blood and urine sampling to measure how well the kidney is removing waste products and to measure how much protein is being lost in the urine. These tests may be repeated during treatment to see how the kidneys are responding.

TREATMENT AND OUTLOOK

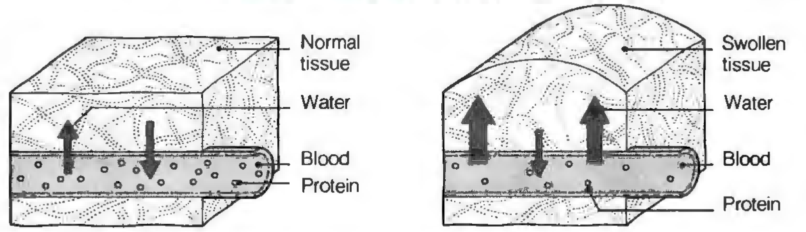
Treatment depends on the type and severity of the disease, as revealed by biopsy. Affected children usually have mild forms characterized by the nephrotic syndrome; they usually recover completely after treatment. Children who experience acute glomerulonephritis after a streptococcal infection usually recover even without specific treatment of the glomerulonephritis.

Adults tend to respond less well to treatment, but drugs may be prescribed to control hypertension and a special diet given to reduce the kidneys' load. This may prevent or delay eventual renal failure. A minority of people with severe glomerulonephritis may be given *immunosuppressant drugs* (to dampen the body's defense system), or *plasmapheresis* to remove substances and particles from the bloodstream that trigger the inflammation (i.e., substances released as a result of the immune response).



Glomerulosclerosis

Scarring that occurs as a result of damage within the glomeruli (filtering units) of the kidney.



THE EFFECTS OF GLOMERULONEPHRITIS

The glomeruli are damaged as a result of inflammation. Red blood cells and protein leak into the urine.

Protein loss from the circulation causes fluid to accumulate in body tissues, causing edema.

Cross section of a damaged glomerulus
Damage to the glomerulus causes red blood cells and protein to pass into the urine, which may be blood-stained.

Healthy tissue
Through osmotic pressure, protein molecules in the blood draw back water lost to surrounding tissues

Edema
If protein is lost into the urine, there is a fall in osmotic pressure and more water escapes into surrounding tissues, causing swelling.

Mild glomerulosclerosis occurs normally with age; a 10 percent decrease in renal function is common each decade after age 30. However, even a 75 percent reduction in renal function is compatible with a normal life.

Glomerulosclerosis may occur in some severe types of *glomerulonephritis* that are difficult to treat and in which damage progresses to destroy the kidneys. Typically, sufferers develop heavy *proteinuria* (the presence of protein in the urine) and severe *edema* (swelling of parts of the body due to fluid collection).

Glomerulosclerosis is also found in some people with *diabetes mellitus*. It is seen in reflux nephropathy (backflow of urine from bladder to kidney sometimes associated with infection) and in some people with hypertension. Intravenous drug abuse may cause glomerulosclerosis. The condition has also been found in some people who have AIDS.

Glomus tumor

A small, painful, bluish swelling in the skin, usually on a finger or toe near or under the nail, that is tender to touch and more painful if the limb is hot or cold. The tumors result from an overgrowth of glomus bodies, structures with numerous nerve endings that normally control blood flow and temperature in the skin. Glomus tumors are surgically removed.

Glossectomy

Removal of all or part of the tongue. Glossectomy may be performed in the treatment of cancer of the tongue, but more usually such cancers are treated by radiation therapy. If a large part of the tongue is removed, speech is impaired and eating is difficult. A liquid diet is then necessary.

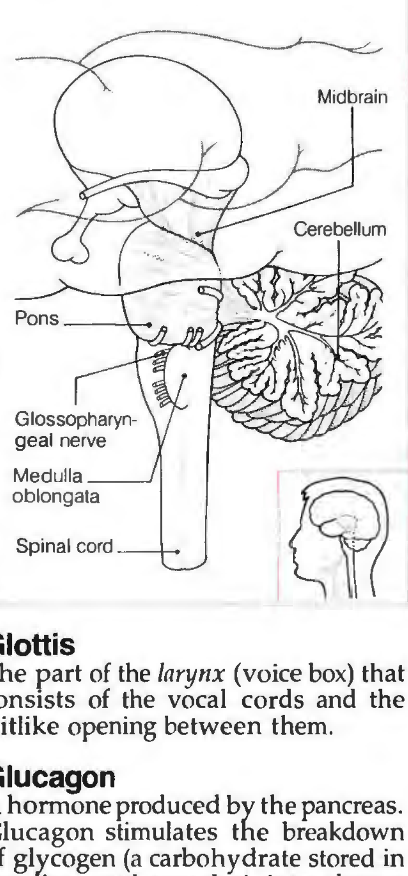
Glossitis

Inflammation of the tongue. The tongue feels sore and swollen and looks red and smooth; adjacent parts of the mouth may also be inflamed.

Glossitis occurs in iron deficiency anemia, in pernicious and megaloblastic anemias, and in other vitamin B deficiencies. Other causes include infection (especially *herpes simplex*) of the mouth, irritation by dentures, and excessive use of alcohol, tobacco, or spices. A congenital form of glossitis affects the middle portion of the back of the tongue.

Treatment is for the underlying cause. Self-help measures include maintaining good oral hygiene, not smoking, and avoiding acidic or spicy foods that aggravate the soreness. Regular rinsing of the mouth with a salt solution may help.

Glossolalia



Speaking in jargon or an imaginary language that has no actual meaning or syntax. Today it occurs almost exclusively at religious meetings. Some Christians regard glossolalia as a sign of possession by the Holy Spirit; scientists tend to view it as a form of *hypnosis* or *hysteria*.

Glossopharyngeal nerve

The ninth *cranial nerve*, the glossopharyngeal nerve performs both sensory and motor functions. It conveys sensations, especially taste, from the back of the tongue, regulates secretion of saliva by the parotid gland, and controls movement of the throat muscles.

LOCATION OF THE GLOSSOPHARYNGEAL NERVE

The nerve arises from the medulla oblongata and branches to the tongue, parotid gland, and pharynx.

Glottis

The part of the *larynx* (voice box) that consists of the vocal cords and the slitlike opening between them.

Glucagon

A hormone produced by the pancreas. Glucagon stimulates the breakdown of glycogen (a carbohydrate stored in the liver and muscles) into glucose (sugar). The glucose is then released into the bloodstream, where it is available as a source of energy for cells anywhere in the body. Glucagon therefore regulates the level of glucose in the blood; when the level falls, glucagon is released from the pancreas. Glucagon opposes the action of *insulin*.

USE AS A DRUG

Glucagon is extracted from the pancreas of pigs or cows for use as a drug. It is given by subcutaneous (under the skin) injection in the emergency treatment of sufferers of *diabetes mellitus* who are unconscious as a result of hypoglycemia (low blood sugar). Glucagon produces recovery within 15 to 20 minutes; the patient is then given glucose by mouth to prevent a relapse. Nausea and vomiting are occasional adverse effects.

Glucocorticoids

Hormones produced by the cortex (outer layer) of the adrenal glands that affect carbohydrate metabolism by increasing the blood sugar level and the amount of glycogen in the liver. The principal glucocorticoid is *hydrocortisone* (also called cortisol), which also has a milder *mineralocorticoid* (affecting sodium and potassium balance) effect.

Glucose

The body's chief source of energy for cell *metabolism*. A monosaccharide (simple sugar) *carbohydrate*, it comes principally from the digestion of other carbohydrates, although a small amount is also produced in cells by the metabolism of fats and proteins.

BLOOD SUGAR LEVELS

Despite wide variation in carbohydrate intake (and, therefore, large fluctuations in the amount of glucose in the body), the concentration of glucose in the blood—the blood sugar level—is normally kept within narrow limits. This is achieved by the actions of several hormones, notably *insulin*, *glucagon*, *epinephrine*, *corticosteroids*, and *growth hormone*. If the blood sugar level is abnormally high (known as *hyperglycemia*), it may cause *glycosuria* (glucose in the urine). An abnormally low blood sugar level is called *hypoglycemia*.

Insulin, released by the pancreas in response to increased blood sugar levels, lowers the level by stimulating the uptake of glucose by cells. Inside the cells, glucose may be "burned" to produce energy, converted to *glycogen* for storage (mainly in the liver and

muscles), or used in the production of triglycerides and fats.

Glucagon is released by the pancreas when the blood sugar level is low. It stimulates the breakdown of stored glycogen to glucose, which is then released into the bloodstream.

Epinephrine (released by the adrenal glands at times of stress) and corticosteroids (also released by the adrenals in response to factors such as infection) have the same basic effect as glucagon. That is, they stimulate the release of glucose to increase the blood sugar level.

Glue sniffing

See *Solvent abuse*.

Gluten

One of the proteins of wheat and certain other grains that gives dough its tough, elastic character. *Celiac sprue*, a sensitivity to gluten, is thought to affect between 0.1 and 0.2 percent of the population.

Gluten enteropathy

See *Celiac sprue*.

Gluten intolerance

See *Celiac sprue*.

Gluteus maximus

The large, powerful muscle in each of the buttocks that helps give them their rounded shape. The gluteus maximus is responsible for moving the thigh sideways and backward.

Glyburide

An oral *hypoglycemic drug* used to treat non-insulin-dependent *diabetes mellitus*. Glyburide stimulates the pancreas to produce insulin, which promotes the uptake of glucose (sugar) into muscle and fat tissue, thereby lowering the level of glucose in the blood.

Glycerin

A colorless syrup made from *glycerol* (an essential constituent of fats) and used in several drug preparations. Glycerin has a high water content, evaporates slowly, is easily absorbed, and has a softening effect.

WHY IT IS USED

Glycerin is used in moisturizing creams to help prevent dryness and cracking of the skin (for example, it is used to protect the nipples during breast-feeding).

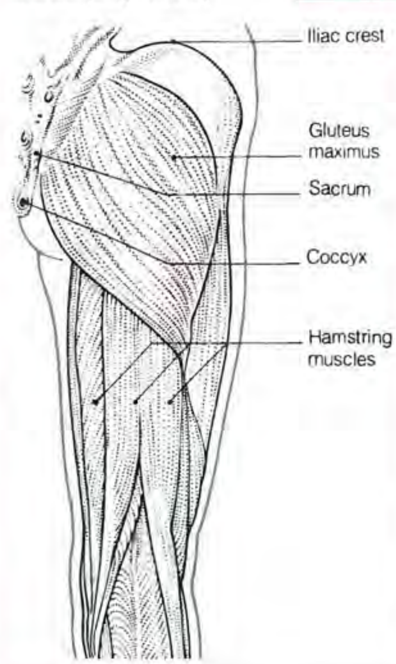
Glycerin is used in ear drops to help soften *earwax* prior to syringing of the ears, and in *cough remedies* to help soothe a dry, irritating cough. Taken as a suppository or an enema, glycerin relieves constipation by softening hard feces.

Glycerol

An essential constituent of fats. Glycerol is released during digestion and absorbed either alone or in combination with fatty acids. When one molecule of glycerol combines with three molecules of fatty acids, the result is a type of fat known as a triglyceride.

Most of the glycerol is deposited in the body's fat stores; the remainder is taken up by the liver, where it may be converted into *glucose* (sugar) to provide energy.

Glycogen



The principal *carbohydrate* storage material in the body. It is a polysaccharide, consisting of many saccharide (sugar) molecules linked to form a long chain, and is found mainly in the liver and muscles.

Glycogen plays an important role in controlling blood sugar levels. When there is too much sugar (glucose) in the blood, the excess is converted to glycogen. This conversion (controlled by *insulin* and *corticosteroid hormones*) takes place chiefly in the liver and muscles. When the blood sugar level is low, glycogen is converted back to glucose (a process regulated by the hormones *glucagon* and *epinephrine*) and released into the bloodstream.

LOCATION OF THE GLUTEUS MAXIMUS

The top is attached to the sacrum, coccyx, and pelvis. The lower part is attached to the femur (thigh bone).

Glycosuria

The presence of glucose (a type of sugar) in the urine.

CAUSES

Glucose is normally filtered from the bloodstream by the kidneys (along with many other normal blood constituents and unwanted waste products). The filtered fluid passes down the many tubules of the kidneys, where all except the unwanted substances are reabsorbed and returned to the bloodstream (see *Kidney*). Glucose is one of the substances that the tubules almost completely reabsorb.

The kidney may fail to reabsorb all the glucose because of *hyperglycemia* (a high level of glucose in the blood) or if the tubules have been damaged and are unable to reabsorb even normal amounts of glucose. Hyperglycemia occurs in *diabetes mellitus*. Damage to the kidney tubules may be a result of rare metabolic disorders present from birth or be a consequence of drug or heavy metal poisoning.

Glycosuria can also sometimes occur in people with healthy kidneys that are unable to reabsorb all of the glucose filtered out of the bloodstream. This condition tends to run in families. Glycosuria often occurs during pregnancy because of hormonal changes, a condition that is usually not serious if it is not accompanied by other symptoms and if the blood glucose level is normal.

DIAGNOSIS AND TREATMENT

Glycosuria by itself does not necessarily indicate a serious condition. It may be found during a routine examination or if the physician is performing specific tests because diabetes mellitus is suspected. Urine can be tested for glucose by using a chemically impregnated strip that changes color when it comes in contact with glucose. Treatment depends on the underlying cause.

Gnat bites

See *Insect bites*.

Goiter

Enlargement of the thyroid gland, visible as a swelling on the neck.

G

CAUSES

The thyroid gland may enlarge (without any disturbance of its function) at puberty, during pregnancy, or as a result of taking the birth-control pill. In many parts of the world the main cause of a goiter is lack of sufficient iodine in the diet. The thyroid requires this mineral to produce the hormone thyroxine; a deficiency causes the gland to swell.

A toxic goiter is one that develops in *Graves' disease* or with other types of overactivity of the thyroid gland in which there is excessive production of thyroid hormones. This leads to *thyrotoxicosis*, characterized by symptoms such as increased appetite, warm, dry skin, weight loss, tremor, insomnia, and occasional muscle weakness and agitation. A goiter also usually is found in *Hashimoto's thyroiditis*, an autoimmune disorder, and de Quervain's *thyroiditis*, an inflammatory condition, both of which damage the gland; it may also be caused by a tumor or nodule in the gland and, in rare cases, by cancer (see *Thyroid cancer*). A goiter can also be caused by taking antithyroid drugs for overactivity of the thyroid gland.

Appearance of goiter
The thyroid may become enlarged for any of various reasons, including dietary deficiency of iodine, inflammation, or an autoimmune disorder affecting the gland.

SYMPTOMS

A goiter can range in size from a barely noticeable lump to an enormous swelling, depending on the cause. Large swellings may press on the esophagus or the trachea, making swallowing or breathing difficult. Any accompanying symptoms must be verified with X-ray pictures.

DIAGNOSIS AND TREATMENT

Diagnosis is based on the nature of the swelling, along with accompanying symptoms and the results of blood tests or *radionuclide scanning* carried out to determine the activity of the thyroid gland.

A goiter not caused by disease may eventually disappear naturally or may be so small that it does not require treatment. However, a large or unsightly goiter, or one that is causing difficulties with swallowing or with breathing may require total or partial removal (see *Thyroidectomy*).

If iodine deficiency is identified as the cause, the patient will be advised to eat more fish and iodized salt, which are rich in the mineral. When a goiter is the result of disease, treatment will be for the underlying disorder. If a drug is the cause, the goiter usually disappears once the course of treatment is over.

Gold

ANTIRHEUMATIC

Capsule Injection

Prescription needed

Not available as generic

Gold is used to treat *rheumatoid arthritis* and arthritis arising as a complication of *psoriasis*. It is usually prescribed in severe active cases when a *nonsteroidal anti-inflammatory drug* (NSAID) has been ineffective.

HOW IT WORKS

Gold has an anti-inflammatory action that relieves joint pain and stiffness and can prevent more damage.

POSSIBLE ADVERSE EFFECTS

A common adverse effect of gold is *dermatitis* (inflammation of the skin); if itching occurs, the drug is usually withdrawn. Gold may damage the kidneys, liver, and bone marrow. Tests are performed during treatment to check the function of these organs.

Gold may cause loss of appetite, nausea, diarrhea, abdominal pain, and, occasionally, *anaphylactic shock* (a serious allergic reaction that requires emergency treatment).

Golfers' elbow

A condition caused by inflammation of the bony prominence (epicondyle) on the inner side of the elbow, to which certain forearm muscles are attached. It is caused by overuse of these muscles, which act to bend the wrist and fingers. Activities that can cause the condition include gripping and twisting (such as using a screwdriver) or playing golf with a faulty grip or swing.

SYMPTOMS AND TREATMENT

The inflammation causes pain and tenderness at the inner side of the elbow and sometimes in the forearm. Treatment consists of resting the elbow, applying ice packs, and taking analgesics (painkillers) and/or anti-inflammatory tablets. If the pain is severe or persistent, injection of a *corticosteroid drug* may be helpful.

If the pain has occurred after participation in a sport, it is wise to take a break from the sport for a week or two to prevent recurrence and to seek advice about playing technique.

Gonadotropin hormones

Hormones that stimulate cell activity in the gonads (ovaries and testes). Gonadotropins are essential for female and male fertility. The most important gonadotropins, follicle-stimulating hormone (FSH) and *luteinizing hormone* (LH), are secreted by the *pituitary gland*. Another gonadotropin, HCG (see *Gonadotropin, human chorionic*), is produced by the placenta.

GONADOTROPIN HORMONE THERAPY

Synthetic HCG is used in the treatment of recurrent *miscarriage* and certain types of female and male *infertility*. Menotropin (a gonadotropin extracted from the urine of women past the menopause) contains both FSH and LH and is used in the treatment of female infertility due to a failure to ovulate.

Gonadotropinlike substances are currently being evaluated as contraceptives and as a treatment for cancer of the prostate gland.

Gonadotropin, human chorionic

A hormone produced by the placenta in early pregnancy. Human chorionic gonadotropin (HCG) stimulates the ovaries to produce *estrogen* and *progesterone*, hormones needed to maintain a healthy pregnancy.

HCG is excreted in the urine; its measurement forms the basis of most pregnancy tests (a high level confirming pregnancy).

HCG THERAPY

HCG extracted from the urine of pregnant women is given by injection to treat certain types of *infertility*. Along with clomiphene tablets it may induce ovulation in women who have not been ovulating. In men, it may be used to increase sperm production.

HCG is occasionally given to prevent *miscarriage* in women whose production of progesterone is deficient.

HCG is also prescribed for the treatment of cryptorchidism (see *Testis, undescended*) in young boys, although surgical correction is usually required.

Gonads

The sex glands—the *testes* in men and the *ovaries* in women. The testes, situated in the scrotum, produce sperm and secrete the hormone *testosterone*. The ovaries, situated in the abdomen, release usually one ovum (egg) between them each month and secrete the hormones *estrogen* and *progesterone*. The activities of the gonads—both male and female—are regulated by *gonadotropin hormones* released by the pituitary gland.

Gonorrhea

A sexually transmitted disease, commonly known as "the clap." It is one of the most common infectious diseases in the world.

CAUSES AND INCIDENCE

Gonorrhea, caused by the bacterium *NEISSERIA GONORRHOEAE*, is most frequently transmitted during sexual intercourse, including oral or anal sex. An infected woman may also transmit the disease to her newborn baby during childbirth.

Gonorrhea is the second most common sexually transmitted disease, after *nonspecific urethritis*, and is most prevalent among young adults who have had multiple sexual partners. There are approximately 1 million cases of gonorrhea reported annually in the US. Since many cases are not reported, the true annual incidence may be closer to 3 million cases.

SYMPTOMS AND SIGNS

Gonorrhea has a short incubation period of two to 10 days. In men, symptoms usually include a urethral discharge and pain on urination. About 60 percent of infected women have no symptoms; if symptoms are present, they usually consist of a vaginal discharge or a burning sensation when urinating.

Infection acquired through anal sex causes gonococcal *proctitis* (inflammation of the rectum and anus). It causes pain and anal discharge in only about 10 percent of infected people. Oral sex with an infected person may lead to gonococcal *pharyngitis*, causing soreness in the throat but, again, most people have no symptoms. A baby exposed to infection in the mother's reproductive tract during childbirth may acquire gonococcal *ophthalmia*, a severe inflammation affecting one or both eyes.

COMPLICATIONS

Untreated gonorrhea may spread to other parts of the body. In men, it may cause *prostatitis* (inflammation of the prostate) or *epididymo-orchitis* (inflammation of the testes), affecting fertility. In women, untreated gonorrhea involves the fallopian tubes, causing *pelvic inflammatory disease* (PID). If the fallopian tubes are damaged, the woman is very likely to become infertile as a result.

Gonococcal bacteria may spread through the bloodstream to cause gonococcal *arthritis*, with pain and swelling of joints around the body. Multiplication of bacteria in the bloodstream causes *septicemia*, with generalized symptoms and signs, including fever and malaise; it can even spread to the brain or heart and cause death.

DIAGNOSIS

Many disorders can cause urethral or vaginal discharge. To confirm a diagnosis of gonorrhea, laboratory tests are necessary. Tests are carried out on a sample of the discharge or on swabs taken from the urethra or cervix.

TREATMENT

Gonorrhea is treated with antibiotics, usually *penicillin* or ampicillin. If the infection is caused by penicillin-resistant *NEISSERIA GONORRHOEAE* or if the infected person is allergic to penicillin, other antibiotics, such as tetracycline, ceftriaxone, or spectinomycin, may be used. Tests are performed to ensure that the infection has been cured.

OUTLOOK

Treatment for gonorrhea is effective but does not protect against reinfection. Sexual partners must be told that they might have gonorrhea even if they have no symptoms; many clinics have counselors (known as contact tracers) who identify and inform all people who might have been infected by the patient.

Goodpasture's syndrome

A rare condition characterized by *glomerulonephritis* (inflammation of the filtering units of the kidney), *coughing up blood* (hemoptysis), and *anemia*. Goodpasture's syndrome is a serious disease; unless treated at an early stage, it may lead to life-threatening bleeding into the lungs and progressive *renal failure*.

Goodpasture's syndrome is an *autoimmune disorder* (one in which the body's *immune system* attacks its own tissues). Antibodies are formed that attack the capillaries (tiny blood vessels) in the lungs and kidneys, eventually resulting in inflammation and disruption of the normal functioning of the lungs and kidneys.

The disease usually affects young men, but can develop at any age. Mild forms may be treated with *immunosuppressant drugs* (drugs that hamper the normal working of the body's immune system) and plasma exchange (*plasmapheresis*). The outlook is not good for people with severe and repeated attacks; they are treated by *dialysis* (a technique for removing waste products from the blood) and, eventually, *kidney transplant*.

Good Samaritan laws

Statutes (in most states) that legally protect a physician who voluntarily aids an injured or unconscious person at the scene of an accident.

Gout

A metabolic disorder that causes attacks of *arthritis*, usually in a single joint. Gout may be associated with kidney stones and ultimately may lead to kidney failure.

SYMPTOMS AND SIGNS

An acute attack of gout usually affects a single joint, most commonly the joint at the base of the big toe, but it can affect other joints, including the knee, ankle, wrist, foot, and small joints of the hand.

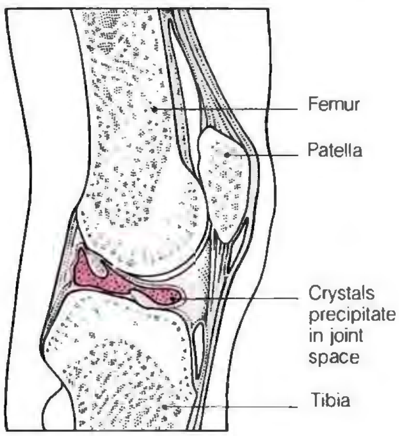
The affected joint is red, swollen, and extremely tender; the pain reaches a peak level of intensity within 24 to 36 hours. The redness and swelling may spread and be confused with *cellulitis* (inflammation of the connective tissue). The intensity of the pain is such that the person may not be able to stand on an affected foot or even tolerate the pressure of bedclothes on it. Sometimes there is a mild fever.

The first attack usually involves only one joint and lasts a few days. Some people never have another attack, but most have a second attack between six months and two years after the first. After the second attack, more and more joints may be involved, and there may be constant pain due to damage to the joint from chronic inflammation.

TREATMENT

Pain and inflammation in gout can be controlled with large doses of a *nonsteroidal anti-inflammatory drug* (NSAID). If use of an NSAID is contraindicated, *colchicine* may be prescribed. For maximal benefit, treatment should start as soon as an attack begins; patients prone to recurrent attacks should carry their gout

G



medication. As the inflammation subsides, usually within two to three days, the dose of medication is reduced and finally stopped. If an attack of gout is not responding to treatment with NSAIDs or colchicine, a *corticosteroid drug* may be injected into the affected joint.

Increased levels of purine (a product of DNA) can raise the level of uric acid in the blood. Although a strict low-purine diet is not necessary, people with gout should avoid foods that are high in purine, such as liver and other organ meats, legumes, and poultry. Excess alcohol consumption should also be avoided because it may precipitate an acute attack in a susceptible individual.

Many people never have more than a few attacks of gout, and further treatment is usually unnecessary. If attacks are recurrent, the frequency can be reduced by lowering the urate levels with drugs that either inhibit the formation of uric acid (such as allopurinol) or increase the excretion of uric acid by the kidneys with uricosuric drugs (such as probenecid and sulfinpyrazone). If the serum urate is very high, these drugs will need to be taken for life, as untreated hyperuricemia may lead to hypertension or kidney disease.

GOUT

Gout is a common joint disease, affecting 10 times more men than women. In men it occurs at any time after puberty; in women it usually occurs only after the menopause. There is often a family history of the disorder. Hyperuricemia (excess uric acid in the blood) leads to formation of uric acid crystals in joints; crystals may also be deposited in soft tissues in the ears and around tendons.

Crystal precipitation
Crystals of uric acid precipitate into the joint space and surrounding tissues of the knee, causing intense inflammation and extreme pain

Appearance of gout
Deposition of uric acid crystals in the joint space have caused inflammation and obvious swelling of the affected right knee.

DIAGNOSIS
Gout is considered as a diagnosis whenever an attack of arthritis affects a single joint. A blood test is usually performed; a high level of uric acid suggests gout.

Aspiration
Fluid is aspirated (removed through a needle into a syringe) from the swollen knee joint and examined under a microscope

Microscopic evidence
The presence of uric acid crystals confirms the diagnosis

Grafting

The process of transplanting healthy tissue from one part of the body to another (autografting), from one person to another (allografting or homografting), or from an animal to a person (xenografting).

Grafting is used to repair or replace diseased or otherwise defective tissue. The primary tissues transplanted are skin (see *Skin graft*); bone (see *Bone graft*); bone marrow (see *Bone marrow transplantation*); the cornea of the eye (see *Corneal graft*); the kidney, the heart, and the liver (see *Kidney transplant; Heart transplant; Liver transplant; Transplant surgery*); heart valves (see *Heart valve surgery*); and blood vessels and nerves (see *Microsurgery*).

COMPLICATIONS

With autografting, the grafted tissue is usually assimilated at the new site without any trouble and soon grows into the surrounding tissue to provide a good repair.

Problems occur, however, with allografting (homografting) and xenografting, both of which are usually carried out to replace rather than repair tissue. Xenografting is not performed clinically except for the use of porcine (pig) heart valves. The major drawback to allografting is that the recipient's defense system automatically attempts to reject the foreign cells of the donor's tissue and to destroy them in the same way that it would invading microorganisms. The only exceptions are in the case of identical twins (because their tissue matches exactly) and in that of corneal grafting, since the cornea has no blood supply (and therefore no white blood cells and antibodies to act as a defense system).

To overcome rejection, as close a match as possible between the tissues of the recipient and donor is sought (see *Tissue-typing*). *Immunosuppressant drugs* (especially *cyclosporine*) are given to suppress the body's defense system—though this can cause other problems, such as decreased kidney function. Cyclosporine, the immunosuppressant drug introduced in 1984, has been particularly effective in the control of organ rejection and *graft-versus-host disease*.

Graft-versus-host disease

A common complication of *bone marrow transplantation*. It is caused by cells called cytotoxic T-*lymphocytes*, present in the transplanted marrow, attacking the transplant recipient's tissues. Lymphocytes form part of the *immune system* and normally play a beneficial role by attacking cells recognized as foreign. However, in transplant procedures, it is just this activity of the lymphocytes that causes disease.

Graft-versus-host (GVH) disease may occur soon after any organ transplantation or may appear some months later. The first sign of the disease is usually a skin rash. Then there may also be diarrhea, abdominal pain, jaundice, inflammation of the eyes and mouth, and breathlessness. Most patients recover within a year, but some gradually get weaker and thinner and about one third die.

Graft-versus-host disease can be prevented by giving *immunosuppressant drugs*, such as cyclosporine, to all transplant recipients. If the disease develops, it is treated with *corticosteroid drugs* and with other immunosuppressants. It may be possible to prevent GVH disease in bone marrow transplants by removing cytotoxic T cells from the donor marrow before the transplant is done.

Gramicidin

An *antibiotic drug* used in combination with other drugs of this class to treat bacterial infections of the eye or skin. It is prescribed in the form of eye drops or an ointment.

Gram's stain

An iodine-based stain widely used in bacteriology to help differentiate among various types of bacteria. It is also known as Gram's iodine.

There are several different methods of Gram staining. Basically, the specimen is stained with gentian violet, followed by Gram's solution, and then treated with a decolorizing agent such as acetone. Finally, the specimen is counterstained with a red dye. Bacteria that retain the dark violet stain are known as gram-positive; those that lose the violet stain after decolorization but take up the counterstain (causing them to appear pink) are gram-negative. Examples of gram-positive bacteria include several species of streptococcus, staphylococcus, and clostridium; gram-negative bacteria include *VIBRIO CHOLERAE* (which causes cholera) and various species of salmonella.

Grand mal

A type of epileptic seizure in which the person, sometimes after warning symptoms, cries out, falls to the ground unconscious, and suffers generalized jerky muscle contractions. The seizure may last for a few minutes. The person usually remains unconscious for a time and may have no recall of the seizure on awakening. (See also *Epilepsy*.)

Granulation tissue

A mass of red, moist, granular tissue that develops on the surface of an ulcer or open wound during the process of healing. The tissue consists mainly of fibroblasts (which make collagen) and numerous small blood vessels. (See also *Healing*; *Wound*.)

Granuloma

An aggregation of cells, of a type associated with chronic inflammation, anywhere in the body.

CAUSES AND TYPES

Granulomas usually occur as a reaction to the presence of certain infectious agents or to a foreign body, but may occur in conditions of unknown cause.

Certain infections, such as *tuberculosis*, *brucellosis*, *leprosy*, and *syphilis*, although caused by different bacteria, give rise to infective granulomas in many different organs of the body. *Sarcoidosis*, a condition of unknown cause, is also characterized by granulomas in different organs. Granulomas may also occur in parasitic and fungal infections.

A foreign body granuloma can occur as a reaction to inorganic material, such as dust, talcum powder, dirt, or a suture. A pyogenic granuloma is a common benign skin tumor that develops on exposed areas following minor injury. It is frequently found on the hands of gardeners. The swellings are raised, moist, and tender and often disappear gradually without treatment. They can be excised surgically, or by *electrocoagulation* or *cryosurgery*.

Many other, largely unrelated, conditions are described as granulomas. For example, a dental granuloma is a swelling arising from poorly fitting false teeth; a granuloma may also form a benign growth on the iris. (See also *Granuloma annulare*; *Granuloma inguinale*; *Granuloma, lethal midline*.)

Granuloma annulare

A harmless skin condition characterized by a circular, raised area of skin, occurring most commonly in children on the knuckles or fingers, or less commonly on the upper part of the feet or on the elbows or ears. The raised area spreads slowly outward to form a ring, 1 to 3 inches in diameter, with raised edges and a flattened center. Rarely, several of these ringlike plaques occur over a wider area. The cause of the condition is unknown.

The diagnosis of granuloma annulare is by means of a skin *biopsy* (removal of a small sample of tissue for microscopic investigation). No treatment is necessary. In most cases, the affected skin heals completely over several months or years.

Granuloma inguinale

A sexually transmitted disease that causes ulceration of the genitals. The infection is caused by bacterialike organisms called Donovan's bodies. Granuloma inguinale is common in the tropics, especially Papua, New Guinea, although it is very rare in developed countries. There are about 100 cases in the US per year, usually occurring in homosexual men.

The first symptoms are painless, raised nodules on the penis or labia or around the anal area. The nodules gradually ulcerate and then form bright red, raised areas that are usually painless. These areas sometimes become purulent (contain pus) and, if left untreated, may eventually heal with extensive scarring.

Diagnosis is based on finding Donovan's bodies in a *biopsy* sample (tissue removed from a sore). The antibiotics tetracycline or gentamicin provide effective therapy.

Granuloma, lethal midline

A rare disorder of unknown cause in which the nose and other facial structures become inflamed and eventually destroyed by progressive damage to the skin and underlying tissues.

Patients with midline granuloma are usually in their 40s or 50s; women are affected more often than men. The first symptoms are usually caused by ulceration within the nose. Tissue destruction may spread to the facial sinuses, the gums, and the eye orbits.

The most effective treatment is *radiation therapy*, which usually halts the progression of the disease and may improve symptoms for years.

Graves' disease

A disorder characterized by toxic *goiter* (an overactive and enlarged thyroid gland), excessive production of

thyroid hormones leading to *thyrotoxicosis*, and sometimes *exophthalmos* (bulging eyeballs). It is a type of *autoimmune disorder* (disturbance in the body's immune system).

Gravida

The medical term for a pregnant woman. The term is often combined with a prefix to indicate the total number of pregnancies (including the present one). For example, primigravida is a woman who is pregnant for the first time, and secundigravida is one who is pregnant for the second time; multigravida is a general term for a woman who has been pregnant at least once before.

Gray

An SI (International System of Units) unit of radiation dosage (see *Radiation* units box).

Gray matter

Regions of the central nervous system (brain and spinal cord) consisting principally of closely packed and interconnected nuclei of nerve cells, rather than their filamentous projections or axons, which make up the white matter.

In the brain, gray matter is primarily found in the outer layers of the *cerebrum* (the main mass of the brain and the region responsible for advanced mental functions) and in some regions deeper within the brain. Gray matter also makes up the inner core of the spinal cord.

Grief

An intensely unhappy and painful emotion caused by the loss of a loved one. (See *Bereavement*.)

Grip

The *hand* is particularly well adapted for gripping, with an opposable thumb (that is, able to touch all the other fingers), specialized skin on the palm and fingers to provide adhesion, and a complex system of muscles, tendons, joints, and nerves that enables precise movements of the digits.

The hand can perform two basic grips: grasping, which is a strength hold that involves the whole hand, and pinching, a precision hold using the thumb and a finger. Both grips are controlled by a combination of long muscles in the forearm and short muscles in the hand itself.

Gripping ability can be reduced by any condition that causes muscular weakness or impairment of sensation in the palms or fingers (e.g., a stroke or nerve injury) or by disorders that affect the bones or joints of the hand or wrist, such as arthritis or a fracture.

Grippe

A term of French origin for any influenzalike illness (see *Influenza*). The term was once used commonly in English-speaking as well as French-speaking countries.

Griseofulvin

ANTIFUNGAL

Tablet Capsule Liquid

Prescription needed

Available as generic

A drug given by mouth to treat *tinea* infections (a group of fungal infections) that have not responded to creams and lotions. Griseofulvin is particularly useful in the treatment of infections affecting the scalp, beard, palms, soles of the feet, and nails.

Common side effects are headache, loss of taste, dry mouth, abdominal pain, and increased sensitivity of the skin to sunlight. During long-term treatment, griseofulvin may cause liver or bone marrow damage; blood tests are usually carried out to check organ function.

Groin

The hollow between the lower abdomen and top of the thigh. (See also *Groin, lump in the; Groin strain*.)

Groin, lump in the

The most common cause of a swelling in the groin is enlargement of a lymph gland as a result of an infection (see *Glands, swollen*). Another common cause is a *hernia*, a protrusion of intestine through a weak area in the abdominal wall.

Other possible causes of a lump in the groin include an *abscess* (a pus-filled sac), a *lipoma* (a painless benign tumor of fat cells), or an undescended testis (see *Testis, undescended*). Rarely, a lump in the groin may be due to a *varicose vein* or an *aneurysm* (a balloonlike swelling in an artery).

INVESTIGATION

Examination of the swelling by a physician usually reveals its cause.

Groin strain

Pain and tenderness in the groin due to overstretching a muscle, typically while running or participating in sports. The muscles commonly affected are the adductors on the inside of the thigh, which rotate and flex the thigh and pull it inward, and the rectus femoris (at the front of the thigh), which also flexes the thigh.

Pain and tenderness in the groin that mimic pain due to muscle strain may sometimes be caused by *osteoarthritis* in the hip or lower spine, pubic *osteitis* (inflammation of the pubic bones, situated at the front and base of the spine), or an inguinal *hernia* (a protrusion of intestine through a weak area in the abdominal wall).

INVESTIGATION AND TREATMENT

When the cause is obviously a simple muscle strain, treatment is with physical therapy. However, if another cause is suspected, or if what was thought to be a muscle strain does not respond to physical therapy, tests such as X rays may be required. An X ray may show that a muscle has pulled a small piece of bone away from the pelvis; surgery to wire the bone back into position may be necessary.

Ground substance

The thick, gellike material, sometimes called tissue matrix, in which the cells, fibers, and blood capillaries of cartilage, bone, and connective tissue are embedded. Ground substance consists principally of a large amount of water chemically linked to complex carbohydrate and protein molecules. The water enables nutrients and gases essential for metabolism and respiration to pass easily from the blood capillaries to the cells. Because of its gellike consistency, ground substance also protects the cells, fibers, and capillaries from damage.

Excess ground substance is produced in *hypothyroidism* (underactivity of the thyroid gland). This results in a condition called myxedema, in which ground substance accumulates in the skin, leading to thickening of the skin and coarsening of the facial features.

Group therapy

Any treatment of emotional or psychological problems in which groups of patients meet regularly with a therapist. Interaction among members of the group is thought to be therapeutic and for certain problems is considered to be more effective than the traditional patient-therapist relationship. The group setting is also useful for job-related therapy.

The group may range in number from three to 40 people, but eight to 10 people is the usual size. Members

meet for an hour or more once or twice a week to discuss their problems openly with one another under the guidance of the therapist.

Group therapy is most useful for people with personality problems and for sufferers from *alcohol dependence*, *drug dependence*, *anxiety disorders*, eating disorders (such as *anorexia nervosa* and *bulimia*), and depressive illnesses (see *Depression*).

Growing pains

Vague aches and pains that occur in the limbs of children. The pains usually are felt at night and most often affect children between 6 and 12 years old. Their cause is unknown, although they do not seem to be related to the process of growth itself.

Growing pains are of no medical significance and require no treatment, though the pains may interfere with the child's sleep and may alarm the parents. If pain is severe or associated with other symptoms, such as joint swelling or malaise, a pediatrician should be consulted.

Growth

An abnormal proliferation of cells within a localized area (see *Tumor*); the increase in height and weight as a child develops (see *Growth, childhood*).

G

Growth, childhood

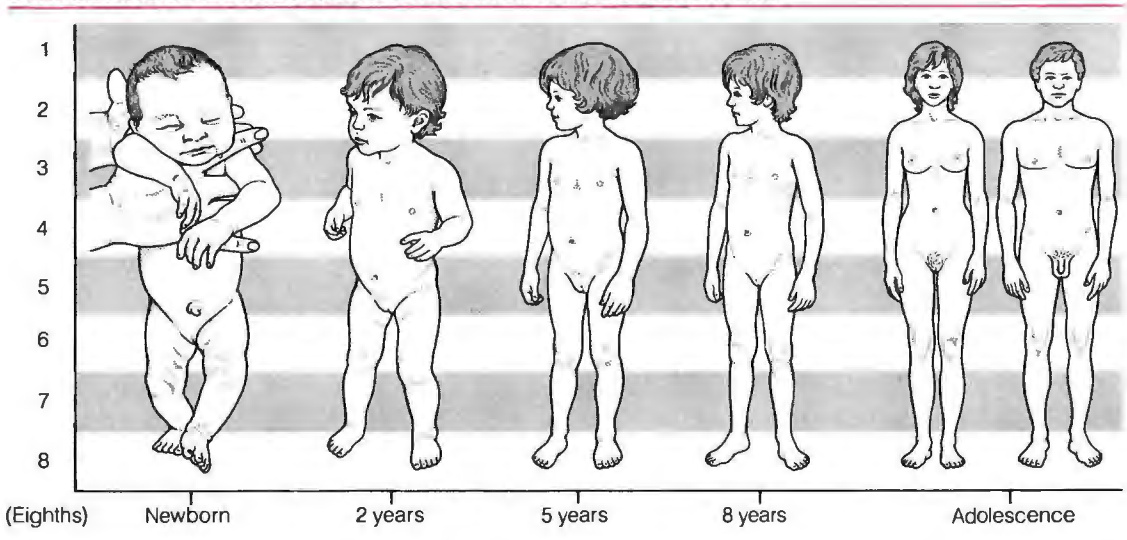
The period of most rapid growth occurs before birth, during embryonic and fetal development. After birth, the growth rate decreases steadily, although it is still very rapid in the first few years of life, especially the first year. At the onset of *puberty* there is another major period of growth and development that continues until full adult height is reached, usually at about the age of 18. As a general rule, increase in weight follows the same pattern as increase in height.

Significant variations occur within the typical overall growth pattern. For example, baby boys grow faster than girls until the age of about 7 months, when girls grow faster than boys. Girls continue to grow more rapidly until about 4 years, when the rate of growth becomes the same, and remains so until puberty. However, in overall height, girls tend to be shorter than boys at all ages until puberty, when they become taller for a few years because they enter the pubertal growth spurt earlier than boys. But because puberty occurs later in boys, their final height is greater.

Growth is not simply a process of becoming taller and heavier. The body shape also changes because different areas grow at different rates. At birth, the head is already about three quarters of its adult size; the head grows to almost full size during the first year. Thereafter, it becomes proportionately smaller because the body grows at a much faster rate. The limbs grow faster than the trunk during early childhood but more slowly during puberty.

Different tissues also grow at different rates. For example, lymphatic tissue grows rapidly until just before adolescence, when it begins to shrink. The brain also grows quickly during the early years, but reaches about nine tenths of its adult weight by the age of 5, after which its growth rate decreases markedly.

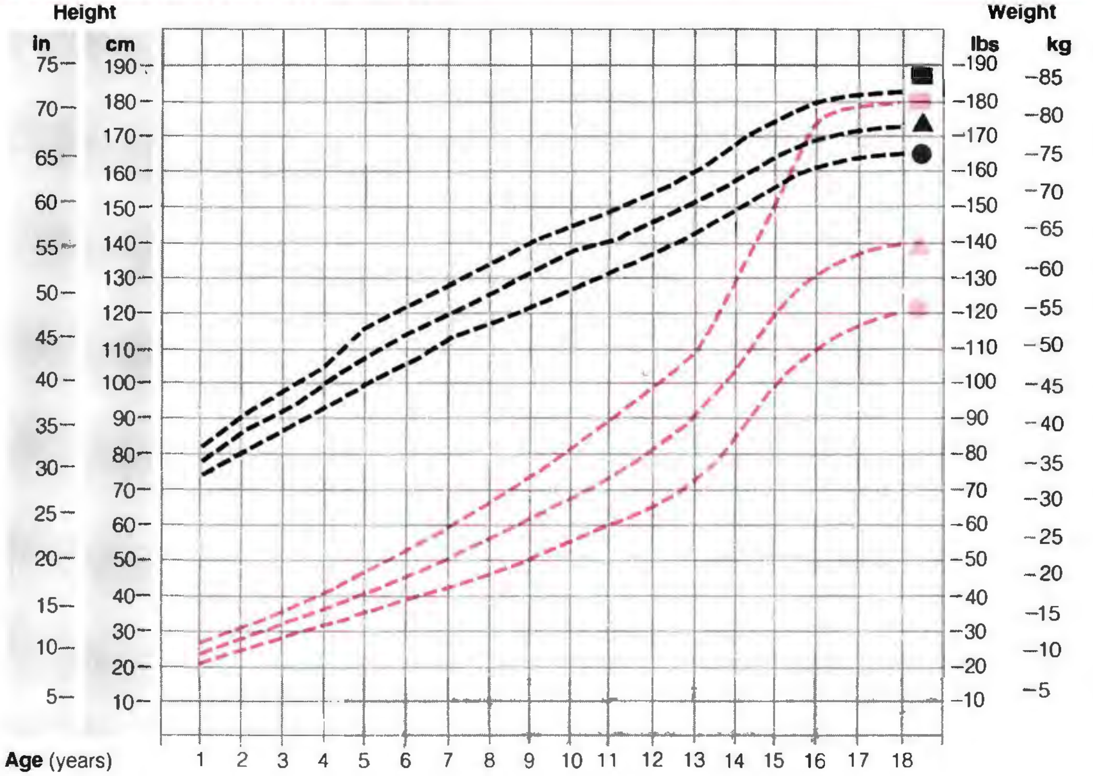
FACTORS THAT INFLUENCE GROWTH



Growth can be influenced by heredity and by environmental factors, such as nutrition, general health, and emotional welfare. Hormones also play an important role, particularly *growth hormone*, thyroid hormone, and, at puberty, the sex hormones.

A child with taller-than-average parents also tends to grow to above-average height because of the effects of heredity. However, this may be counteracted by poor health or inadequate nutrition. In infancy, weight is the best indicator of health and the state of nutrition. Thereafter, height is equally important. Regular measurement of height, weight, and, in babies, head circumference, provides an invaluable record of a child's growth rate.

A chronic illness, such as *asthma*, will retard growth if it is undetected. Even a minor, short-lived illness can slow growth, although the growth rate usually catches up again when the child recovers. In some cases, slow growth may be the only indication that a child is ill, malnourished, or emotionally distressed or deprived. However, there is wide individual variation in the rate at which children grow and *short stature* does not necessarily indicate poor health. Each case of slow growth requires assessment by a pediatrician.



Abnormally rapid growth is rare. Usually, it is a familial trait but occasionally it may indicate an underlying disorder, such as a pituitary gland tumor. (See also *Age*; *Child development*; *Gigantism*.)

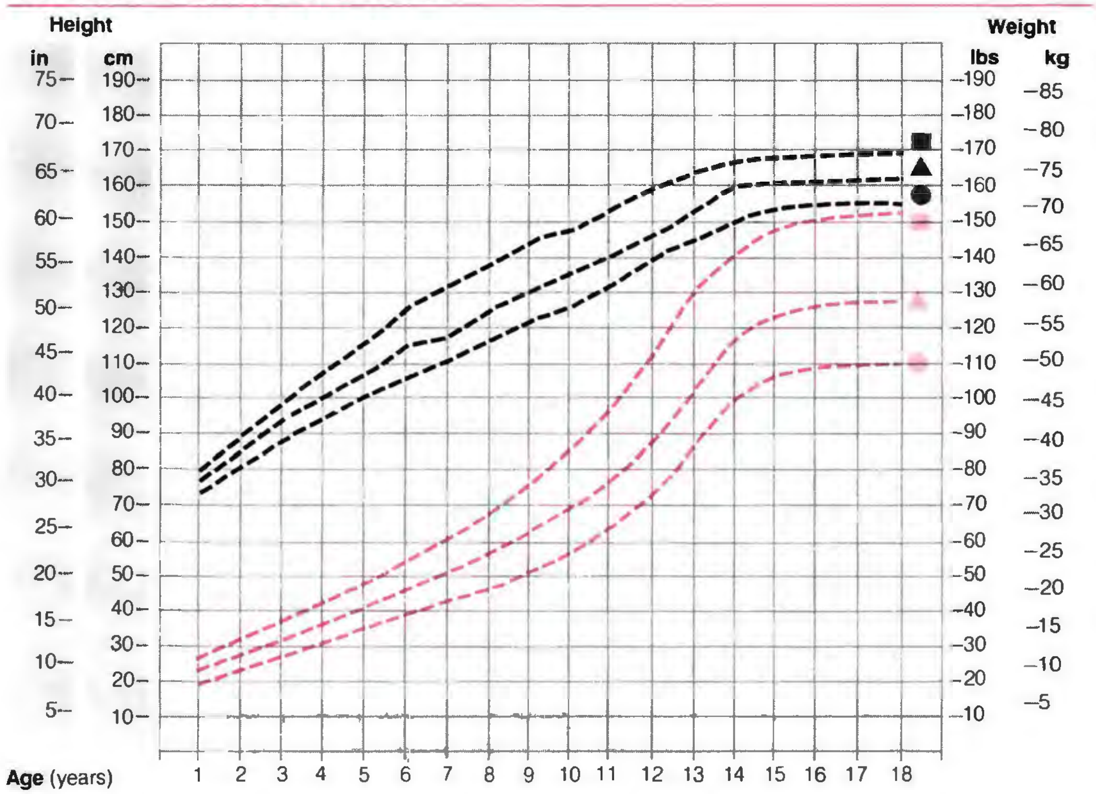
CHANGES IN BODY PROPORTIONS BETWEEN BIRTH AND ADOLESCENCE

If the body is divided into eight equal parts, it can be seen that proportions change radically in relation to the body's overall length. For example, a newborn baby's legs account for only three eighths of his or her height while an adolescent's legs account for one half. A newborn's head accounts for as much as one fourth of his or her height while an adolescent's head accounts for only one eighth.

GROWTH CHART: BOYS 1 TO 18 YEARS

Growth in boys
Normally, there is a steady increase in weight until the end of puberty. Height increases steadily until a sudden spurt occurs during puberty (between the ages of 13 and 16). This chart was constructed using the height and weight of thousands of children; it is used by physicians to check whether growth of a particular boy is significantly above or below average.

Key



Height

- ■ Tall
- ▲ Average
- ● Short

Weight

GROWTH CHART: GIRLS 1 TO 18 YEARS

Growth in girls
Normally, there is a steady increase in weight that levels out by age 14. Height increases steadily until a sudden spurt occurs during puberty (between the ages of 11 and 14). This chart was constructed using the height and weight of thousands of children; it is used by physicians to check whether growth of a particular girl is significantly above or below average.

Growth hormone

A substance produced by the *pituitary gland* that stimulates normal body growth and development by altering chemical activity in cells. Growth hormone stimulates the production of protein in muscle cells and the release of energy from the breakdown of fats.

GROWTH HORMONE THERAPY

In the past, growth hormone was extracted from human corpses; it is now prepared synthetically. Growth hormone therapy is used to treat *short stature* when the underlying cause is a pituitary gland disorder. Treatment is usually started in early childhood. Growth hormone is sometimes given with an anabolic *steroid*, which also promotes tissue growth.

POSSIBLE ADVERSE EFFECTS

There is a slight risk that *diabetes mellitus* may develop during treatment. Some people produce *antibodies* to growth hormone, but this does not seem to reduce its effectiveness.

Guanethidine

An *antihypertensive drug* used to treat severe *hypertension* (high blood pressure) that has not responded to other drugs. Adverse effects of guanethidine include dizziness or fainting, diarrhea, and impotence.

Guanethidine is currently under investigation as a treatment for *glaucoma* (raised pressure in the eyeball) in combination with *epinephrine*, in the form of eye drops.

Guar gum

A high-fiber plant substance used to help control the blood glucose (sugar) level in people with *diabetes mellitus*. Guar gum granules are either sprinkled on food or dissolved in water to form a thick gel for drinking.

HOW IT WORKS

Guar gum forms a sticky solution in the stomach and slows the movement of nutrients from there into the small intestine. This action slows the rate at which glucose is absorbed from the small intestine into the bloodstream, thus preventing a sudden rise in blood glucose after a meal.

POSSIBLE ADVERSE EFFECTS

Guar gum has an unpleasant taste and may cause flatulence, nausea, and abdominal discomfort.

Guillain-Barré syndrome

A rare form of damage to the peripheral nerves (see *Peripheral nervous system*) that causes weakness of the limbs. The nerves become inflamed, particularly where their roots leave the spine, impairing both movement and sensation. The disease is also known as acute polyneuritis and ascending paralysis.

CAUSES AND INCIDENCE

The cause of the disease is believed to be an allergic reaction to an infection, usually viral; the nerves are inflamed by antibodies produced by the reaction. In most cases the disease develops two or three weeks after the onset of an infection, usually an infection of the upper respiratory tract, such as a sore throat or influenza, or a gastrointestinal upset. In 1976, an epidemic occurred in the US following mass vaccination against swine flu. The incidence is about 15 cases per million population per year in the US.

SYMPTOMS

Weakness, often accompanied by numbness and tingling, usually starts in the legs and spreads to the arms. It becomes progressively worse and may develop into paralysis. The muscles of the face and those that control speech, swallowing, and breathing may also be affected, causing difficulty with all three activities.

DIAGNOSIS

The diagnosis is made from the patient's symptoms and signs, from the results of electrical tests to measure how fast nerve impulses are being conducted, and from a *lumbar puncture*, in which a sample of cerebrospinal fluid is taken from the spinal canal for analysis.

TREATMENT AND OUTLOOK

Patients are treated in the hospital, where their condition (particularly any breathing difficulty) can be closely monitored. If it becomes severe, *intubation* (inserting a breathing tube down the throat) and mechanical *ventilation* are carried out. *Plasmapheresis* (in which blood plasma is withdrawn from the patient, treated to remove antibodies, and replaced) may be employed in severe cases.

Most people recover completely without specific treatment, but some are left with permanent weakness in affected areas and/or suffer from further attacks of the disease.

Guilt

A painful feeling that arises from the awareness of having broken a moral or legal code. Guilt is self-inflicted, unlike shame, which depends on others knowing about the transgression. Some psychoanalysts see guilt as a result of the prohibitions of the *superego* (conscience) instilled by parental authority in early life. Others see guilt as a conditioned response to actions that in the past have led to punishment.

Feeling guilty from time to time is normal. However, feeling very guilty for no reason or experiencing guilt at an imagined crime is one of the main symptoms of psychotic *depression*.

Guinea worm disease

A tropical disease caused by a female parasitic worm more than 3 feet (1 meter) long. Infection is the result of drinking water containing the crustacean water flea *CYCLOPS*, which harbors larvae of the worm. The larvae pass through the intestinal wall of the infected person and mature in connective tissue. After about a year, the adult female worm, now pregnant, approaches the surface of the skin, and creates an inflamed blister that bursts, exposing the end of the worm.

The disease occurs in Africa, South America, the Caribbean, the Middle East, and India.

SYMPTOMS AND TREATMENT

Urticaria (hives), nausea, vomiting, and diarrhea often develop while the blister is forming.

The traditional remedy is to wind the worm gently from the skin onto a small stick. Once the worm is out, the condition usually clears up.

The drugs niridazole and thiabendazole are given to reduce inflammation and make extraction of the worm safer, antibiotics are given to control secondary infection, and the patient is immunized against tetanus.

Gum

Also called the gingiva, the soft tissue surrounding the teeth that protects underlying structures and helps keep the teeth tightly in position in the jaw. The gingival margin, a cuff of gum about 2 mm thick, fits tightly around the base of the teeth and is anchored within the bony socket by the periodontal ligaments.

Normal, healthy gums are pink or brown and firm. Careful *oral hygiene*, including daily brushing and flossing, is needed to avoid gum disease, especially on reaching middle age.

DISORDERS

Gingivitis (an early, reversible stage of gum disease characterized by inflammation of the gums) may occur if plaque, which contains bacteria, is allowed to collect around the base of the teeth. Bleeding gums are nearly always a symptom of gingivitis; rarely, they are due to *leukemia* (blood

cell cancer) or *scurvy* (vitamin C deficiency). Bruised gums are more likely to be caused by a *bleeding disorder*. Gingival *hyperplasia* (fleshy thickening of the gums) is most commonly a side effect of *anticonvulsant drug* treatment with phenytoin.

Untreated gingivitis may lead to *periodontitis*, the advanced stage of gum disease, in which infected pockets form between the gums and the teeth.

Gumma
A soft tumor that is characteristic of the late stages of untreated *syphilis*.

G

Gut
Popular name for the *intestine*.

Guthrie test
A blood test performed routinely on babies between the eighth and fourteenth day after birth to check for *phenylketonuria*. This is an inherited disorder in which the amino acid phenylalanine accumulates in the blood and tissues, usually leading to severe brain damage unless treated. The Guthrie test measures the amount of phenylalanine in the blood.

Carrying out a Guthrie test
A few drops of blood are taken from the baby's heel and sent to the laboratory to be tested for phenylalanine content.

HOW IT IS DONE
The baby's heel is pricked with a needle and a few drops of blood are soaked onto a piece of absorbent filter paper. The paper is then placed onto a nutrient medium containing bacteria whose growth is activated by phenylalanine. The size of the area of bacterial growth that appears is directly related to the concentration of phenylalanine in the blood.

RESULTS
A concentration of phenylalanine above 20 mg/ml indicates that phenylketonuria may be present; other, more accurate tests are performed to confirm the diagnosis.

Gynecologist
A physician who specializes in diagnosing and treating problems of the female reproductive tract, including disorders relating to *menstruation* and *menopause* and sexual dysfunctions that may have a physical cause. A gynecologist also offers advice on *contraception* and treats *infertility*.

From the time a woman starts menstruating, she should see a gynecologist every one to three years for a *pelvic examination* and a *cervical smear* (Pap test). These tests are often performed on a preventive basis, because cervical smears can detect cancer of the cervix at an early stage. A gynecologist also investigates and treats menstrual disorders, such as *amenorrhea* (lack of menstruation), *menorrhagia* (excessive menstrual bleeding), *dysmenorrhea* (painful menstruation), and *premenstrual syndrome* as well as structural disorders, including uterine *fibroids*, cervical *polyps*, and ovarian *cysts*.

Although an *obstetrician* deals with the management of pregnancy, the gynecologist treats disorders of early pregnancy, including recurrent *miscarriage*. Many gynecologists are also obstetricians.

Gynecology
The study of the female *reproductive system* and the diagnosis and treatment of disorders affecting it. Gynecology involves both medical treatment, using drugs including hormones, and surgical procedures, such as *D and C* (dilatation and curettage) and *hysterectomy* (removal of the uterus). The specialty also involves the investigation and treatment of *infertility*, including *artificial insemination* and *in vitro fertilization*, and advice on *contraception*, including *sterilization*. (See also *Gynecologist*.)

Gynecomastia
Enlargement of one or both breasts in the male, almost always due to an excess of the female sex hormone *estrogen* in the blood.

CAUSES
Estrogen, which is responsible for female secondary sexual characteristics, is produced in large quantities in women, but is also produced in small amounts in all men (just as all women produce small amounts of male sex hormones). In some males, however, an abnormal amount of estrogen is produced, usually for reasons that are not fully understood, but sometimes because of disease.

Gynecomastia is quite common at puberty, taking the form of a slight swelling in one or both breasts, often accompanied by some tenderness. A young boy with gynecomastia is likely to be worried and embarrassed; he should be reassured that his masculinity is not threatened and that the problem will soon pass. Gynecomastia of this mild, temporary kind can also occur at birth.

If the condition develops later—most commonly when a man is over the age of 50—the enlargement may be greater, especially in an already obese man. Such cases are usually not serious, but investigation is necessary to rule out the possibility of an underlying disease. This disease could be *cirrhosis* of the liver, in which the liver is unable to break down estrogen; a tumor of the testis (see *Testis, cancer of*), which can raise the level of estrogen in the blood; or, if only one breast is affected, *breast cancer*, in which case the swelling is caused by a tumor.

Adult gynecomastia can also occur when any one of a number of drugs changes the balance of sex hormones in the blood.

DIAGNOSIS
The physician may arrange for blood tests. If cancer is suspected, a *biopsy* (removal of the entire nodule or a piece of tissue for analysis) will be performed; early treatment is essential for breast cancer.

TREATMENT
The treatment depends on the underlying cause. If a drug is responsible, an alternative drug will be prescribed if possible; otherwise, the gynecomastia must be weighed against the effects of withdrawing drug treatment.

If there is no underlying disease, the swelling usually subsides without treatment, although it may take a few years. A man who is embarrassed by enlarged breasts may prefer to have cosmetic surgery.

If the swelling is moderate or bothersome, an operation can be performed that leaves only a small, unnoticeable scar around part of the areola (the dark skin surrounding the nipple). In many cases, this operation can be carried out as an office procedure using a local anesthetic. *Mammoplasty*, an operation more frequently performed on women, is used when breast enlargement is severe. This operation takes longer, requires a general anesthetic, and leaves extensive and obvious scarring.

H

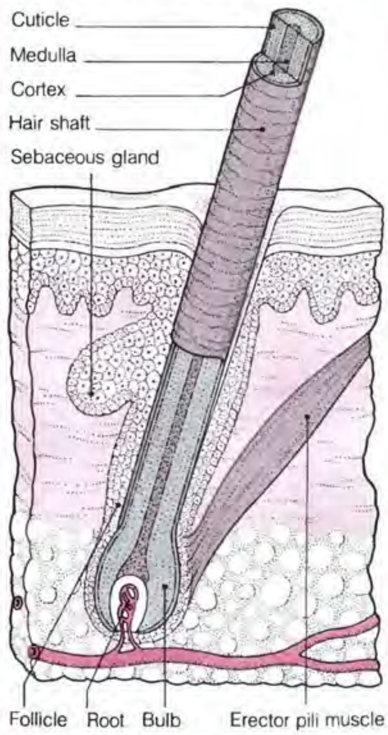
H-2 receptor antagonists
See *Histamine-2 receptor antagonists.*

Habituation
The effect of becoming accustomed to an experience. In general, the more a person is exposed to a stimulus, the less he or she is aroused by it. Experiments have shown that frightening pictures make the pulse rate rise less the more they are seen. Likewise, people can become habituated to drugs (see *Tolerance*).

Habsburg jaw
An inherited prominence of the lower jaw named for the European royal house of Habsburg.

Hair
A threadlike structure composed of dead cells filled with *keratin*, the protein that makes up nails and the outer skin layer.

STRUCTURE



The root of each hair is embedded in a tiny pit in the skin called a hair follicle. Each shaft of hair consists of a spongy semihollow core (the medulla), a surrounding layer of long, thin fibers (the cortex), and, on the outside, several layers of overlapping cells (the cuticle). During the growing phase of a hair the root is firmly enclosed by live tissue called a bulb, which supplies the hair with keratin; the bulb is the pale swelling that sometimes can be seen when a hair is pulled out. The upgrowth of dead cells and keratin from the root forms the hair.

TYPES

There are three types of human hair. From the fourth month of gestation, the fetus is covered with downy hair called lanugo, which is shed during the ninth month. After birth and until puberty, vellus hair, which is fine, short, and colorless, covers most of the body. The third type, terminal hair, is thicker, longer, and often pigmented; it grows on the scalp, the eyebrows, and the eyelashes. At puberty, terminal hair replaces vellus in the pubic area and the armpits. In most men and some women the process continues on the face, limbs, and trunk (see *Hirsutism*).

THE STRUCTURE OF A HAIR

The hair shaft contains dead cells and keratin (a type of protein). The root is embedded in the skin.

Cross section through hairs
The central medulla, cortex, and outer cuticle can all be clearly differentiated in this microscope photograph.

COLOR AND TEXTURE

Hair color is determined by the amount of pigment called *melanin* in the hair shaft. Melanin is produced by special pigment-producing cells called melanocytes at the base of the hair follicle. Red melanin is responsible for red and auburn hair, black melanin for all other colors. If cells receive no pigment, the cortex of each hair becomes transparent and the resulting hair appears white.

The degree of curliness of a hair depends on the shape of its follicle (see box, overleaf).

DISORDERS

Many hair disorders appear to be purely cosmetic, but they can also be a symptom of a more serious underlying disorder.

Brittle hair, which breaks easily and splits at the ends, is usually due to excessive shampooing, combing, or blow-drying. Occasionally, it can be a sign of severe vitamin or mineral deficiency, or may indicate *hypothyroidism*. Very dry hair is often the result of excessive use of hot rollers or curling irons, or frequent perming, tinting, or bleaching; it can also be caused by malnutrition.

Ingrown hairs occur primarily in blacks or people with very curly hair. The free-growing end of the hair penetrates the skin near the follicle, often causing severe inflammation.

Hairball
A ball of hair in the stomach. Also known as a trichobezoar, it is found in people who nervously pull, suck, or chew their hair. (See *Bezoar*.)

Hairiness, excessive
See *Hirsutism*; *Hypertrichosis*.

Hair removal
Hair is usually removed from different parts of the body for cosmetic reasons. It may also be shaved from around an incision site to allow thorough cleansing before surgical operations.

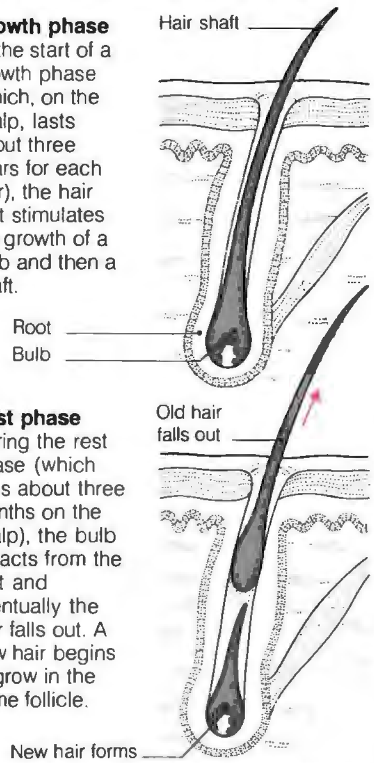
HOW IT IS DONE

The method used depends on the part of the body involved and the degree of permanency required.

Shaving removes hair at skin level and is suitable for the legs, for armpit and pubic hair, and for the facial beard in men. Shaving is quick and safe, but the hair soon grows back.

Depilatory creams dissolve the hair just below the skin surface, creating a smoother effect than shaving. However, depilatories may irritate sensitive areas and their use is generally best restricted to the legs.

Waxing, a method often used in beauty salons, is suitable for the legs and face. The wax is applied to the area and peeled off, pulling out the hair with it. Plucking with tweezers is suitable for small areas. After each of these methods, hair takes several weeks to regrow.

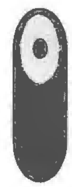


Permanent removal of hair requires *electrolysis*, in which an electric current is used to destroy the growing part of

HAIR GROWTH

Hair on the scalp grows about half an inch per month. There are about 300,000 hairs on the scalp at any given time, though there is considerable individual variation. The exact number of hairs depends on the number of hair follicles, which is established before birth. Each hair goes through alternating periods of growth and rest. On average, each person sheds 100 to 150 hairs a day from the scalp.

Growth phase
At the start of a growth phase (which, on the scalp, lasts about three years for each hair), the hair root stimulates the growth of a bulb and then a shaft.



Rest phase
During the rest phase (which lasts about three months on the scalp), the bulb retracts from the root and eventually the hair falls out. A new hair begins to grow in the same follicle.

TYPES OF HAIR
There are three types of hair—straight, curly, and wavy.

Straight hair
Grows from a more or less round follicle and is round in cross section.

Curly hair
Oval in cross section and grows from a highly curved follicle.

Wavy hair
Kidney-shaped in cross section; the extent of the curl depends on the curve of the follicle.

the hair. Electrolysis requires expertise, is very time-consuming, and is expensive, so it is usually used only for small areas.

Hair transplant

A cosmetic operation in which hairy sections of scalp are removed and transplanted to hairless areas as a treatment of baldness.

HOW IT IS DONE

One or a combination of the following techniques may be employed.

PUNCH GRAFTING This is the most common method of hair transplantation; it is performed using a local anesthetic and is an outpatient procedure. A punch is used to remove small areas of bald scalp, about 0.25 inch (0.6 cm) across, which are replaced with areas of hairy scalp. The grafts are taped into position until the natural healing process takes effect.

STRIP GRAFTING This requires a general anesthetic and is carried out in the hospital. Strips of bald skin are cut from the top of the head; strips of hairy scalp are then stitched in position to replace them.

FLAP GRAFTING This is often used to form a new hairline. It is similar to strip grafting, except that flaps of hairy skin are lifted, swiveled, and stitched to replace areas of bald skin.

MALE PATTERN BALDNESS REDUCTION This relatively new technique consists of cutting out areas of bald skin and then stretching surrounding areas of hair-bearing scalp to replace the bald areas.

RESULTS

The success of hair transplantation varies. The hair in punch grafts often falls out after transplantation, leaving unsightly patches for several months until new hair grows. Also, hair does not always grow properly in the areas from which graft skin is taken. Even successful transplants do not last indefinitely; as time passes, the transplanted areas also become bald.

Half-life

The time taken for the activity of a substance to reduce to half its original level. The term is usually used to refer to the time taken for the level of radiation emitted by a radioactive substance to decay to half its original value. This is useful in *radiation therapy* to assess the length of time radioactive material will remain in the body.

The term half-life is also used in pharmacology to refer to the time the body takes to eliminate enough of a drug so that the amount remaining in the bloodstream is halved.

Halitosis

The medical term for bad breath. Halitosis is occasionally a sign of illness, but is usually simply a result of smoking, drinking alcohol, eating garlic or onions, or poor oral and dental hygiene. Contrary to popular belief, neither constipation nor indigestion is a cause.

If bad breath is persistent and is not due to any of the above causes, it may be a symptom of a mouth infection, *sinusitis*, or certain lung disorders, such as *bronchiectasis*.

Hallucination

A perception that occurs when there is no external stimulus (for example, hearing voices or seeing faces when there is no one there). Hallucination differs from an *illusion*, in which a real stimulus is present but has been misinterpreted (thinking that the ticking of a clock is a bomb, for example).

TYPES AND CAUSES

Auditory hallucinations (the hearing of voices) are the most common type. They are a major symptom of *schizophrenia*, but may also be caused by *manic-depressive illness* and certain brain disorders. Visual hallucinations (seeing visions) are most often found in states of *delirium* brought on either by a physical illness (such as pneumonia) or by alcohol withdrawal (see *Delirium tremens*). *Hallucinogenic drugs*, such as mescaline, are another common cause. Hallucinations of smell are often a sign of *temporal lobe epilepsy*, especially when the epilepsy is caused by a tumor. Hallucinations of touch and taste are uncommon; they probably occur primarily in people with schizophrenia.

There is evidence that people subjected to *sensory deprivation* or to overwhelming physical stress hallucinate temporarily.

Hallucinogenic drug

A drug that causes a *hallucination*. Hallucinogens include drugs of abuse, also called psychedelic drugs, such as

LSD, *marijuana*, *mescaline*, and *psilocybin*. Alcohol may also have a hallucinogenic effect if taken in large amounts; hallucinations also occur during alcohol withdrawal. Certain prescription drugs, including *anticholinergic drugs*, *levodopa*, and *timolol*, may cause takers to have hallucinations in rare instances.

Hallux
The medical name for the big toe.

Hallux rigidus
Loss of movement in the large joint at the base of the big toe due to *osteoarthritis*. The condition often follows an injury and is aggravated by sports that involve running and jumping. The joint is usually tender and swollen, and pain is worse during walking or running.

Hallux rigidus, which may be mistaken for *gout*, is diagnosed if X rays reveal degeneration of the joint. Treatment consists of resting the toe and wearing an insert in the shoe to support the front of the foot and to reduce movements of the toe during walking. If severe symptoms persist, surgery may be required.

Hallux valgus
A deformity of the big toe in which the joint at the base projects outward and the top of the toe turns inward. The condition (which is more common in women) is usually caused by wearing narrow, pointed shoes with high heels, but is sometimes caused by an inherited weakness in the joint. A hallux valgus often results in a *bunion* (a firm, fluid-filled, sometimes painful swelling over the joint) or *osteoarthritis* in the joint.

Treatment is required only if the bunion becomes very large or persistently inflamed or if the osteoarthritis causes pain and limits foot movement. In these cases, the toe may be straightened by means of *osteotomy* (removing part of a bone and realigning its ends) or *arthrodesis* (fusing the bones of a joint).

Haloperidol
An *antipsychotic drug* used in the treatment of mental illnesses such as *schizophrenia* and *mania*. Haloperidol is also given to control the symptoms of *Gilles de la Tourette's syndrome* (a rare neurological disorder) and is used to sedate aggressive or hostile people with *dementia*. Because haloperidol has a powerful *antiemetic* effect, it is sometimes used to relieve nausea and vomiting caused by *narcotic drugs*, *anesthesia*, *anticancer drugs*, and *radiation therapy*.

POSSIBLE ADVERSE EFFECTS
Adverse effects include drowsiness, lethargy, weight gain, dizziness, and, more seriously, *parkinsonism* (a neurological disorder that causes symptoms such as abnormal involuntary movements and stiffness of the face and limbs).

Halothane
A colorless liquid inhaled as a vapor to induce and help maintain general anesthesia (see *Anesthesia, general*). In rare cases it may cause *arrhythmia* (irregular heart beat) or liver damage.

Hamartoma
A benign, tumorlike mass consisting of an overgrowth of tissues that are normally found in the affected part of the body. Hamartomas are most frequent in the skin (the most common is a *hemangioma*, an overgrowth of blood vessels in the skin), but also occur in the lungs, heart, or kidneys.

Hammer toe
A deformity of the toe (usually the second toe) in which the main toe joint is bent upward like a claw. There is often a painful *corn* on this joint due to pressure from the overlying shoe. The deformity is caused by an abnormality of the tendons in the toe.

A protective felt pad usually eases pressure on the joint and thus relieves pain. If pain persists, the deformity may require surgical correction.

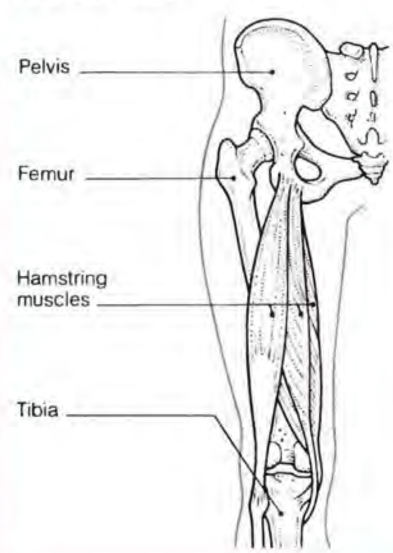
Hamstring muscles
A group of muscles at the back of the thigh that bends the knee and swings the leg backward from the thigh.

DISORDERS
Tearing of the muscles is common in sports, particularly in sprinting. The injury happens suddenly and is very painful. Bruising over the area develops several days later. Repeated strenuous exercise may cause a sprain of the muscles, with pain coming on gradually (see *Overuse injury*). Both types of injury can often be prevented by warm-up exercises.

Sciatica (pain down the back of the leg caused by pressure on the sciatic nerve) may be particularly severe in the hamstring muscles. Painful spasms of the muscles may also occur as a protective response to a knee injury. By restricting movement of the damaged knee joint, the spasms limit further injury.

Hand
The most flexible part of the skeleton, the hand allows humans (and other primates) to hold and manipulate objects. This movement is primarily due to the ability of the thumb and fingers to move independently of, and oppose, each other (see *Grip*).

STRUCTURE
The hand is made up of the wrist, palm, and fingers (see next page).



Movements of the hand are achieved mainly by tendons that attach the muscles of the forearm to the bones of the hand. These tendons are surrounded by synovial sheaths containing a lubricating fluid to prevent friction. Other movements are controlled by short muscles in the palm of the hand, some of which make up the prominent areas along the sides of the hand from the bases of the thumb and little fingers to the wrist.

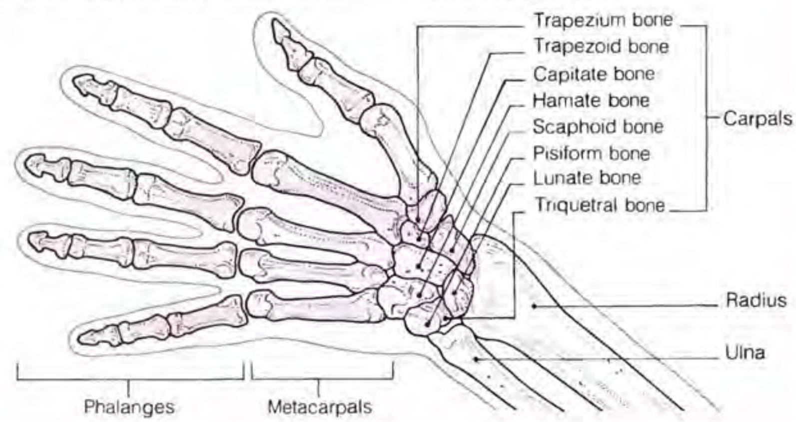
Blood is supplied to the hand by two arteries (the radial on the thumb side of the wrist and the ulnar on the little finger side) and is carried away by veins prominent on the back of the hand. Sensation and movement in the hand are controlled by the radial, ulnar, and median nerves.

DISORDERS
Because they are so frequently used, the hands are susceptible to injury, including cuts, burns, bites, fractures,

ANATOMY OF THE HAMSTRING MUSCLES

The upper ends of these muscles are attached by tendons to the pelvis, and the lower ends by tendons called hamstrings to the tibia and fibula.

H



and, occasionally, tendon injuries. *Dermatitis* is also common, since the hands are exposed to a variety of irritating agents.

The hand may be affected by contracture, a deformity caused by shrinkage of tissues in the palm of the hand (see *Dupuytren's contracture*) or damage to muscles in the forearm (see *Volkmann's contracture*). Degeneration of a synovial sheath on the upper side of the wrist may cause a harmless swelling known as a *ganglion*.

Osteoarthritis commonly attacks the joint at the base of the thumb, rendering it painful and immobile. *Rheumatoid arthritis* may cause deformity by attacking the joints at the base of the fingers and rupturing tendons.

THE SKELETAL STRUCTURE OF THE HAND AND WRIST

Four of the eight wrist bones (carpals) articulate with the radius and ulna. The rest are connected to the five bones of the palm (metacarpals), each of which is joined to a phalanx.

Handedness

Preference for using the right or left hand. Some 90 percent of healthy adults use the right hand for writing; two thirds favor the right hand for most activities requiring coordination and skill. The remainder are either left-handed or ambidextrous (able to use both hands equally) to a varying degree. There is no male-female difference in these proportions.

It is uncertain why all humans are not simply ambidextrous. Up to the age of about 12, it is possible to switch handedness if a person's dominant hemisphere of the brain is damaged.

CAUSES

Inheritance is probably the most important factor in determining handedness. Studies have shown a greater number of nerves going to one side of the brain even in the newborn. A child made to use the right hand despite natural preference, however, may "become" right-handed. In earlier times, left-handed people were considered to be unlucky or evil (the word sinister is derived from the Latin word for left), so children were trained to be right-handed. Even today, so many people are naturally right-handed that the pressure to conform is high, especially in some cultures where the left hand is reserved for wiping the anus after defecation. Some left-handed people have been known to rebel subconsciously when forced to use the right hand.

Handedness is related to the division of the human brain into two hemispheres, each of which controls movement and sensation on the opposite side of the body. In most right-handed people, the speech center is in the left hemisphere, so that a *stroke* affecting this side of the brain causes *aphasia* (speech impairment) as well as paralysis and weakness of the right arm and leg. In 70 percent of left-handed people, the speech center is on the right, and left hemisphere damage does not cause aphasia.

EFFECTS OF HANDEDNESS

It is not clear whether handedness is related to special abilities. Left-handed tennis players or "southpaw" pitchers seem to succeed because their shots or balls come from an unusual angle. While the left brain is related to verbal ability and logical reasoning, and the right to emotional and spatial awareness, there is no evidence that more artists are left-handed or more philosophers are right-handed.

Hand-foot-and-mouth disease

A common infectious disease of toddlers, caused by a type of virus called coxsackievirus. Hand-foot-and-mouth disease often occurs in small epidemics in nursery schools, usually in the summer months.

The illness is usually mild and lasts only a few days. Symptoms include blistering of the palms, soles, and inside of the mouth, reluctance to eat, and a slight fever.

There is no treatment other than mild *analgesics* (painkillers) to relieve the discomfort of the blisters. The illness is unrelated to foot-and-mouth disease in cattle.

Handicap

The extent to which a physical or mental *disability* (loss or permanent impairment of a faculty) prevents a person from performing everyday activities such as walking or dressing.

The management and treatment of a handicap involves assessment of the specific disability, the provision of suitable aids, and, in severe cases, institutional care.

Hangnail

A strip of skin torn away from the side or base of a fingernail, exposing a raw, painful area. It usually occurs after frequent immersion in water has dried the skin on the fingers. Biting the nails is another common cause. The raw area may become infected and develop into a *paronychia*.

A hangnail should be trimmed with scissors and covered until it heals. The condition may be prevented by applying a moisturizing cream.

Hangover

The unpleasant effects sometimes experienced on waking after overindulgence in *alcohol*. Characterized by headache, nausea, vertigo, and depression, the severity of a hangover is determined by the amount and type of alcohol consumed. Brandy, bourbon, and red wine have high concentrations of congeners (secondary products of alcohol fermentation) and usually produce bad hangovers.

Alcohol has a diuretic effect and some of the symptoms of a hangover are due to mild dehydration; drinking a large quantity of water before going to sleep may help. Recovery from a hangover is usually just a matter of time, but, in alcoholics (see *Alcohol dependence*) there may be withdrawal symptoms or the hangover may be more severe and persistent. (See also *Alcohol intoxication*.)

Hansen's disease
See *Leprosy*.

Hardening of the arteries
The popular term for *arteriosclerosis*, the most common form of which is *atherosclerosis*.

Hare lip
A common term for the congenital defect in which there is a split in the upper lip due to failure of the two halves to fuse during fetal development. Also called cleft lip, it is often associated with a similar failure of the two halves of the palate to join. (See *Cleft lip and palate*.)

Hashimoto's thyroiditis
An *autoimmune disorder* in which the body's immune system develops antibodies against its own thyroid gland cells. As a result, the thyroid gland becomes unable to produce enough hormones, a condition called *hypothyroidism*.

The principal symptoms are tiredness, muscle weakness, and weight gain. Enlargement of the thyroid gland (goiter) is present.

The condition is diagnosed by blood tests to measure the level of thyroid hormones and detect the presence of thyroid antibodies. Treatment consists of thyroid hormone replacement therapy, which is continued for life. It does not always cure the goiter, which may require surgery.

Hay fever
The popular name for allergic *rhinitis*.

Headache
One of the most common types of pain; a headache is very rarely a sign of some underlying, serious disorder. The pain of a headache comes from outside the brain (the brain tissue itself does not contain sensory nerves). Pain arises from the *meninges* (the outer linings of the brain) and from the scalp and its blood vessels and muscles. It is produced by tension in, or stretching of, these structures.

The pain may be felt all over the head or may occur in one part only—for example, in the back of the neck, the forehead, or one side of the head. Sometimes the pain moves to another part of the head during the course of the headache. The pain may be superficial or deep, throbbing or sharp, and there may be accompanying or preliminary symptoms, such as nausea, vomiting, and visual or sensory disturbances.

TYPES
Many headaches are simply the body's response to some adverse stimulus, such as hunger or a change in the weather. These headaches usually clear up in a few hours and leave no aftereffects.

Tension headaches, caused by tightening in the muscles of the face, neck, and scalp as a result of stress or poor posture, are also common. They may last for days or weeks and can cause variable degrees of discomfort.

Some types of headaches are especially painful and persistent, but, despite these symptoms, do not indicate any progressive disorder. *Migraine* is a severe, incapacitating headache preceded or accompanied by visual and/or stomach disturbances. Cluster headaches cause intense pain behind one eye and may wake the sufferer nightly for periods of weeks or months.

CAUSES
Common causes of headache include *hangover*, irregular meals, prolonged travel, poor posture, a noisy or stuffy work environment, excitement, and excessive sleep. Recent research has shown that certain foods (such as cheese, chocolate, and red wine) trigger migraine attacks in susceptible people. *Food additives* may also cause headache. Other causes include *sinusitis*, toothache, ear infection, head injury, and *cervical osteoarthritis*. (See also chart, overleaf.)

Among the rare causes of headache are *brain tumor*, *hypertension* (high blood pressure), *temporal arteritis* (inflammation of the arteries of the brain and scalp), *aneurysm* (localized swelling of a blood vessel), and increased pressure within the skull.

INVESTIGATION
If headaches are persistent, without obvious cause, and do not respond to self-help treatment, medical advice should be sought. The physician will ask about the nature and site of the pain and at what intervals the headaches occur. A careful general physical and neurological examination will be performed. *CT scanning* or *MRI* (magnetic resonance imaging) may be carried out if a neurological cause is suspected.

TREATMENT
Prevention is more important than treatment; many of the known causes can easily be avoided, particularly if the sufferer knows what triggers the headaches. Once a headache has started, however (if it is not a migraine or cluster headache), one or more of the following measures should ease the pain: relaxing in a hot bath, lying down, avoidance of aggravating factors (such as excessive noise or a stuffy room), stretching and massaging the muscles in the shoulders, neck, face, and scalp, taking a mild analgesic, such as acetaminophen, and, if convenient, sleeping for a few hours.

Head injury
Injury to the head may occur as the result of traffic accidents, sports injuries, falls, assault, accidents at work and at home, or bullet wounds. Most people have a head injury at least once in their lives, but very few of the injuries are severe enough to require treatment by a neurosurgeon. One percent of all deaths are caused by head injury, half of them as a result of traffic accidents.

A head injury can damage the scalp, skull, or brain in any combination. Minor injuries cause no damage to the underlying brain. Even when there is a *skull fracture*, or the scalp is split, the brain may not be damaged. However, a blow may severely shake the brain, sometimes causing *brain damage*, even when there are no signs of external injury (closed head injury).

A blow often bruises the brain tissue, causing death of some of the brain cells in the injured area. When an object actually penetrates the skull, foreign material and dirt may be implanted into the brain and lead to infection. A blow or a penetrating injury may tear blood vessels and cause *brain hemorrhage* (bleeding in or around the brain). Head injury may cause edema (swelling) of the brain; this is particularly notable after bullet wounds because their high velocity causes extensive damage. If the skull is fractured, bone may be driven into the underlying brain.

SYMPTOMS AND SIGNS
If the head injury is mild, there may be no symptoms other than a slight headache. In some cases there is *concussion*, which may cause confusion, dizziness, and blurred vision (sometimes persisting for several days). More severe head injuries, particularly blows to the head, may result in unconsciousness that lasts longer than a few minutes, or *coma*, which may be fatal.

Postconcussive *amnesia* (loss of memory of events that occurred after an accident) may occur, especially if the skull has been fractured. It usually lasts more than an hour after consciousness is regained. There may also

H

HEADACHE

Pain in the head that may be anything from mild to severe and incapacitating.

? Is your temperature 100°F (38°C) or above?

- **YES** → Many feverish illnesses may cause a headache. See • *Fever*
- **NO** ↓

? Have you injured your head within the past few days?

- **YES** → Are you feeling unusually drowsy AND/OR have you felt nauseated or been vomiting?
  - **YES** → ☎ **EMERGENCY! GET MEDICAL HELP NOW!** This suggests the possibility of a brain injury. See • *Extradural hemorrhage*
  - **NO** → A persistent headache is common following a head injury. See • *Head injury*
- **NO** ↓

? Have you felt nauseated or been vomiting?

- **YES** → Do you have severe pain in and around one eye AND is your vision in that eye blurred?
  - **YES** → ☎ **Call your physician without delay!** This suggests the possibility of raised pressure inside the eye. See • *Glaucoma*
  - **NO** ↓

  Do you have two or more of the following symptoms?
  - pain when you touch your chin to your chest
  - dislike of bright light
  - drowsiness or confusion

  - **YES** → ☎ **EMERGENCY! GET MEDICAL HELP NOW!** These symptoms suggest the possibility of a brain injury or irritation of the meninges. See • *Subarachnoid hemorrhage*
  - **NO** ↓

  Have you suddenly begun to have a severe throbbing pain in one or both temples?

  - **YES** → ☎ **Consult your physician without delay!** Inflammation of the arteries in the head is a possibility, especially if you are over 50. See • *Temporal arteritis*
  - **NO** ↓

  Was the pain one-sided, preceded by disturbed vision, AND/OR accompanied by vomiting?

  - **YES** → You may have a migraine. See • *Migraine*
  - **NO** ↓
- **NO** ↓

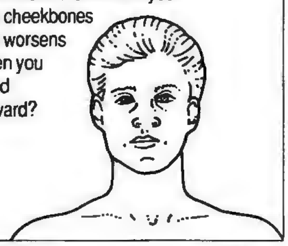
Continued on next page

Have you had a similar headache on waking several days or more out of the past week?

YES → Do the headaches only occur when you have drunk a lot of alcohol the night before?

YES → You probably have a hangover.

See • *Hangover*



NO → **Consult your physician without delay!** Such headaches may be a symptom of tension (when felt at the back of the head) or high blood pressure but, in very rare cases, may indicate a brain tumor.

See • *Brain tumor*
• *Hypertension*

NO ↓

Have you recently had OR do you now have a runny or stuffy nose?

YES → Do you have a dull pain and tenderness around the eyes and cheekbones that worsens when you bend forward?

YES → You may have an infection of the sinuses.

See • *Sinusitis*

NO → You may have a common cold.

See • *Cold, common*

NO ↓

Are you feeling tense or under stress AND/OR are you sleeping poorly?

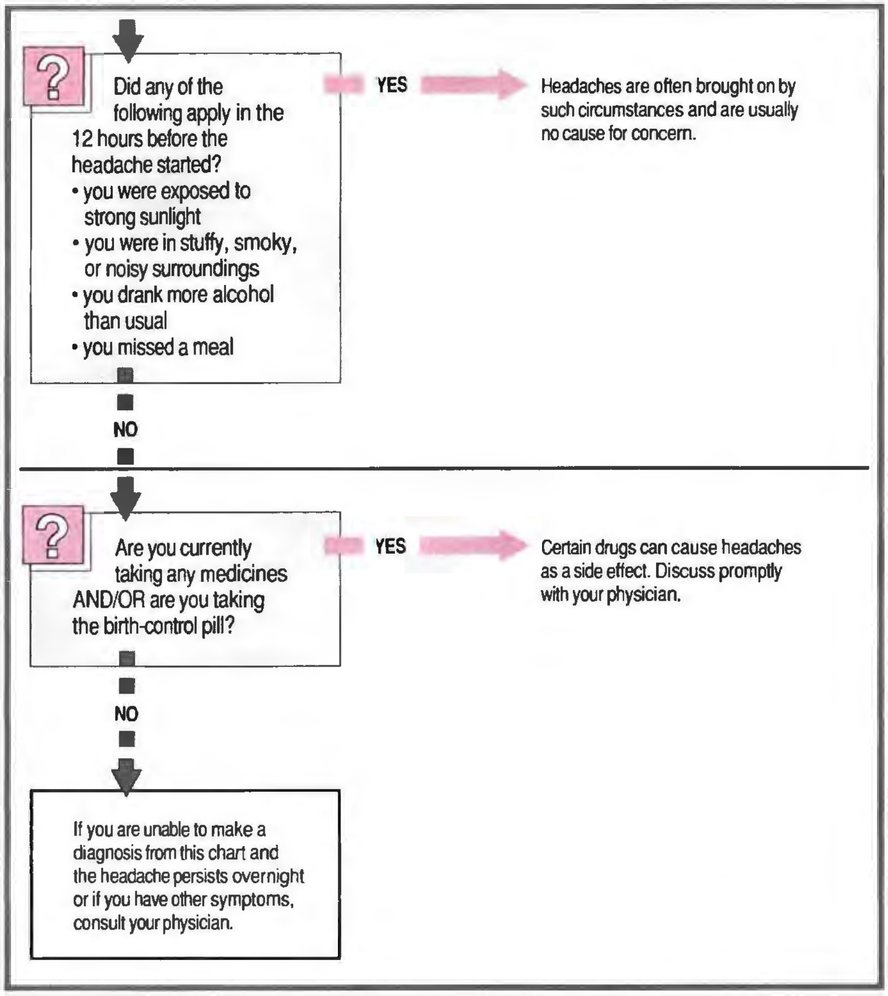
YES → Anxiety often causes tension headaches.

See • *Anxiety*
• *Headache*

NO ↓

Did the headache occur after you had been reading or doing close work such as sewing?

YES → Strain on your neck muscles may have caused the headache.



See • *Headache*

NO ↓

CANCER WATCH
A recurrent headache that is present on waking AND is accompanied by nausea or vomiting may, in rare cases, indicate a brain tumor.
Consult your physician without delay!

Continued on next page

H

be preconcussive amnesia (loss of memory of events that occurred before the accident). The longer the period of unconsciousness and the longer the period of amnesia, the more serious the injury to the brain.

After severe brain injury the person may have some muscular weakness or paralysis and loss of sensation.

Symptoms such as persistent vomiting, pupils of unequal size, double vision, or a deteriorating level of consciousness suggest progressive brain damage. The symptoms may begin immediately after the injury or after apparent recovery.

INVESTIGATION

Any person suffering loss of consciousness, however brief, should see a physician. The person may be hospitalized for observation; skull X rays are performed to identify any fracture. If brain hemorrhage is suspected, *CT scanning* is carried out.

TREATMENT

Cuts to the scalp may require stitching using local anesthesia. People whose consciousness is deteriorating may be kept in a neurosurgical unit for close observation. If a blood clot forms inside the skull, the clot may be life-threatening and requires surgical removal; severe skull fractures may also require surgery.

OUTLOOK

Recovery from a minor head injury may be delayed due to persistent symptoms of concussion, but these symptoms usually improve within a few days. Survival following a major head injury has improved due to advances in nursing and medical care, but permanent physical or mental disability (including changes in personality) has been observed if there has been permanent damage to the brain. Epileptic seizures sometimes occur after severe head injury (usually after penetrating injuries, a severe skull fracture, or serious brain hemorrhage). Recovery from a major head injury is very slow, and victims may continue to show signs of progressive recovery for as long as five years.

Head lag

The backward flopping of the head that occurs when an infant is placed in a sitting position. Head lag is notable in the newborn because the neck muscles are still weak, but, by 4 months of age, the baby can hold the head upright in line with the trunk. The disappearance of head lag is a measure of motor development (see *Child development*); good control of the head is essential before a baby can learn to sit.

Healing

The process by which the body repairs bone, tissue, or organ damage caused by injury, infection, or disease. In popular usage, the term means simply "restoring to health."

THE HEALING PROCESS

The initial stages of healing are the same for all parts of the body. After injury, the blood clots in damaged areas of tissue, and white blood cells and various chemicals (including *histamine*, *enzymes*, and proteins from which new cells can be made) accumulate at the site of damage. Fibrous tissue is laid down within the blood clot to form a supportive structure; any dead cells are broken down and absorbed by the white blood cells.

Some tissues, such as bone, are then able to regenerate by proliferation of the cells that remain around the damaged area. In such cases, the original structure and function are fully restored. In other cases, however, the cells may be unable to proliferate (nerve cells, for example) or there may be an inadequate blood supply or persistent infection that prevents tissue regeneration. If this occurs, the fibrous tissue that forms in the blood clot may develop into tough scar tissue that keeps the tissue structure intact, but may impair its function (e.g., the restriction of movement that may occur after a muscle tear).

WOUND HEALING

There are two processes by which the body repairs skin wounds—healing by first intention and healing by second intention.

Healing by first intention occurs when the edges of the wound are close together and there has been minimal loss of tissue. If the wound is deep, the edges of the skin may need to be held together with stitches or a butterfly bandage. The blood that seeps from the edges of the wound forms a clot that becomes the base on which scar tissue is laid down. When healing is complete, only a fine scar remains.

Healing by second intention occurs when the edges of the wound are not brought together. In this slower type of healing, pink *granulation tissue* grows from the exposed tissue. It is eventually covered by skin that grows over the wound from the cut edges. By the time healing is complete, the granulation tissue has developed into tough scar tissue.

Health
At its simplest, health is the absence of physical and mental disease. However, the wider concept promoted by the World Health Organization is that all people should have the opportunity to fulfill their genetic potential. This includes the ability to grow and develop physically and mentally without the impediments of inadequate nutrition or environmental contamination, and to be protected as much as possible against infectious diseases. (See also *Diet and disease; Health hazards.*)

Health food

A term applied to products that are meant to promote health, including unprocessed and whole grains, organically grown fruits and vegetables, and dietary supplements. The term is misleading because it suggests that only "health foods" are good for people. In fact, a healthy diet is based on sound *nutrition*.

Health hazards
Environmental factors that are known or suspected to cause disease. Some health hazards are obvious, such as contamination of water supplies with sewage or other effluents, and pollution of the air with smoke or poisonous chemicals. Others are less apparent—for example, radioactivity (which is detectable only with special instruments) and sunlight.

TYPES

For people in developing countries (the majority of the world's population), the main hazards come from lack of access to safe, pure water, from inadequate means of disposal of sewage and domestic refuse, and from insufficient or contaminated food. Foods contaminated with microorganisms (such as bacteria and molds) present far greater health hazards than those associated with the additives that are used in developed countries to combat such contamination (see *Food additives; Food-borne infection; Food poisoning*).

There are four other main types of health hazard, all of which are present worldwide. First, there are many *infectious diseases* transmitted by contact or by insects or other animals. (See *Bacteria; Fungal infections; Insects and disease; Viruses; Zoonoses.*)

The second type comprises work-related hazards (such as industrial accidents) and the wide variety of occupational disorders—for example, *asbestosis, pneumoconiosis, lead poisoning,* and cancers associated with exposure to chemicals. (See *Accidents; Occupational disease and injury.*)

The third category of hazards includes those associated with domestic and social life, such as *accidents* in the home or on the road, and injuries and other hazards (such as drowning) from sports activities. In many developed countries, domestic and traffic accidents are the most important risks to health in early adult life. Alcohol and tobacco are other primary hazards to health.

Finally, there are many types of global environmental hazards, ranging from sunlight and cosmic radiation to air *pollution* and background radioactivity. (See *Radiation hazards.*)

Health Maintenance Organization
A form of prepaid hospital and medical insurance that first received attention in about 1970. A person or family enrolling in a Health Maintenance Organization (HMO) pays the same monthly premium regardless of the amount of services needed. Care may be provided by HMO staff physicians (closed panel) or by members of an outside group (independent practice association).

According to original theory, HMOs would limit costs by encouraging preventive medicine. Since the HMO's financial performance would depend on premium income exceeding the cost of services, the HMO theoretically would have a financial incentive to keep patients healthy through periodic checkups and screenings. Recent studies indicate that HMOs do reduce medical costs. But the reason appears to be reduced rates of hospitalization rather than preventive care.

Hearing
The sense that enables sound to be perceived. The *ear* (the organ of hearing) transforms the sound waves it receives into nerve impulses that pass to the brain.

MECHANISM OF HEARING

Almost all sound is heard by a mechanism known as air conduction (see box, next page). This process, in which sound waves are channeled down the ear, is supplemented by a secondary form of hearing called bone conduction. Some sound waves set up vibrations in the skull bones that pass directly to the inner ear. This form of hearing affects the way a person hears his or her own voice.

HEARING DISORDERS

Problems with hearing (from minor sound distortions to total deafness) result when any part of the sound-transmitting and analyzing mechanism is damaged. (See also *Deafness.*)

Hearing aids
Electronic devices that improve hearing in people with certain types of *deafness*. A hearing aid consists of a tiny microphone (to pick up sounds), an amplifier (to increase their volume), and a tiny speaker (to transmit sounds to the ear).

HOW IT WORKS

A tiny microphone collects sound and transforms it into electric current. The amplifier increases the strength of the current and feeds it along a tube to an earpiece, which fits into the outer-ear canal and converts the current back to (now amplified) sound.

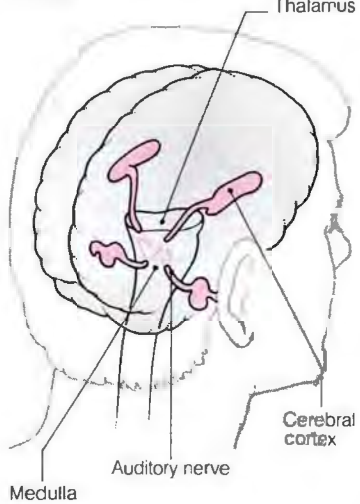
A volume control on the aid, usually operated by turning a tiny wheel, enables the level of incoming sound to be adjusted. The aid is designed at the factory to amplify those pitches for which the user has the most loss. Further modifications of this sort may be made by the hearing aid dispenser.

TYPES

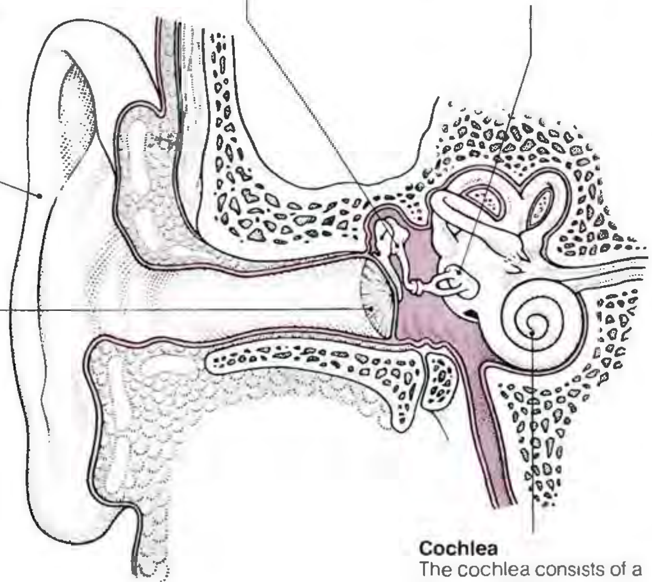
The most common types of hearing aids are inconspicuous. The mechanical parts, along with a battery to power them, are contained in a small plastic case that fits comfortably behind the ear, in the side piece of an eyeglass frame, or entirely within the ear canal. Aids that fit entirely in the ear are most popular today.

More powerful aids that amplify sound to a greater degree are also available, but rarely used anymore. In these aids, the microphone, amplifier, and battery are contained in a larger case worn on the body; the current is carried to the earpiece by a thin wire.

Most modern hearing aids include switches that enable normal reception of sound by the microphone to be replaced by a process known as electromagnetic induction. This process picks up transmitted speech in



HEARING

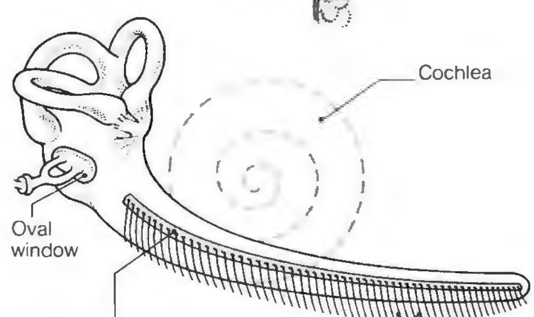


The ears are the organs of hearing. Each ear has three separate regions—the outer ear, middle ear, and inner ear. Sound waves are channeled into the ear canal to the middle ear, where a complex system of membranes and tiny bones conveys the vibrations to the inner ear. A part of the auditory nerve converts the vibrations to nerve impulses, which are then transmitted to the brain.

To function properly, the eardrum must have equal air pressure on each side so that it can vibrate freely. Pressure is equalized via the eustachian tube, which runs from the back of the throat to the middle ear.

ROUTE TO THE BRAIN

Auditory sensations are picked up by nerve fibers in the cochlea and travel along the auditory nerve to the medulla. From there, they pass via the thalamus to the superior temporal gyrus—the part of the cerebral cortex involved in receiving and perceiving sound.

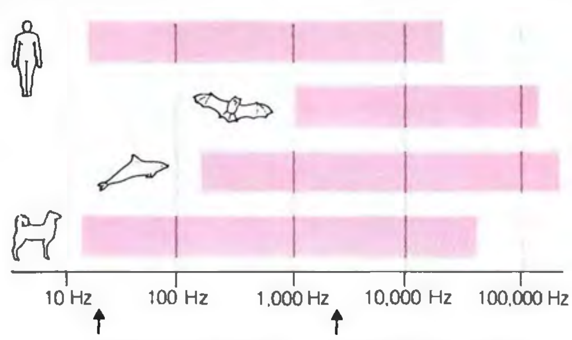


Outer ear
The pinna (the visible part of the ear) channels sound waves into the outer-ear canal (auditory canal) toward the eardrum Hairs and waxy cerumen line the canal

Malleus (hammer) and incus (anvil)
The malleus, attached to the eardrum, transmits vibration to the incus

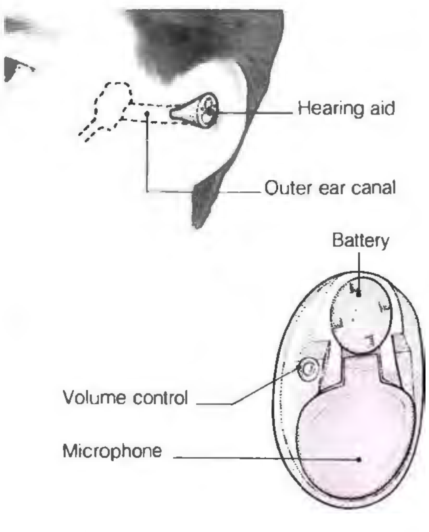
Stapes (stirrup) and oval window
The incus in turn transmits vibration to the stapes and the oval window membrane

Eardrum
The tympanic membrane (eardrum) is a taut membrane between the outer and middle ears. Sound waves of different frequencies cause the eardrum to vibrate at different speeds



Cochlea
The cochlea consists of a hollow spiral passage in the temporal bone. The cochlear duct, a fluid-filled membranous tube, virtually divides the cochlea lengthwise: it is full of microscopic hairs that stimulate nerve cells in response to sound vibrations, transmitted through the oval window

Function of cochlea
Inside the cochlea (shown uncoiled), the first part of the basilar membrane responds most to high-frequency vibrations; the far end registers only lower frequencies.



COMPARISON OF FREQUENCY RANGES

Different animals are able to hear different ranges of sound frequencies. The diagram shows the normal ranges of sound, in hertz (cycles per second), that can be heard by a human, a bat, a dolphin, and a dog.

Electron micrograph of inner ear
The section shows four rows of hair cells, which convert sound waves into electrical impulses to be sent to the brain.

Hearing aids
Hearing aids amplify sound waves for people who are hearing impaired. Many hearing aids include an earpiece, a microphone, an amplifier, volume control, and a battery

telephones and in many public buildings that have been equipped for the purpose. The greatest advantage of electromagnetic induction is that it obscures amplified background noise.

Other devices are available for the hard-of-hearing. They include amplified telephone receivers, flashing lights instead of doorbells and telephones that ring, vibrators that respond to sound, headphones for television sets, and teletypewriters. Exciting developments include the *cochlear implant* and *temporal bone implant*, which aid nerve and bone conduction deafness, respectively.

Hearing loss

See *Deafness*.

Hearing tests

Tests performed to determine whether a person has a hearing loss, how bad the hearing loss is, and what part of the ear may be causing the loss. The tests may be done routinely as part of a general assessment of *child development* or during a general medical examination. The tests may be used for a person who complains of impaired hearing or in whom hearing loss is suspected (such as a child with poor speech development or an elderly person suffering from apparent *dementia*). Hearing tests may be carried out regularly as a safeguard for people who are exposed to high noise levels in their work. A hearing test can also help determine the cause of *tinnitus* and dizziness.

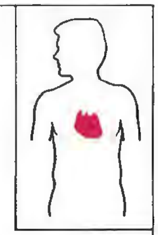
AIMS OF TESTING

The physician attempts to establish the extent and pattern of any hearing deficit by testing the ability to hear sounds of different frequencies and volumes; the physician also tries to ascertain whether any hearing loss is conductive or sensorineural.

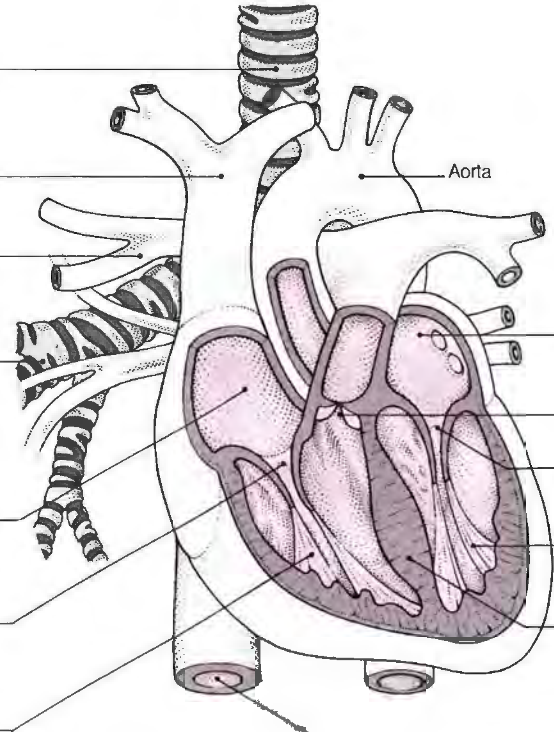
Conductive hearing loss is caused by a defect in sound conduction through the outer-ear canal or middle ear. Sensorineural loss is caused by damage to the inner ear, acoustic nerve, or hearing centers in the brain; the inner ear is isolated for testing by placing a speaker directly on the mastoid bone behind the ear.

The lowest level at which a person can hear and repeat words (the speech reception threshold) is tested, as is the ability to hear words clearly (speech discrimination).

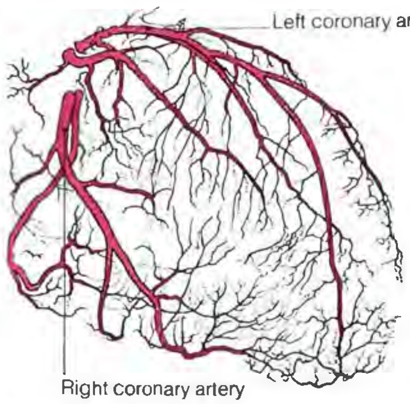
The results of hearing tests (see box, below) enable the physician and patient to decide on treatment, usually a *hearing aid* or surgery.



TYPES OF HEARING TEST



Tests	Function
Tuning fork tests	These tests are used to determine whether hearing loss is conductive or sensorineural. In the Rinne test, the patient is asked whether the sound is louder with the vibrating tines held near the opening of the ear canal (air conduction) or with the base of the fork held against the mastoid bone (bone conduction). In a normal ear or in one with sensorineural loss, air conduction is greater than bone conduction. In conductive loss, bone conduction is greater than or equal to air conduction. Weber's test, in which the base of the fork is placed on the forehead, is useful for diagnosing unilateral hearing loss. If hearing loss is conductive, the patient hears the tuning fork better in the ear with the poorer hearing.
Pure-tone audiometry	This is a test in which an audiometer is used to generate sounds of varying frequency and intensity. The audiometer is an electrical instrument that measures a person's ability to hear sounds of different frequencies and intensities. Hearing is first assessed by transmitting the sounds through one earphone while the other ear is prevented from hearing them. The sound frequencies range from 250 to 8,000 hertz (cycles per second); for each frequency, the sound is decreased in intensity until it can no longer be heard. The person whose hearing is being tested gives a signal at the moment when he or she detects each sound, and the results are recorded on a graph called an audiogram. Bone conduction hearing is then assessed using a rubber rod connected to the audiometer (the rod is placed against the mastoid bone behind the ear and kept in place by a headband).
Auditory evoked response	In this form of testing, the brain's response to sound stimulation by the audiometer is analyzed by means of electrodes placed on the scalp. This test attempts to evaluate the presence of hearing in a person who is unable to cooperate with other tests (because of mental handicap, for example). Auditory evoked response is commonly used to assess hearing in very young babies. The test can also help rule out acoustic neuroma (a benign tumor within the auditory canal).
Impedance audiometry	This test is used to determine the type of middle-ear damage occurring in cases of conductive deafness. A probe is fitted tightly into the entrance to the outer-ear canal, sealing it off from outside air pressure and sound. The probe emits a continuous sound. Air is pumped through the probe at varying pressures and, at the same time, a microphone in the probe registers the differing reflections of sounds from the eardrum as pressure changes in the ear canal. The reflections are recorded on a graph known as a tympanogram. The pattern of differing reflections reveals the extent of elasticity in the eardrum and middle-ear bones, thus indicating the type of disease that is causing the deafness. This device can also measure the air pressure in an air-filled middle ear.



THE HEART

The heart is positioned centrally in the chest, with its right margin directly underneath the right side of the sternum (breastbone). The rest of the heart points to the left, with its lowest point (the apex) located directly underneath the left nipple.

The heart acts as a dual pump. Deoxygenated blood from the body arrives, via the vena cava, in the right atrium (upper heart chamber), is transferred to the right ventricle (lower chamber), and is then pumped via the pulmonary artery to the lungs. There it is reoxygenated and returns, via the pulmonary veins, to the left side of the heart. It enters the left atrium, is transferred to the left ventricle, and is then pumped, via a large vessel (the aorta) to all parts of the body.

Blood supply
Although the heart muscle is continually pumping blood, it cannot obtain much oxygen from this flow, so it needs its own blood supply. This is furnished by the two coronary arteries, which arise from the aorta. With their branches, these arteries supply the entire heart muscle.

Angiogram of coronary arteries
The image at left gives a view of the heart from the rear and shows clearly the coronary arteries. The image was achieved by angiography—an X ray of the heart was taken after injecting the coronary arteries with a contrast medium.

Heart

The muscular pump in the chest that, throughout life, beats continuously and rhythmically to send blood to the lungs and to the rest of the body. During an average lifetime, the heart contracts more than 2.5 billion times.

STRUCTURE

Much of the heart consists of a special type of muscle, called myocardium. The myocardium, given sufficient oxygen and nutrients, contracts rhythmically and automatically without any other stimulation.

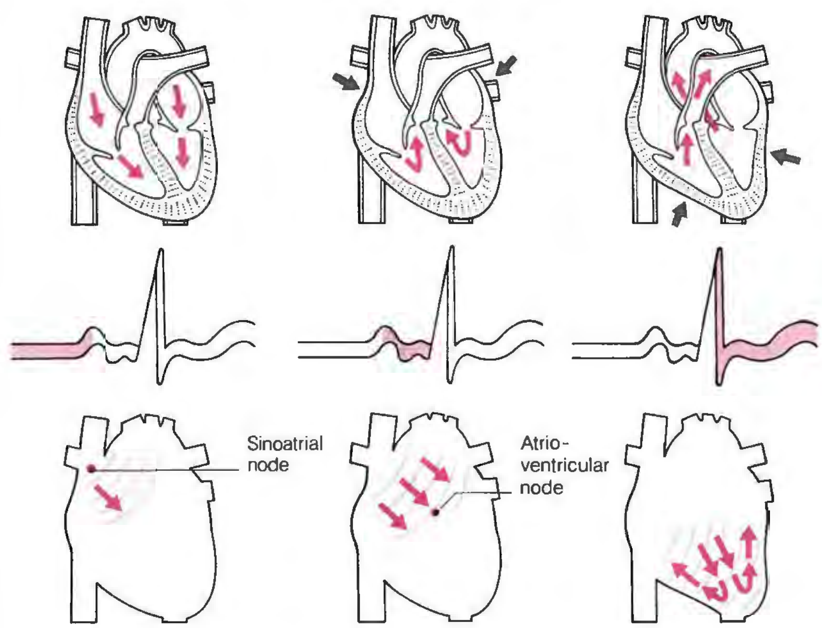
The interior of the heart consists of four distinct chambers. A thick central muscular wall (the septum) divides the cavity into right and left halves. Each half consists of an upper chamber (atrium) and a larger lower chamber (ventricle). Various large blood vessels emerge from the top and sides of the heart; they deliver blood to the atria or carry blood pumped out by the ventricles.

The internal surface of the heart is lined with a smooth membrane (the endocardium) and the entire heart is enclosed in a tough, membranous bag (the pericardium).

FUNCTION

The two sides of the heart have distinct, although interdependent, functions. The right side receives deoxygenated blood from the entire body via two large veins called the vena cava. This blood arrives in the right atrium and, after transfer to the right ventricle, is pumped to the lungs via the pulmonary artery to be oxygenated (receive oxygen from the *alveoli*) and to lose carbon dioxide. The left side receives oxygenated blood from the lungs (via the pulmonary veins, which drain into the left atrium); this blood is first transferred to the left ventricle and then pumped to all tissues in the body. The heart can thus be viewed as a dual pump.

Nonreturn (one-way) valves situated at the exits from each heart cham-



HEART CYCLE

The pumping action of the heart has three main phases for each heart beat. Each beat is brought about by electrical waves that emanate from the heart's own pacemaker, the sinoatrial node. The electrocardiogram tracing also shows the phases of the cycle.

Diastole
During this resting phase, the heart fills with blood. Deoxygenated blood flows into the right side of the heart; at the same time, oxygenated blood flows into the left side.

Atrial systole
In this second phase, the two atria (upper chambers of the heart) contract simultaneously, squeezing more blood into the two ventricles, which become fully filled.

Ventricular systole
The ventricles contract to pump deoxygenated blood into the pulmonary artery and oxygenated blood into the aorta. When the heart is emptied, diastole begins again.

In diastole, the heart muscle is at rest. Toward the end of this phase of the heart cycle, an electrical impulse begins to emanate from the sinoatrial node.

Atrial systole is brought about by the impulse from the sinoatrial node spreading over the atria. The impulse soon reaches another node, the atrioventricular node.

Ventricular systole is brought about by waves of electrical activity carried from the atrioventricular node to all parts of the ventricles by means of special fibers.

ber guarantee that blood can flow through the circuit in one direction only (see *Heart valves*).

THE CARDIAC CYCLE

The pumping action of the heart consists of three phases, which together make up a cycle corresponding to one heart beat. These phases are called diastole, atrial systole, and ventricular systole (see illustration).

To work efficiently, the different parts of the heart must contract in a precise sequence. This sequence is brought about by electrical impulses that emanate from the sinoatrial node, the heart's own pacemaker situated at the top of the right atrium. The electrical impulses are carried partly by the heart muscle itself and partly by specialized nerve fibers.

To avoid bottlenecks developing in the blood circulation, the volume pumped at each stroke by the two sides of the heart must exactly balance each other. However, resistance to blood flow through the general circulation is much greater than resistance to flow through the lungs; this means that the left side of the heart must contract much more forcibly than the right side. Hence, the muscular bulk of the left side of the heart is considerably greater than that of the right side.

FACTORS AFFECTING HEART RATE AND OUTPUT

The rate at which the heart beats, and the amount of blood it puts out with each contraction, can vary considerably according to the demands of the body's muscles for oxygen, and thus blood. At rest, the heart contracts at 60 to 80 beats per minute and puts out about one sixth of a pint of blood at each stroke, thus pumping about 12 pints per minute. However, during extreme exercise, the heart rate may increase to 200 contractions per minute and the output may increase to almost half a pint per beat, thereby increasing the total output to 100 pints per minute.

Such changes in heart rate and output are brought about in two ways. First, the heart muscle is able to respond automatically to any increase in the amount of blood returned to it from active muscles by increasing its output. This occurs because the more the ventricles are filled with blood during the filling phase of the heart's cycle, the more forcibly they contract during ventricular systole to expel the blood. Second, the heart rate is under external control of the *autonomic nervous system* (the part of the nervous system concerned with automatic control of body functions). The parts of the autonomic nervous system concerned with heart action are a nucleus of nerve cells called the cardiac center in the brain stem, and two sets of nerves (parasympathetic and sympathetic) whose activities, controlled by the cardiac center, exert opposite effects on the heart.

At rest it is the parasympathetic nerves—particularly the *vagus nerve*—that are active. Signals carried along the vagus nerve act on the sinoatrial node to slow the heart rate from its inherent rate of about 140 impulses per minute to a rate closer to 70 per minute. This phenomenon is called vagal inhibition. During or in anticipation of muscular activity, the vagal inhibition lessens, the heart rate speeds up, and may speed up even more when the sympathetic nerves come into action. The nerves release norepinephrine, which increases the heart rate and the force of contraction.

The switch from parasympathetic to sympathetic activity is triggered by any influence on the cardiac center that signals an extra need for increased blood output from the heart. Such influences may include fear or anger, low blood pressure, or a reduction of oxygen in the blood.

Heart, artificial

An implantable mechanical device that takes over the heart's action in pumping blood to maintain the circulation. First used in humans in 1985 after years of research in animals, the presently available artificial heart is now seen as a temporary measure to keep a patient alive from a few days to weeks until heart transplant surgery can be performed.

HOW IT WORKS

The type of artificial heart used most frequently, but not exclusively, to date (the Jarvik 7) is a metal and plastic device installed in the patient's chest in place of the diseased heart. During installation, the device is sewn to parts of the two atria (upper chambers) remaining from the original heart and to the pulmonary artery and aorta (main blood vessels carrying blood out of the heart).

The device is powered by an external machine connected to the device by air lines passing through the chest wall. Pulses of pressure sent through these lines operate the device's pumping action. The patient's movements are restricted by the need to be continuously connected to the machine.

LIMITATIONS AND RISKS

As a temporary measure, the artificial heart has a place in the treatment of life-threatening heart disease, but medical opinion is, at present, strongly against attempts to employ it on a permanent basis. The complications of its use have included *renal failure*, infection, internal bleeding, mental confusion, and *stroke* from blood clots being formed in the heart and carried to the brain. Up to early 1987, all four US patients in whom an artificial heart had been installed on a permanent basis had died. Several of these people experienced strokes and serious infection, which contributed to their deaths.

ALTERNATIVES

A device known as the intra-aortic balloon pump has been in use since the middle 1970s; it has been found helpful as an alternative method of maintaining the circulation when the heart is grossly diseased. The balloon is inflated automatically between each heart beat to provide extra force to the circulation. It has the extra advantage of increasing the pressure in the arteries that supply blood to the heart muscle and of relieving the strain on the heart.

H

Heart attack

See *Myocardial infarction*.

Heart beat

A contraction of the heart to pump blood to the lungs and rest of the body. The heart beat is readily felt on the left side of the chest, where the apex of the left ventricle (lower heart chamber) lies close beneath the skin (see *Heart*). The rate at which contractions occur is called the *heart rate*. The term *pulse* refers to the character and rate of the heart beat when felt (at the wrist, for example).

Heart block

A disorder of the heart beat that may lead to episodes of dizziness, fainting attacks, or strokes. Heart block is caused by an interruption to the passage of impulses through the specialized conducting system of the heart. Consequently, although the atria beat normally, the ventricles lag behind or contract less often than the atria. This is a completely different problem from the blockage of vessels associated with atherosclerosis.

TYPES

There are several grades of heart block. In the least severe form, the delay between the contractions of the atria and ventricles is just slightly longer than normal (called a prolonged P-R interval from its appearance on an *ECG*). Sometimes the delay lengthens with successive beats, until eventually a ventricular beat is dropped. In more severe cases, only a half, a third, or a quarter of the atrial beats is conducted to the ventricles. In complete heart block, the atria and ventricles beat independently. Thus, while the rate of atrial contraction varies according to the patient's activity, the ventricles contract at a fairly constant rate of about 40 beats per minute.

CAUSES AND INCIDENCE

Heart block may occur as a result of *coronary heart disease*, in active *myocarditis* (inflammation of heart muscle), with an overdose of a *digitalis drug*, in *rheumatic fever*, or in syphilitic *aortitis*. In about half the cases, the patient has no history of heart disease.

Heart block is a common disorder. It develops in about 30 persons per 100,000 annually in the US.

SYMPTOMS

A prolonged P-R interval causes no symptoms even though it can be detected on an *ECG*. Dropped beats may also be symptomless.

In other cases, the rate of the ventricular beat is slower than normal; in complete heart block, the rate does not increase in response to exercise. Sometimes the ventricles are able to compensate by expelling more blood with each contraction. In other cases, the blood output from the ventricles is inadequate, and the patient may become breathless due to *heart failure*, may develop the chest pains of *angina pectoris*, or may faint.

If the ventricular beat becomes very slow, or stops altogether for a few seconds, the patient may black out and have a seizure due to insufficient blood reaching the brain. However, the ventricular beat usually restarts within a few seconds. If the delay is prolonged and cerebral *atherosclerosis* exists, *stroke* may result.

DIAGNOSIS

Heart block may be diagnosed by a physician who finds a slow regular heart beat (below 50 beats per minute) that does not accelerate during exercise and is confirmed by an ECG.

TREATMENT

Some cases of heart block do not require treatment (e.g., when there are no symptoms or in the case of an elderly person whose only symptom is slight uneasiness). If the heart block is causing fainting attacks, it usually is treated by fitting an artificial *pacemaker*, which overrides the natural pacemaker and faulty electrical conducting system in the heart.

Less commonly, the condition may be treated with drugs (such as isoproterenol), although usually only in emergencies or as a temporary measure until an artificial pacemaker can be fitted.

Heartburn

A burning pain in the center of the chest that may travel from the tip of the breastbone to the throat.

Heartburn may be caused by overeating, eating rich or spicy food, or drinking alcohol. Recurrent heartburn is a symptom of *esophagitis*, which is usually caused by *acid reflux* (backflow of stomach acid). This backflow of acid is associated with the inability of the lower esophageal segment to close completely (sometimes accompanied by a *hiatal hernia*). Heartburn is often brought on by lying down or bending forward.

Occasionally, heartburn may cause chest pain that is mistaken for the pain of heart disease.

DISORDERS OF THE HEART

Heart disorders are by far the most common cause of death in developed countries. They also impair the quality of life of millions of people, restricting activity by causing pain, breathlessness, fatigue, fainting spells, and anxiety. A wide range of conditions can affect the heart by ultimately interfering with the pumping action of the heart.

GENETIC DISORDERS

In general, inherited or genetic factors do not play a large part in the causation of heart disorders. However, they do contribute to the *hyperlipidemias* that predispose a person to *atherosclerosis* and *coronary heart disease.*

CONGENITAL DEFECTS

Structural abnormalities in the heart are among the most common birth defects, but are usually treatable. They result from errors of development in the fetus and include such conditions as *septal defects* ("holes in the heart") and some types of abnormal *heart valves.* (See *Heart disease, congenital.*)

INFECTION

Endocarditis is an infection of the heart valves, usually occurring in people whose hearts have already been damaged by *rheumatic fever* or are abnormal because of some congenital or degenerative disorder. It may also affect drug addicts who inject themselves intravenously with nonsterile needles. The infection may cause deformity and malfunctioning of any of the heart valves, leading to, for example, *mitral insufficiency* or *aortic insufficiency* (although heart valve disease can also have other causes). Some types of cardiomyopathy are triggered by viral infection.

TUMORS

Tumors arising from the heart tissues are rare, the most common being the benign *myxoma* (which grows inside one of the chambers of the heart and may interfere with blood flow or valve action). Occasionally a malignant *sarcoma* develops. Secondary tumors, spreading from cancer elsewhere in the body (such as the breast or lung) are several times more common than primary tumors. These *metastases* usually grow within the heart muscle or the pericardium (sac that surrounds the heart), but seldom affect the valves. The tumors may produce electrocardiographic (see *ECG*) abnormalities and, if extensive, result in congestive *heart failure.*

MUSCLE DISORDERS

Cardiomyopathy is a general term for disease of the heart muscle itself. One type of cardiomyopathy is inherited; others may be caused by vitamin deficiency or alcohol poisoning, or may be triggered by a viral infection.

Myocarditis is inflammation of the heart muscle. It may be caused by a viral infection or by toxins released during a bacterial infection. Rarely, it results from drugs or radiation therapy.

INJURY

Blunt injury to the heart usually occurs in car accidents through impact with the steering wheel. The heart is compressed between the sternum (breastbone) and the spine and may suffer injury ranging from mild bruising to complete rupture. In immediately fatal car accidents, up to two thirds of the victims have suffered rupture of a heart chamber. Seat belt use could probably prevent some of these deaths.

Stab wounds to the heart are often fatal within minutes, but, of patients who reach the hospital, the great majority survive. Bullet wounds are more serious; about 10 percent of people shot in the heart reach the hospital alive.

NUTRITIONAL DISORDERS

The heart muscle is sensitive to severe nutritional deficiency and may become thin and flabby from simple lack of protein and calories. Thiamine (vitamin B_1) deficiency, which is common in chronic alcoholics, causes *beriberi* with congestive heart failure. *Obesity* is another important factor in causing heart disease, probably through its effect on other risk factors such as *hypertension, diabetes,* and *cholesterol.*

IMPAIRED BLOOD SUPPLY

The major cause of heart disease in developed countries is impaired blood supply. The coronary arteries (which supply blood to the heart) become narrowed due to *atherosclerosis* and parts of the heart muscle are deprived of oxygen. The result of coronary heart disease may be *angina pectoris* or, eventually, a *myocardial infarction.*

POISONING

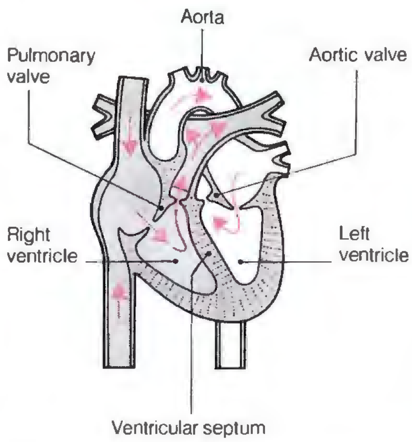
The most common toxic substance affecting the heart is alcohol. A large intake for many years may cause a type of cardiomyopathy in which the heart becomes enlarged and heart failure develops. If alcohol intake is stopped, recovery is possible.

DRUGS

Certain drugs may disturb the heart beat or even cause permanent damage to the heart muscle. These drugs include the anticancer drug doxorubicin, the tricyclic antidepressants, and even many drugs used to treat heart disease.

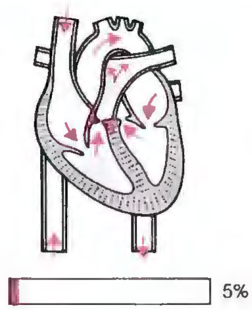
OTHER DISORDERS

Many common and important heart disorders may result from some other underlying condition, such as coronary heart disease, cardiomyopathy, or a congenital defect. Such disorders include cardiac *arrhythmia* (a disturbance in the rhythm of the heart beat), some cases of *heart block* (in which contractions of the upper and lower parts of the heart are not synchronized), and heart failure (inability of the heart to keep up with its work load). *Cor pulmonale* is a failure of the right side of the heart; it is a consequence of lung diseases (such as *emphysema*), which increase resistance to blood flow.

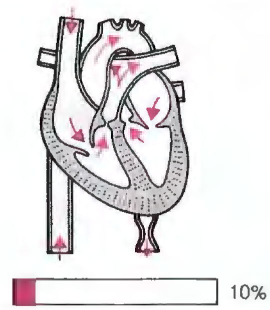


INVESTIGATION

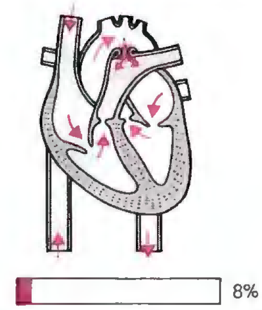
Heart disease and disorders are investigated by such techniques as auscultation (listening to the heart sounds) and *ECG* (electrocardiography); heart *imaging techniques* such as chest X ray, echocardiography, coronary angiography, *CT scanning,* and *MRI*; cardiac catheterization; blood tests; and, in rare cases, by a *biopsy* of the heart muscle (removal of a small sample of tissue for analysis).



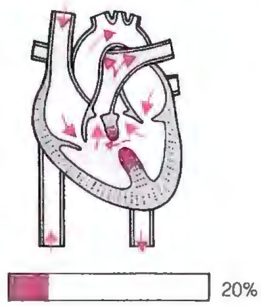
TYPES OF CONGENITAL HEART DISEASE



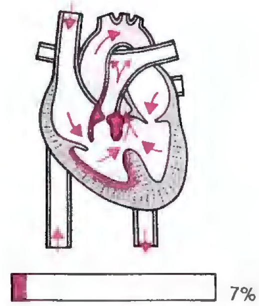
The major malformations are *septal defects, coarctation of the aorta, transposition of the great vessels, patent ductus arteriosus, tetralogy of Fallot, hypoplastic left heart syndrome, pulmonary stenosis*, and *aortic stenosis*. The bars (right) show the incidence of each type of malformation among affected babies.



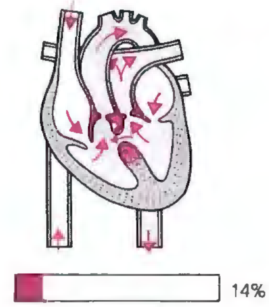
How blood circulates
Deoxygenated blood (gray) is pumped from the right ventricle into the lungs, where it exchanges carbon dioxide for oxygen. The newly oxygenated blood (pink) enters the left side of the heart and is then pumped out of the left ventricle to all body tissues.



Pulmonary stenosis
Narrowing of the pulmonary valve, or (rarely) of the upper right ventricle, which reduces blood flow to the lungs.



Coarctation of the aorta
In this disorder, localized narrowing of the aorta reduces the supply of blood to the lower part of the body.



Patent ductus arteriosus
The ductus arteriosus fails to close after birth and blood from the aorta continues to flow through it into the pulmonary artery.

Ventricular septal defect
A hole in the ventricular septum, causing blood to flow from the left ventricle to the right and into the lungs.

Tetralogy of Fallot
A hole in the ventricular septum, displacement of the aorta, pulmonary stenosis, and thickening of the right ventricle.

Transposition of the great vessels
Oxygenated blood passes back to the lungs, instead of through the aorta to the tissues.

Heart disease, congenital

Any heart abnormality that has been present from birth. Congenital heart defects are the most common major malformations compatible with life.

CAUSES AND INCIDENCE

About 700 babies per 100,000 are born with a congenital heart defect. The errors of development leading to defects arise early in the life of the embryo. In most cases, there is no known cause. Of known causes, the most significant is *rubella* in the mother during the first three months of pregnancy. This can be prevented by vaccination. About one third of babies with *Down's syndrome* have a congenital heart defect, and congenital heart disease often accompanies other birth defects.

Hereditary factors do not seem to play a significant role. If a couple has an affected child, there is little increased risk of a second child being affected. People born with heart defects have little increased risk of having an affected child.

SYMPTOMS AND COMPLICATIONS

The symptoms of congenital heart disease arise from insufficient or excessive circulation of blood to the lungs or to the body. The defects in heart anatomy can also mean that some deoxygenated blood is pumped to the body instead of to the lungs or some oxygenated blood to the lungs instead of to the body. These anomalies can result in *cyanosis* (blueness caused by a reduced oxygen level in the general blood circulation), breathlessness, or both.

Symptoms may first appear at any time over a wide range of ages, according to the defect. Similarly, recognition of a defect may occur any time from before birth to adulthood.

Apart from cyanosis and breathlessness, an untreated heart defect can cause stunted growth and underdeveloped limbs and muscles. Colds repeatedly lead to pneumonia. With prolonged cyanosis, *clubbing* (thickening and broadening) of the tips of fingers and toes may develop. If there is insufficient capacity of the heart to increase blood flow during exercise, the child may rapidly tire and be unable to take part in physical exercise. In some untreated cases, a serious complication called *Eisenmenger complex* (in which there is increased resistance of the lungs to blood flow) develops.

DIAGNOSIS

A heart defect may be diagnosed by procedures such as *chest X rays, ECG, echocardiography*, and, less commonly, cardiac *catheterization*.

TREATMENT

Rest, oxygen, and various drugs to assist the circulation and lung function may improve matters for a limited time or sometimes indefinitely. Some conditions, such as small septal defects, may get smaller or disappear on their own. Other defects are likely to worsen, and surgical correction often is a consideration.

Today, surgical correction is available for most affected children; the risk of death from unsuccessful sur-

gery lessens every year. One condition—hypoplastic left heart syndrome (in which the left side of the heart is severely underdeveloped)—can be treated only by performing a *heart transplant* operation.

Narrowed heart valves can now frequently be treated by balloon *valvuloplasty*, in which a special catheter is introduced into the heart to widen the narrowed valve.

In other cases, *open heart surgery* is necessary. Sometimes, any of a range of *prostheses* (artificial spare parts), such as replacement heart valves or blood vessels, may be used. In some cases, a heart transplant or *heart-lung transplant* may be necessary.

OUTLOOK

Following successful heart surgery, recovery to good health with resumption of growth, increased activity, and better appetite follow rapidly, and the child usually has a near-normal life expectancy. Full activities, including sports, are generally possible after three to six months.

Children with heart defects (corrected or uncorrected) are at an increased risk of bacterial *endocarditis*, a potentially dangerous infection of the lining of the heart. Preventive antibiotics may be prescribed.

Heart disease, ischemic

The most common form of heart disease, in which there is a reduced blood supply resulting from narrowing or obstruction of the coronary arteries. (See *Coronary heart disease*.)

Heart failure

A medical term that describes an inability of the heart to keep up its work load of pumping blood to the lungs and to the rest of the body. Although it sounds life-threatening, heart failure is usually a treatable condition and compatible with survival for many years.

TYPES AND CAUSES

Failure of the heart is conventionally divided into left- or right-sided failure.

LEFT-SIDED FAILURE Left-sided heart failure may be due to *hypertension*, *anemia*, or *hyperthyroidism*, to a heart valve defect (such as *aortic stenosis* or *aortic insufficiency*), or to a congenital heart defect (such as *coarctation of the aorta*). In all these conditions, the left side of the heart must work harder to pump the same amount of blood. Sometimes, the extra load can be compensated for by an increase in the size of the left side of the heart and in the thickness of its muscular walls, or by an increase in heart rate. Compensation is only temporary, however, and heart failure follows.

Other causes of left-sided heart failure include heart *arrhythmias*, *myocardial infarction* (death of part of the heart muscle due to interruption of its blood supply), and *cardiomyopathy* (intrinsic muscle disease). In cardiomyopathy, the pumping power of the heart is reduced and it can no longer deal with its normal load.

Whatever the cause, the left side of the heart fails to empty completely with each contraction or has difficulty accepting blood returning from the lungs. The retained blood creates a back pressure that causes the lungs to become congested with blood. This in turn leads to pulmonary *edema* (excess fluid in the lungs), of which the main symptom is shortness of breath.

RIGHT-SIDED FAILURE Right-sided failure most often results from *pulmonary hypertension* (raised pressure and resistance to blood flow through the lungs)—itself caused by left-sided failure or by lung disease (such as chronic *bronchitis* or *emphysema*). Right-sided failure can also be due to a valve defect (such as *tricuspid insufficiency*) or a congenital heart defect (such as a *septal defect*, *pulmonary stenosis*, or *tetralogy of Fallot*).

In all types of right-sided failure, there is a back pressure in the blood circulation from the heart into the venous system, causing distended neck veins, enlarged liver, and *edema* (fluid in the tissues).

SYMPTOMS

Fatigue is an early symptom of heart failure. Breathing difficulty is the most frequent symptom of left-sided heart failure caused by fluid in the lungs. Breathlessness may first be noticed only during or after exercise, but worsens and is eventually apparent even at rest. The patient may be able to breathe easily only when well propped up in bed. Sometimes he or she may awaken at night with an attack of breathlessness, wheezing, and sweating. Such paroxysms may subside on their own or may require urgent, lifesaving treatment.

Right-sided heart failure produces less breathlessness and more swelling of the ankles and legs, often with enlargement of the liver and congestion of the intestines, causing discomfort and indigestion.

TREATMENT

Immediate treatment of the heart failure is followed by treatment of its underlying cause.

Immediate treatment consists of bed rest, with the patient sitting up. The patient is given *diuretic drugs* (which increase the output of urine from the kidneys), thus ridding the body of excess fluid and reducing blood volume. In some cases, *vasodilator drugs* (which ease the work load of the heart) or digitalis (which strengthens the contractions of the heart beat) may also be given. Morphine is sometimes given as an emergency treatment in acute left-sided failure. These measures usually bring about a significant improvement within a few days.

Once the heart failure is treated, attention is directed to treating the underlying cause. If a defective heart valve is responsible, it may be treated by *heart valve surgery* (although, ideally, defective heart valves should be corrected surgically before severe heart failure develops).

Many other causes of heart failure are also treatable; hypertension and arrhythmias are treated through drug treatment and congenital septal defects are treated by open heart surgery. However, when the cause is a long-standing disease of the heart muscle (a cardiomyopathy) or chronic lung disease, the outlook is generally not as good.

Heart imaging

Techniques that provide images of the heart and its structure. Imaging is performed to detect structural abnormality, disease, or impaired function.

TYPES

A *chest X ray* is the simplest and most widely used method of obtaining an image of the heart. It can show the heart size and shape, and whether or not abnormal calcification is present in the valves, major blood vessels, or the pericardium. Pulmonary *edema* (accumulation of fluid in the lungs) and engorgement of the vessels connecting the heart and lungs are usually detectable on a chest X ray, which may indicate the presence of *heart failure*. Pacemakers and artificial heart valves show up clearly on X ray and can be checked for position.

Angiography may be performed to show the heart chambers. Children with complex forms of congenital heart disease (such as *tetralogy of Fallot*) may benefit from this procedure. Angiography is also performed to evaluate the state of the coronary arteries in patients with *coronary heart disease* and helps with decisions about valve replacement.

Echocardiography (cardiac ultrasound) is most useful as the first step in investigating congenital heart abnormalities or in evaluating valvular or heart wall abnormalities. *Doppler* techniques enable the physician to measure blood flow across valves. *Radionuclide scanning* produces images that give less anatomical detail but some information about heart function. For example, radionuclide scanning can show how well the heart wall moves and how effectively it empties.

A new generation of extremely fast CT scanners has been developed with heart imaging in mind; previous scanners were too slow to "freeze" a heart beat (see *CT scanning*).

Magnetic resonance imaging (*MRI*) techniques are also capable of producing high quality cardiac images. These techniques are sometimes used to test graft efficiency after a *coronary artery bypass*. They eliminate the need for angiography and for other techniques used previously to investigate congenital heart disease.

Heart-lung machine

A machine that temporarily takes over the function of the heart and lungs to facilitate certain operations in the chest. A heart-lung machine consists principally of a pump (to replace the heart) and an oxygenator (to replace the lungs). The machine is sometimes called a cardiopulmonary bypass or pump oxygenator.

Once the machine is connected and working, the patient's heart and lungs are effectively bypassed and the heart can be stopped. The surgeon can then operate unhurriedly in a blood-free surgical field to perform *open heart surgery*, a *heart transplant*, or a *heart-lung transplant*.

HOW IT WORKS

Blood is taken via cannulas (tubes) inserted into the inferior and superior venae cavae (the main veins draining blood into the heart) and pumped through the oxygenator, which acts as an artificial lung, putting oxygen into the blood and removing carbon dioxide from it. The freshly oxygenated blood is then returned to the arterial circulation via a cannula inserted into the aorta (the main artery carrying blood from the heart) or the femoral artery (a large artery in the leg).

There are two main types of oxygenator. In one type, the blood is passed up a column, through which a gas mixture with a high oxygen content is bubbled. This adds oxygen and removes carbon dioxide. The blood is then treated with a defoaming agent and held in a reservoir until it is returned to the patient. In the second type, called a membrane oxygenator, the blood and gas flow on either side of a thin, semipermeable membrane, through which oxygen passes from gas into blood; carbon dioxide passes in the opposing direction. This method more closely mimics the function of the lungs.

A heat exchanger is another component of the machine. Generally, it is used to rewarm blood before returning it to the patient (otherwise, blood cools in the machine); sometimes the blood is intentionally cooled to cause a drop in the patient's temperature (see *Hypothermia, surgical*), giving surgeons more time for the operation.

PRECAUTIONS AND LIMITATIONS

The main difficulty with heart-lung machines is they tend to damage red blood cells and cause the blood to clot. To minimize these problems, the patient is given the anticoagulant drug heparin before the bypass is started. During operation of the machine, the supply of blood to the patient's vital organs is less efficient than normal. A patient can thus be kept on a heart-lung machine only for a few hours.

Heart-lung transplant

A radical procedure in which both the heart and lungs of a person are removed and replaced with organs from a donor who has been declared brain dead. (See illustrated box for how and why the operation is done.)

RISKS AND COMPLICATIONS

The early attempts at heart-lung transplant were unsuccessful. In the early 1980s the risk of donor organ rejection was reduced by the introduction of the drug cyclosporine. Some centers are now obtaining very good results. Nevertheless, the operation carries substantial risks. Problems may arise from airway obstruction and other lung complications (including *bronchiolitis*) in addition to the risks of organ rejection. Patients face the long-term problems associated with receiving any form of organ transplant (see *Transplant surgery*).

Heart rate

The rate at which the heart beats—that is, contracts to pump blood around the body.

Most people have a heart rate of between 60 and 100 beats per minute at rest. This rate remains fairly constant throughout life, although it tends to be faster in childhood and to slow slightly with age. Some athletes have a resting rate below 60 beats per minute. Their hearts are very well developed and can pump blood around the body as efficiently at a slow rate as the normal heart can pump it at a faster rate.

Exercise or stress causes an increase in heart rate. In either case, the increase is due to the release of the hormones epinephrine and norepinephrine by the adrenal glands and of norepinephrine by the sympathetic nerves around the sinoatrial node, the heart's own pacemaker. A small decrease in heart rate occurs during total relaxation and sleep.

Many people have a harmless irregularity of heart rhythm in which the rate is more rapid during breathing in than breathing out.

MEASURING HEART RATE

A physician uses one of two methods to measure heart rate and rhythm (the regularity of the beat). One is to feel the pulse (the expansion of an artery in response to contractions of the heart). The other method, which can be more accurate, is to listen with a stethoscope placed just below the left nipple (see *Heart sounds*).

An even more accurate record is provided by an *ECG* (electrocardiogram), which registers the pattern of electrical activity from the heart muscle that precedes each beat.

DISORDERS OF HEART RATE

A resting heart rate above 100 beats per minute is termed a *tachycardia* and a rate below 60 beats per minute a *bradycardia*. Tachycardias and bradycardias are considered abnormal when the cause is a condition affecting nerve conduction pathways through the heart or the activity of the sinoatrial node, rather than a response of the heart to exercise or relaxation. Irregularities may also occur in the rhythm of the heart's contractions. (See also *Arrhythmia, cardiac.*)

Heart sounds

The sounds made by the heart with each beat. The two main sounds can be heard simply by putting an ear to someone's chest. Classically, the sounds are said to sound like "lubb" followed by a higher-pitched "dupp." A pause follows each lubb-dupp. These sounds are caused by the slamming shut of the heart valves in each heart cycle, and are sometimes called the first and second heart sounds.

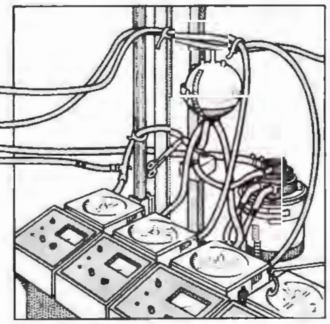
Using a stethoscope, a physician can hear the heart sounds much more clearly (and may sometimes hear

HEART-LUNG TRANSPLANT

In this procedure, both the heart and lungs of a patient are removed and replaced with organs taken from a brain-dead donor. The removed heart can sometimes be given to another patient.

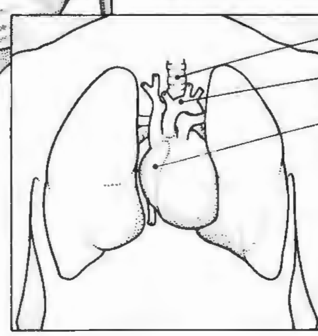
HOW IT IS DONE

Heart and lungs must be removed from both donor and patient; the donor organs then are inserted into the patient.

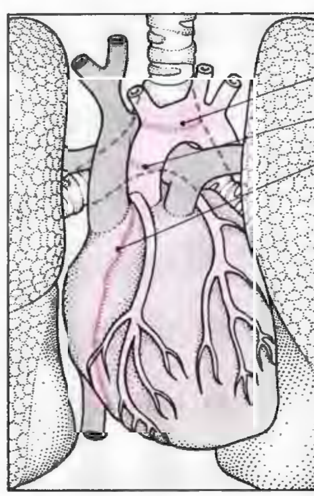


1 The donor heart and lungs must be healthy, and the lungs must match the size of the patient's chest, as measured by chest X rays.

2 In both donor and patient, the heart and lungs are reached via an incision made in the breastbone, and the chest is opened up.

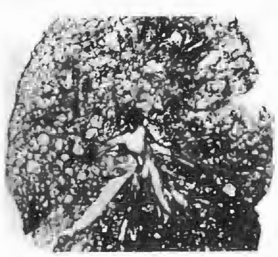


Site of incision



3 The patient is connected to a heart-lung machine. It takes over the function of heart and lungs, oxygenating blood taken from the venae cavae and pumping it back to the body via the aorta.

4 In both patient and donor, heart and lungs are removed through cuts in the trachea, aorta, and where the heart connects to the venae cavae. The blood vessels linking donor heart and lungs are left intact.



5 Insertion of the donor organs into the patient is, in some respects, easier than in the heart transplant, since fewer reconnections have to be made. The main reconnections are between the patient's and donor's tracheas and aortas and between the right atrium of the donor heart and the patient's venae cavae.

WHY IT IS DONE

Subject to availability of a donor, a heart-lung transplant can offer hope to someone who is dying of an end-stage chronic lung disease, whether or not he or she is also suffering from heart disease. Diseases treated include *emphysema*, *cystic fibrosis*, *sarcoidosis*, or *interstitial pulmonary fibrosis*. The heart-lung transplant operation has a better success record than that of lung transplant alone.

These sections were taken from a healthy lung (at left) and an emphysematous lung; transplanting of heart and lungs may give an emphysema patient new hope.

abnormal additional sounds or an abnormality of one of the two main sounds). Interpretation of these sounds can be important in the diagnosis of heart valve disorders and other heart abnormalities.

FIRST AND SECOND SOUNDS

The first sound (lubb) results from the closure of the tricuspid and mitral valves at the exits from the upper chambers of the heart. This occurs when the ventricles (lower chambers) begin contracting to pump blood out of the heart. The second heart sound (dupp) is caused by closure of the pulmonary and aortic valves at the exits from the ventricles when they have finished contracting.

Through a stethoscope, the second heart sound is heard to consist of a double sound, especially in children and young adults. This is due to a slight time gap between the closure of the aortic and pulmonary valves, and is normal.

ADDITIONAL SOUNDS

In children and young adults, there is often a normal low-pitched third heart sound after the second sound. It is thought to be caused by vibration of muscle fibers in the ventricles as they begin to refill. In people over age 40, this sound is abnormal and a sign of heart failure.

A fourth sound, preceding the first sound and also low-pitched, is occasionally heard; it always indicates an abnormality of heart muscle. The sound is often present after a *myocardial infarction* (heart attack) or in someone with a *cardiomyopathy*.

An opening "snap" is an abnormal sound that may occur during opening of the mitral valve. It is high pitched, heard shortly after the second heart sound, may be accompanied by a presystolic *murmur*, and is associated with *mitral stenosis*.

Ejection sounds or "clicks" are high-pitched sounds caused by the abrupt halting of valve opening. They can occur in *hypertension* (high blood pressure) or in the heart valve defects *mitral valve prolapse*, *aortic stenosis*, or *pulmonary stenosis*.

Heart *murmurs* are abnormal sounds caused by turbulent blood flow. They may occur as a result of any of various heart valve defects or types of congenital heart disease.

Heart surgery

Any operation performed on the heart. Heart surgery was a rare and hazardous undertaking until the early 1950s, when an operation called mitral valvotomy, performed to correct a narrowed heart valve (by means of a finger passed into the beating heart to stretch open the tight valve), became a standard and successful procedure.

Such "closed" operations on the heart are still occasionally performed, but have largely been superseded in developed countries by *open heart surgery*, in which the heart beat is deliberately stopped and the heart opened to make repairs. Open heart surgery became possible through developments such as controlled surgical *hypothermia* (cooling of the patient before surgery) and the *heart-lung machine*, introduced in the middle 1950s. The machine allows the circulation of oxygenated blood to the brain and other tissues to be maintained with the heart stopped, considerably prolonging the time during which the surgeons can work.

Open heart surgery allows the treatment of many previously serious or fatal conditions, including most types of congenital *heart disease* (heart defects present at birth) and various disorders of the heart valves (see *Heart valve surgery*). *Coronary artery bypass* (for the treatment of obstructed arteries supplying the heart muscle) was first performed in 1967, and, within five years, was being done all over the world. In the same year, the first *heart transplant* was performed in South Africa; the results have since improved largely because of advances in preventing organ rejection.

Another significant development was the introduction in 1979 of balloon *angioplasty*. In this procedure, a fine catheter with an inflatable segment is carefully passed along a narrowed coronary artery and then inflated to stretch the constriction. The results are excellent and many lives have been saved because of it. Angioplasty balloons are also being used to open up narrowed heart valves.

Balloon angioplasty is not without risk; the vessel may fracture or the fatty plaque narrowing the vessel may rupture, permitting cholesterol-rich material to travel down the vessel, thus plugging it. The procedure is most safely performed at centers where facilities for emergency open heart surgery are available.

Experimental work using lasers to open up more stubborn narrowing in arteries is also being done.

Heart transplant

Replacement of a person's damaged or diseased heart by a healthy human heart taken from a donor in whom *brain death* has been certified.

HISTORY

Heart transplantation was first achieved in animals in 1959, but it was not until 1967 that Professor Christiaan Barnard in South Africa carried out the first human heart transplant. Early results were disappointing, with few patients surviving beyond a month or two, but, in 1969, the Stanford University team led by Professor Norman Shumway began its program, which, in 1984, showed that as many as 85 percent of patients could be expected to survive for at least a year after surgery.

WHY IT IS DONE

Heart transplantation is considered for the treatment of patients with progressive, irremediable heart disease, but who are otherwise in good health. Many such patients have advanced *coronary heart disease*; most of the others have *cardiomyopathy* (disease of the heart muscle). If the heart disorder is associated with lung disease, a *heart-lung transplant* may be performed.

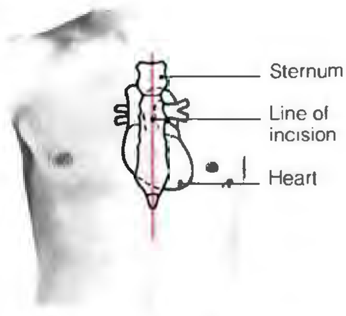
HOW IT IS DONE

Heart transplantation poses some special problems compared with the more common procedure of kidney transplantation. First, there can be a problem of timing. Whereas the condition of a patient with kidney failure can be maintained in health by *dialysis* until a donor kidney becomes available, there is no equivalent method for maintaining the condition of someone with a nonfunctioning heart for a prolonged period. Hence, heart transplantation is possible only when a suitable donor heart is available at the right time. Furthermore, heart transplantation has no "fall back" system; if the heart is rejected (attacked by the body's *immune system*), the only hope for the patient is another transplant.

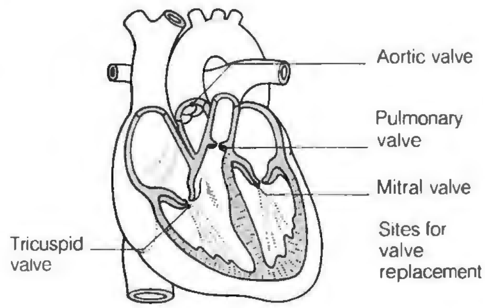
The mechanical, artificial heart is a possible solution to these problems, though in practice the best it seems able to offer is a temporary respite for a patient until the desperately needed new heart becomes available (see *Heart, artificial*).

A further limitation of heart transplantation is that the heart must be removed from the donor while it is still beating for the operation to have the best chance of success. One reason for the success of the Stanford heart transplant program was that California was the first state to allow physicians to certify death with the heart

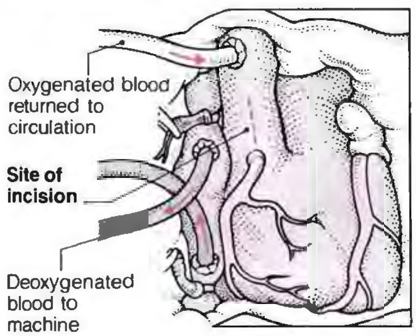
still beating (provided the brain was irreversibly destroyed by disease or accident). Certification of brain death in a patient connected to an artificial ventilator is now permitted in most developed countries, allowing the heart to be removed in optimum condition. The donor heart can then be chilled in saline at 40°F (4°C) and transported many miles by air before being implanted in the recipient.



The actual heart transplant operation is no more or less difficult than other major heart surgery. The first step is to connect the patient's major blood vessels to a *heart-lung machine*, which pumps oxygenated blood to the brain and other vital organs while the surgeon operates. Once the bypass is working, the surgeon removes the diseased heart, leaving the back walls of the atria (upper heart chambers) in place, and then inserts the donor heart, which is kept cooled in saline after its removal. The major blood vessels are reconnected and the new heart is ready to function. The nerves that help control the heart rate are severed during the procedure, but the heart functions without them.

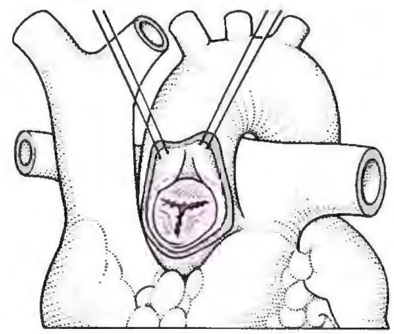


OUTLOOK

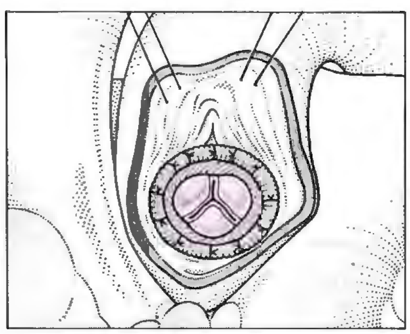


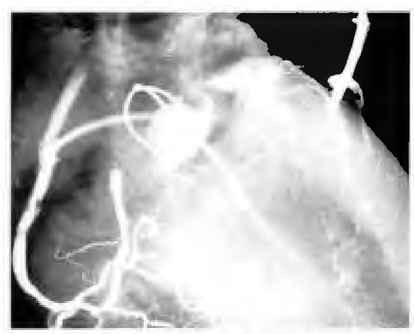
Once the immediate postoperative period is over, the outlook is good, with better than 80 percent of patients surviving the first year at certain centers; there is a death rate of around 5 percent per year thereafter. These results are much better than for the surgical treatment of lung or stomach cancer. The main problems are rejection (countered by *immunosuppressant drugs* such as cyclosporine, prednisone, and cyclophosphamide) and infection, which is always a hazard for people taking immunosuppressives, since these drugs weaken the body's natural defenses.

HEART VALVE REPLACEMENT



Any one of the four heart valves (aortic, pulmonary, mitral, or tricuspid) may require replacing (see diagram below right). Replacement of the aortic heart valve is described in the steps below.





1 In nearly all surgery on the heart valves, the incision into the chest cavity is made through the sternum (breastbone). The patient is put on a *heart-lung machine*, the beating of the heart is stopped, and the heart is opened.

2 The valve is first examined to determine whether it can be repaired or whether it requires replacement. If the latter is necessary (as here), the valve is excised (dotted line indicates where the incision is made).

3 A prosthesis is sutured into position and the aorta is closed. The patient is disconnected from the machine and the chest wall is sewn up. The operation takes between two and four hours.

Artificial heart valve in place
This chest X ray shows the metal components of an artificial heart valve. A ball-and-socket valve has been used to replace the patient's diseased valve.

Heart valve

A structure at the exit of a heart chamber that allows blood to flow out of the chamber, but which prevents backwash. There are four heart valves (one at the exit of each heart chamber). Their correct functioning is vital to the efficiency of the heart as a pump. (See *Heart* illustration.)

e opening and, more particularly, the closing of heart valves during the cycle of a heart beat are responsible for *heart sounds*.

DISORDERS

Any of the four heart valves may be affected either by stenosis (narrowing)—so that it takes more work for the heart to force blood through the valve—or by insufficiency or incompetence (inability to prevent backwash of blood). With these valve defects, characteristic murmurs are heard by the physician.

Valve defects may be present at birth, either alone or with other defects (see *Heart disease, congenital*), or may be acquired later in life. The most common congenital valve defects are *aortic stenosis* and *pulmonary stenosis*.

Acquired heart valve disease is usually the result of degenerative changes or ischemia (diminished blood supply) affecting part of the heart and leading to aortic stenosis or *mitral insufficiency*.

Rheumatic fever was once the main cause of *mitral stenosis* and insuffi-

ciency, aortic valve defects, and, less commonly, *tricuspid stenosis* and *tricuspid insufficiency*. Rheumatic fever is now rare in developed countries, but still prevalent in poorer countries.

Valves are also destroyed by bacterial *endocarditis*, seen often among intravenous drug users. Bacterial endocarditis is, however, a possible complication of any valve disorder.

The symptoms and signs of valve disorders vary, but generally they lead to *heart failure*, rhythm irregularities, or symptoms resulting from reduced blood supply to body tissues.

Valve defects may be diagnosed by *auscultation* (listening to the heart sounds), *chest X ray*, *ECG*, *echocardiography*, *Doppler* echocardiography, and cardiac *catheterization*. They may be corrected by *heart valve surgery*.

Heart valve surgery

An operation to correct a *heart valve* defect or, in many cases, to remove the diseased or damaged valve. The valve is replaced by a mechanical valve (made from metal and plastic), a valve fashioned from human or bovine tissue, a pig valve, or a human valve taken from a corpse.

WHY IT IS DONE

A heart valve may need to be corrected or replaced either because it is stenotic (narrowed) or insufficient (leaky). The mitral and aortic valves (on the left side of the heart) are the ones that most often need correction or replacement, followed by the tricuspid; pulmonary valve surgery is performed only rarely in adults.

In general, heart valve surgery is considered only when the potential effects of the malfunctioning valve on the heart and on general health are so severe that they will soon be a threat to the patient.

The timing of the operation is crucial; it is based on the patient's symptoms and on the results of tests (such as *ECG*, *chest X rays*, *echocardiography*, and cardiac *catheterization*).

HOW IT IS DONE

The illustration on the previous page shows how an aortic valve is replaced.

Valvuloplasty, a new technique, uses a balloon catheter that is inserted into the circulatory system through the skin without opening the chest. It can be used in the treatment of some cases of stenotic valves.

RECOVERY AND OUTLOOK

After the operation, the patient is usually kept in an intensive-care unit for 24 hours, followed by a few days in the hospital. However, a longer hospital stay may result if complications develop or if the patient had been suffering from severe heart failure before the operation.

Symptoms such as breathlessness may take many weeks to improve and may require continuing medication to maintain the improvement. Some people (those with a mechanical replacement valve and those with heart rhythm abnormalities, for example) require long-term treatment

TYPES OF REPLACEMENT HEART VALVES

The three main types

There are three main types of replacement valve—biological, mechanical, and homograft. Biological valves are taken from pigs or made from bovine tissue or the patient's own tissue; examples include the Carpentier-Edwards and Ionescu-Shiley valves. Mechanical valves are made from metal, plastic, and carbon fiber. There are two main types—ball-and-cage valves (such as the Starr-Edwards valve) and those with one or more tilting disks (such as the Bjork-Shiley and St. Jude valves). Homografts are human valves that have been removed from people who have died of a disease that does not affect the heart.

	Biological	Mechanical	Homograft
Examples	Carpentier-Edwards; Ionescu-Shiley	Starr-Edwards (ball-and-cage); Bjork-Shiley (tilting disk); St. Jude (two tilting disks)	Taken from cadaver
Availability	Readily available	Readily available	Some centers only
Ease of insertion	Routine	Routine	Specialized
Suitable age group	Over 35	All ages	All ages
Duration	About seven years	More than 12 years	More than 12 years
Postoperative drug therapy	Short-term anticoagulants	Lifelong anticoagulants	None necessary
Possible complications	Infection; stroke; damage to blood cells	Infection; stroke; calcification	Infection; calcification

with anticoagulant drugs. This treatment prevents blood clots from forming around the new valve, prevents them from becoming detached, and prevents them from being carried to the brain or other organs. All patients need long-term follow-up examinations to ensure that the corrected or replaced valve is working well. In addition, most need to take antibiotics before any dental and certain other operative procedures to reduce the risk of the valve becoming infected.

Most heart valve surgery is successful; the death rate is low and is continuing to decline. If a replacement valve malfunctions, it is often possible to insert a new one.

FIRST AID: HEAT EXHAUSTION

1 Offer plenty of saltwater to drink (about 0.25 teaspoon to a glass) and seek medical help immediately.

2 Lay the victim down in a cool place and raise the feet about 12 inches off the ground.

Heat cramps

Painful spasms in a muscle caused by excessive salt loss due to profuse sweating. Heat cramps are usually brought on by strenuous physical activity in extreme heat. The condition may occur by itself or as a symptom of *heat exhaustion* or *heat stroke*.

Treatment (and prevention) consists of the use of salt tablets or drinking enough of a weak salt solution (0.25 level teaspoon of salt to a pint of cold water) to keep the urine pale.

Heat disorders

The body functions most efficiently at a temperature of 98.6°F (37°C); any major deviation disrupts the body processes. Malfunctioning or overload of the body's mechanisms for keeping its temperature constant may lead to a heat disorder. For example, poor adaptation to heat may lead to *heat cramps*, *heat exhaustion*, or *heat stroke*; excessive environmental heat may result in *prickly heat*. In addition, excessive heat production by the body due to a very high fever-producing infection may be damaging.

HEAT REGULATION

The mechanisms by which the body loses unwanted heat to maintain the optimum internal temperature are controlled by the *hypothalamus* (part of the brain). When the hypothalamus is disrupted (for example, by drugs or a fever) the body may overheat progressively, which may lead to fatal heat stroke if emergency treatment is not given.

When the temperature of the blood rises, the hypothalamus sends nerve impulses to stimulate the sweat glands and dilate blood vessels in the skin. Sweating itself does not cool the body; the cooling effect is caused by the evaporation of sweat from the skin. However, excessive sweating can result in an imbalance of salts and fluids in the body, which can lead to heat cramps or heat exhaustion. Dilation of the blood vessels increases the blood flow near the surface of the skin, thereby increasing the amount of heat that is lost by convection and radiation.

ACCLIMATION

Most heat disorders can be prevented by gradual acclimation to hot conditions. Full acclimation takes one to three weeks. It involves spending gradually longer periods in the heat, alternating with rest periods in cool conditions. Strenuous exercise should be avoided. Frequent cool baths or showers should be taken and salt tablets or dilute salt solution used (0.25 level teaspoon of salt dissolved in a pint of cold water) to replace salt lost by sweating. It is also helpful to eat a light diet, avoid alcohol, and wear loose, lightweight clothes.

Heat exhaustion

Fatigue, sometimes culminating in collapse, caused by overexposure to heat. It is most common in people unaccustomed to working in a hot environment. Unless treated, heat exhaustion may develop into *heat stroke*, which is a life-threatening condition.

CAUSES

There are three principal causes of heat exhaustion—insufficient water intake, insufficient salt intake, and a deficiency in the production of sweat, the evaporation of which helps to cool the body (see *Heat disorders*).

SYMPTOMS AND SIGNS

Heat exhaustion causes fatigue, faintness, dizziness, nausea, restlessness, headache, and, when salt loss is heavy, *heat cramps* in the legs, arms, back, or abdomen. The skin is usually pale and clammy, breathing is fast and shallow, and the pulse is rapid and weak. There may also be vomiting, and the victim may faint.

TREATMENT

The victim should lie down in a cool place and, if conscious, should take 1 to 2 grams of sodium chloride (salt) tablets or continual sips of weak salt solution made up of 0.25 level teaspoon of salt to a pint of cold water. If the victim is unconscious, he or she should be placed in the *recovery position* until consciousness returns, when salt can be administered.

With rest and replacement of lost water and salt, a full recovery usually takes place. However, the victim should consult a physician because of the risk of heat stroke.

Heat stroke

A life-threatening condition in which overexposure to extreme heat and a consequent breakdown of the body's heat-regulating mechanisms cause the body to become overheated to a dangerous degree. In some cases, body temperature may reach 107°F (41.5°C) or more. Without emergency treatment, the victim lapses into a coma and death soon follows.

CAUSES

Heat stroke is most commonly brought on by prolonged, unaccustomed exposure to the sun in a hot climate. It is more likely to occur in humid conditions, which reduce the body's ability to cool itself by the evaporation of sweat.

Heat stroke can also be caused by working in an extremely hot environment or, very rarely, by a severe fever. Susceptibility is greater in those with a disorder of the skin or sweat glands, those taking *anticholinergic drugs* (which reduce sweating), and in older people in poor health. Overstrenuous

FIRST AID: HEAT STROKE

1 Move the victim to a cool, shady place and remove clothing. Place him or her in a half-sitting position and support the head and shoulders (for example, using pillows).

2 Cover the victim with a wet sheet and keep it wet. Fan him or her with a magazine or use an electric fan until the temperature drops to 101°F. Seek medical help immediately.

activity, unsuitable clothing, overeating, and drinking too much alcohol are sometimes contributory factors.

SYMPTOMS AND SIGNS

Heat stroke is often preceded by *heat exhaustion*, with fatigue, weakness, faintness, and profuse sweating. However, with the onset of heat stroke itself, sweating diminishes markedly and often stops completely. The skin becomes hot, dry, and flushed, breathing is shallow, and the pulse is rapid and weak. As the condition progresses, body temperature rises dramatically, and, without treatment, the victim may quickly lose consciousness and die.

TREATMENT

Emergency medical help should be summoned as soon as possible. The victim should be wrapped naked in a cold, wet sheet; the material should be kept continuously wet. Alternatively, the victim should be constantly sponged with cold water. Cooling should be increased by fanning. If the victim is unconscious, he or she should be placed in the *recovery position* while being cooled.

The above treatment should be continued until the victim's rectal temperature falls to 101°F (38.3°C) or until the body feels cool to the touch. If the victim is conscious, he or she may be given sodium chloride (salt) tablets or a weak salt solution to sip (0.25 level teaspoon of salt dissolved in a pint of water).

If heat stroke is treated early, the victim usually recovers fully.

PREVENTION

The key to preventing heat stroke is acclimation (see *Heat disorders*).

Heat treatment

The use of heat to treat disease or aid recovery from injury.

Moist heat may be administered by soaking the affected part in a warm bath or by applying a hot *compress* or *poultice*. Dry heat may take the form of a heating pad, hot-water bottle, or heat lamp that produces *infrared* rays. More precise methods of administering heat to tissues deeper in the body include *ultrasound treatment* and shortwave *diathermy*.

WHY IT IS USED

Heat is used to aid recovery from injury, such as a muscle tear or ligament sprain; by stimulating blood flow, it is thought to help tissues heal more rapidly. Heat is also useful in relieving pain and stiffness in joints and muscles caused by excessive exercise or by rheumatic disorders, such as osteoarthritis. A hot compress is effective in encouraging the formation and drainage of pus from skin infections.

To avoid the risk of internal bleeding and swelling, heat usually should not be used within 48 hours after an injury. This allows time for the blood vessels to heal.

Heel

The part of the foot below the ankle and behind the arch. The heel consists of the *calcaneus* (heel bone), an underlying pad of fat (which acts as a protective cushion), and a layer of skin that usually has thickened (especially on the ball of the heel) as a result of pressure from walking.

Heimlich maneuver

A first-aid treatment for *choking*.

Heliotherapy

Treatment by exposure to sunlight; a form of *phototherapy*.

Helminth infestation

An infestation by any species of parasitic worm (see *Worm infestation*).

Hem-

A prefix indicating blood, as in *hemoglobin* (an important protein in red blood cells).

Hemangioblastoma

A rare type of brain tumor that consists of blood-vessel cells. It usually develops in the form of cysts in the *cerebellum* and affects mainly children and young adults. The principal symptoms include headache, vomiting, *ataxia* (incoordination), and *nystagmus* (rapid, involuntary eye movements).

The tumor, which is slow-growing, is normally clearly differentiated from the surrounding brain tissue so it can usually be removed surgically. In most cases, such treatment completely cures the condition.

Hemangioma

A red-purple birthmark caused by an abnormal distribution of blood vessels in the skin.

TYPES

There are two types of hemangioma—flat and raised. Large, flat, purple-red marks are known as port-wine stains. They are permanent and can be unsightly. In rare cases, they are associated with abnormalities in the blood vessels of the brain (see *Sturge-Weber syndrome*). Small, flat marks are common in newborn babies, particularly on the back of the neck (where they are called stork bites); they fade about three weeks after birth.

Raised marks may be bright red and protuberant (when they are known as strawberry marks) or may be tinged with blue, caused by the presence of blood from a vein. They usually enlarge rapidly for the first few weeks after birth. After the age of about 6 months, the redness gradually fades and the lump subsides. By the age of about 7 years, the mark may have disappeared altogether.

COMPLICATIONS AND TREATMENT

Hemangiomas do not usually require treatment unless they are causing a particular problem. If a hemangioma starts to bleed, medical advice should be sought; meanwhile, the bleeding can be controlled by firm pressure with a clean handkerchief.

A hemangioma that bleeds persistently may require removal, especially if it is on the lip or tongue, where it may easily be bitten, or if it is on the vulva (external female genitalia) or anus, where it is subject to repeated pressure. It may also be necessary to remove a hemangioma from the eyelid because it interferes with vision and threatens blindness in the affected eye. A hemangioma on the face may need to be removed if it is causing psychological distress.

Removal is carried out by *laser treatment* (most successful in young people), *cryosurgery* (destroying tissue by extreme cold), or plastic surgery. If removal is not possible, the marks can be disguised with cosmetics.

Hemarthrosis

Bleeding into a joint, causing the capsule that encloses the joint to swell.

CAUSES

Hemarthrosis is usually the result of severe damage to a joint, such as a torn capsule, torn ligaments, or fracture of a bone forming part of the joint. The most common cause is a sports injury to the knee.

A rarer cause is a *bleeding disorder*, such as *hemophilia* (in which failure of the blood-clotting mechanism causes all bleeding to persist). Any joint may be affected and bleeding into the joint may occur spontaneously or be caused by even the slightest knock. Overuse of *anticoagulant drugs* can cause hemarthrosis.

SYMPTOMS AND SIGNS

Hemarthrosis causes a joint to swell immediately after injury; swelling that occurs 12 to 24 hours later is probably caused by *synovitis* (inflammation of the lining of the joint). In addition to swelling and pain, hemarthrosis may cause the joint to stiffen into a fixed position as a result of spasm in surrounding muscles.

DIAGNOSIS AND TREATMENT

As a first-aid measure, *ice packs* may be used to reduce swelling and pain. After a sports injury, *aspiration* (withdrawing fluid from the joint through a needle) is used to diagnose the condition and to relieve pain; X rays may be necessary if fracture is suspected. Hemophiliacs are given *factor VIII* to promote blood clotting.

To prevent further bleeding, the physician will bandage the joint and advise resting it in an elevated position; cells in the joint capsule gradually absorb any remaining blood. Surgery (such as *ligament* repair) is sometimes necessary.

Repeated hemarthrosis may damage the surfaces of the joint, causing *osteoarthritis* (characterized by persistent pain and stiffness).

Hematemesis

The medical term for *vomiting blood*.

Hematologist

A physician who specializes in diagnosing and treating disorders of the *blood* and blood-forming organs.

Hematology

The study of *blood* and disorders of the blood. Measurements of blood constituents are used in the diagnosis of a wide range of disorders, not only those of the blood. Microscopic examination and the counting of blood and bone marrow cells are essential procedures in diagnosing different types of blood disorders, such as *anemia* or *leukemia*.

Hematoma

A localized collection of blood (usually clotted) caused by bleeding from a ruptured blood vessel. A hematoma may occur almost anywhere in the body and, depending on the site and amount of accumulated blood, may vary in seriousness from a minor to a potentially fatal disorder.

TYPES

Less serious types include subungual hematoma (under a fingernail or toenail), hematoma auris (in the tissues of the outer ear, better known as *cauliflower ear*), and perianal hematoma (under the skin around the anus). The accumulated blood presses on the surrounding tissues, which may cause considerable pain. In such cases, a physician may lance and drain the hematoma to relieve the pressure and alleviate the pain. Most hematomas disappear on their own within a few days.

Among the more serious types are those that press on the brain, notably extradural and subdural hematomas (see *Extradural hemorrhage*; *Subdural hemorrhage*). They usually are due to an injury that ruptures a blood vessel just under the skull and may be fatal unless treated promptly. (See also *Intracerebral hemorrhage*.)

Hematoma auris

The medical term for *cauliflower ear*.

Hematuria

Red blood cells in the urine. Blood in the urine may be readily visible or small amounts may give the urine a smoky appearance. However, sometimes the blood is not visible to the naked eye. Hematuria can be caused by blood entering the urine at any point along the urinary tract, from the kidney to the urethral opening.

CAUSES

Almost any disorder of the urinary tract can cause hematuria. Infection (including *cystitis*, *urethritis*, and *pyelonephritis*) is one of the most common causes; *prostatitis* often causes hematuria in men. Cysts, tumors, and kidney or bladder stones may cause blood in the sufferer's urine, as can *glomerulonephritis*, in which the glomeruli (the filtering units of the kidney) become inflamed. *Bleeding disorders* may also cause hematuria.

INVESTIGATION

If the blood is not visible to the naked eye, it may be discovered during a urine test when the urinary sediment is examined under the microscope. Urine dip sticks have a small patch that is impregnated with a dye at one end; when dipped in urine containing blood, the patch turns blue.

To determine the cause of blood in the urine, it may be necessary to obtain images of the urinary tract by *ultrasound scanning*, *CT scanning*, or intravenous *pyelography*. These tests usually detect conditions such as cysts, stones, and tumors. If bladder disease is thought to be the cause, a *cystoscopy* (direct examination of the bladder through a viewing tube passed through the urethra) is performed. If a kidney tumor seems likely, *angiography* may be performed to show the blood vessels of the affected kidney.

Hemianopia

Loss of one half of the field of vision in each eye. Hemianopia may be homonymous (affecting the same side of each eye) or heteronymous (affecting opposite sides of each eye). In either case the visual loss may be temporary or permanent.

Hemianopia is not caused by any disorder of the eyes themselves; it is caused by damage to the nerve tracts or brain. Transient homonymous hemianopia in young people is usually caused by *migraine*. In older people it occurs in *transient ischemic attacks* (symptoms of *stroke* lasting less than 24 hours). Permanent homonymous hemianopia is usually caused by stroke, but may be caused by damage to the back of the brain from tumor, injury, or infection. Hemianopia may also be caused by a

H

tumor of the pituitary gland pressing on the optic nerve. In this case, the outer half of the field of vision in each eye is lost.

Hemiballismus

Irregular, uncontrollable, flinging movements of the arm and leg on one side of the body, caused by disease of the *basal ganglia* (part of the brain). The movements are unpredictable in timing and strength, and may be so severe that they cause injury to the afflicted person or others. (See also *Athetosis; Chorea.*)

Hemicolectomy

Surgical removal of half or a major portion of the *colon*. The surgeon may remove either the portion between the beginning of the colon and a point two thirds of the way across the transverse colon, or the portion between this point of the colon and the end, including (or excluding) the rectum. (See also *Colectomy*.)

Hemiparesis

Muscular weakness or partial paralysis affecting one side of the body only. (See *Paralysis*.)

Hemiplegia

Paralysis or weakness in the arm, leg, trunk, and sometimes the face on one side of the body only. One or more sites may be involved at the same time. When the affected muscles are stiff, the disorder is known as spastic hemiplegia; when the muscles are limp and wasted, the term flaccid hemiplegia is used.

CAUSES AND SYMPTOMS

A common cause of hemiplegia is a *stroke* (associated with *hypertension* or *diabetes mellitus*). Others are *head injuries, brain tumor, brain hemorrhage, encephalitis* (inflammation of the brain), *multiple sclerosis*, complications of *meningitis*, or a *conversion disorder* (a type of psychological illness).

TREATMENT AND OUTLOOK

Treatment is directed at the underlying cause and is carried out in conjunction with *physical therapy* to exercise the unused muscles. The prospects for a person with hemiplegia depend on how successfully the underlying cause can be treated and on how motivated the person is to recover.

Hemochromatosis

An inherited disease (also known as "bronze diabetes") in which too much dietary iron is absorbed. Over the years the excess iron accumulates in the liver, pancreas, heart, testes, and, to a lesser extent, in other organs.

CAUSES

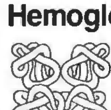
The disease is confined almost entirely to men. Women are very rarely affected because they regularly lose iron in their menstrual blood. Although the disease is known to be genetic in origin, the exact mode of inheritance is unclear. Male relatives of an affected person are at risk.

SYMPTOMS, COMPLICATIONS, AND DIAGNOSIS

Hemochromatosis rarely causes problems until middle age. A loss of sexual drive and a reduction in the size of the testes are often the first signs. Eventually the iron overload causes liver enlargement and *cirrhosis* (chronic liver damage), deficient insulin production by the pancreas leading to *diabetes mellitus*, bronzed skin coloration due to iron pigment deposition under the skin (hence the alternative name), cardiac *arrhythmia* and other heart disorders, and, during the late stages of the disease, *liver failure* and *liver cancer*.

The diagnosis is based on *blood tests* that reveal a high level of iron in the blood and a *liver biopsy* (removal of a small sample of tissue for analysis).

TREATMENT

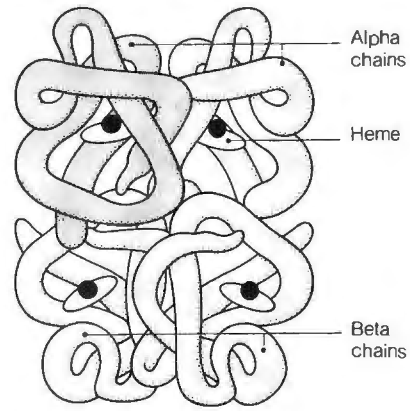


The disease is treated by *venesection* (removing blood) in the same way that blood is removed during blood donation. Initially, venesection is performed once or twice a week. Once the iron level has returned to normal, the procedure is required only three or four times a year.

For young men, treatment can prevent the development of complications; for those who have the fully developed disease, regular venesection can prolong life. *Chelating agents* (such as deferoxamine) have been investigated as an alternative to venesection. (See also *Hemosiderosis*.)

Hemodialysis

One of the two means of *dialysis* (purification of the blood by means of blood filtration to treat *renal failure*).



Hemoglobin

The oxygen-carrying pigment found in red blood cells. Hemoglobin binds with oxygen to form oxyhemoglobin, a compound that gives oxygenated blood its bright red color. There are 350 million hemoglobin molecules in the average blood cell, and each can carry four molecules of oxygen.

STRUCTURE

Hemoglobin is a large molecule made in the bone marrow from two components, heme and globin.

Structure of hemoglobin
Each molecule contains four globin chains—two alpha and two beta. Each chain carries a heme component capable of binding oxygen.

The composition of the globin chains can vary, giving rise to several different normal and abnormal forms of hemoglobin. Hemoglobin F is the normal form in fetal life and infancy. It is replaced by the normal adult forms, hemoglobin A and A_2.

FUNCTION

The principal function of hemoglobin is to combine with and transport oxygen from the lungs and deliver it to all body tissues, where it is required to provide energy for the chemical reactions of all living cells. Carbon dioxide, which is produced as the waste product of these reactions, is transported to the lungs for excretion during breathing out.

Defects in hemoglobin production may be either genetic in origin (for example, *sickle cell anemia*) or acquired (see *Anemia, iron-deficiency; Anemia, megaloblastic*). The genetic defects are subdivided into errors of heme production known as *porphyria* and those of globin production known collectively as the *hemoglobinopathies*.

Hemoglobinopathy

A term used to describe a variety of genetic (inherited) disorders in which there are errors in the production of globin chains (one of the main components of *hemoglobin*, the oxygen-carrying substance in the blood).

There are two primary categories of hemoglobinopathy. In the first category, abnormal globin chains are produced, giving rise to abnormal hemoglobin molecules. This is the underlying defect in *sickle cell anemia*.

In the second category, normal globin chains are produced in abnormal amounts (known as the *thalassemias*). Combined forms also occur.

The hemoglobinopathies cause anemia and chronic sickness in millions of people in Asia, Africa, and the Caribbean, and in many blacks and Hispanics in the US.

Hemoglobinuria

The presence of hemoglobin in the urine. *Hemoglobin* (the oxygen-carrying pigment in the blood) is mainly contained within red blood cells, although a small amount is free in plasma. Excessive *hemolysis* (breakdown of red cells), which may be caused by heavy exercise, cold weather, falciparum *malaria* (blackwater fever), and hemolytic *anemia*, increases the concentration of hemoglobin in the plasma.

Hemolysis

The destruction of red blood cells, a process that releases iron (which is repackaged into new red cells), bilirubin (which is excreted by the liver in bile), and other breakdown products of the red cell.

Hemolysis is usually a normal process, occurring when red cells age and lose their elasticity; it takes place mainly in the spleen. When red cells are destroyed prematurely, the hemolysis is considered abnormal and may cause anemia and jaundice (see *Anemia, hemolytic*).

Hemolytic anemia

See *Anemia, hemolytic*.

Hemolytic disease of the newborn

Excessive destruction of red blood cells (hemolysis) in the fetus and newborn infant by antibodies produced by the mother. Hemolytic disease of the newborn is typically caused by *Rh incompatibility* factor (a blood group incompatibility between mother and baby, named after the Rhesus monkey in which the Rh factor was discovered), although a milder form of the disease may result from ABO and more rare blood group incompatibilities.

CAUSE

Hemolytic disease may occur if the woman's blood is Rh negative, if she is carrying a baby whose blood is Rh positive, and if she has previously had a baby whose blood was Rh positive. A previous miscarriage, elective abortion, or *amniocentesis* in which the fetus's blood was Rh positive can also sensitize the woman. In each of these situations, blood has passed at some stage from the fetus to the woman. This causes the woman to produce Rh antibodies (directed against the Rh-positive blood cells) because her *immune system* recognizes the fetal blood cells as "foreign." The Rh antibodies have not formed sufficiently to harm the first baby, but, during a subsequent pregnancy, they cross the placenta and attack the fetal blood cells. A mismatched *blood transfusion* (giving Rh-positive blood to a woman who is Rh negative) also sensitizes the woman so that she produces Rh antibodies.

DIAGNOSIS

All pregnant women have their blood groups tested at the first prenatal check. Rh-negative women are tested for Rh antibodies at this visit and again at 32 and 38 weeks' gestation. They are tested more frequently if there has been a previous pregnancy.

If the pregnant woman shows rising levels of Rh antibodies, amniocentesis is performed at intervals to measure *bilirubin* levels in the *amniotic fluid*. Bilirubin is a breakdown product of red blood cells, so the bilirubin level indicates the severity of blood cell destruction in the fetus.

SYMPTOMS AND SIGNS

In mild cases, the newborn baby becomes mildly jaundiced during the first 24 hours of life (due to excess bilirubin in the blood) and slightly anemic. In more severe cases, the blood level of bilirubin may increase to a dangerous level, risking a form of brain damage known as *kernicterus*. The most severely affected babies have marked anemia in the uterus, become very swollen (hydrops fetalis), and are often stillborn.

TREATMENT

If the condition is very mild, no treatment is required. In other cases, the aim is to deliver the baby before anemia becomes very severe. This usually means *induction of labor* between 35 and 39 weeks' gestation. If the baby is severely affected before he or she is mature enough to be delivered safely (about 30 weeks' gestation), fetal blood transfusions may be necessary. Rh-negative blood is injected into the fetal abdominal cavity at 30 to 32 weeks' gestation, with the procedure being monitored by *ultrasound scanning*.

After the baby is born, frequent blood tests are performed to assess jaundice and anemia. *Phototherapy* (light treatment that breaks down bilirubin in the skin) and plenty of fluids help reduce the jaundice. However, if the bilirubin level becomes dangerously high, exchange transfusion is performed (blood is removed from the baby and replaced by Rh-negative blood).

PREVENTION AND OUTLOOK

The disorder is far less common since the introduction and use of *$Rh_0(D)$ immune globulin* (anti-D serum) in the early 1970s. It is given by injection to any Rh-negative woman within 72 hours of childbirth, miscarriage, or elective abortion, destroying Rh-positive blood cells from the fetus before they have had time to sensitize the woman's immune system.

Improved general obstetric and pediatric care have also resulted in a reduction in the severity of the cases that still occur.

Hemolytic-uremic syndrome

A rare disease in which red blood cells are destroyed prematurely and the kidneys are severely damaged, causing *renal failure*. Hemolytic-uremic syndrome occurs mostly in infants and young children.

CAUSES

The precise cause of the disorder is unknown. It is thought that the lining of small blood vessels in the kidneys becomes damaged, causing small clots to form. These clots cause *hemolysis* (breakdown of red cells) as blood flows past them, leading to anemia. The resultant damage to the kidneys causes them to fail; this often occurs in epidemics and appears to be triggered by a bacterial or viral infection.

SYMPTOMS AND SIGNS

The onset of the disease is sudden, with headache, fatigue, shortness of breath, and sometimes jaundice. Little urine is passed and what is passed may contain blood. Severe *hypertension* (high blood pressure) is common and may cause *seizures*.

DIAGNOSIS AND TREATMENT

Blood and urine tests are performed to determine the degree of kidney damage. *Dialysis* (artificial removal of waste products from the blood) is necessary until the kidneys have recovered. *Antihypertensive drugs* are given to lower the blood pressure and transfusions of red blood cells may be given to control the anemia. In severe cases, transfusion of plasma (the fluid in which blood cells are suspended) may be required to prevent continual blood clotting and red cell breakdown. Most children make a full recovery.

Hemophilia

An inherited *bleeding disorder* caused by a deficiency of a particular blood protein. Hemophiliacs (who are almost exclusively male) suffer recurrent bleeding, most often into their joints. Bleeding may occur spontaneously and/or after injury. In recent years, the problems of hemophiliacs have been compounded by the very high incidence of *AIDS* among their numbers as a direct result of the treatment of their condition.

INCIDENCE AND CAUSES

About one male in 10,000 is born with hemophilia. The blood protein lacking is called *factor VIII*; it is one of a series of proteins essential to the process of *blood clotting*.

The lack of factor VIII is due to a defective gene, which shows a sex-linked pattern of inheritance (see *Genetic disorders*). Affected males pass the defective gene on to none of their sons but to all of their daughters, who are carriers of the condition. Some of the sons of carrier females may be affected, and some of the daughters of carriers may themselves be carriers. Many hemophiliacs have an uncle, brother, or grandfather who is affected, but, in about one third of the cases, there is no family history.

SYMPTOMS

The severity of the disorder varies markedly among affected individuals. Hemorrhage into joints and muscles makes up the majority of the bleeding episodes. The episodes often start when an affected child reaches weight-bearing age as a toddler. The bleeding episodes are painful and, unless treated promptly, can lead to crippling deformities of the knees, ankles, and joints.

Injury and even minor operations such as tooth extraction may lead to profuse bleeding. Internal bleeding can give rise to symptoms such as *hematuria* (blood in the urine) or extensive bruises.

DIAGNOSIS AND TREATMENT

Hemophilia is diagnosed by *blood-clotting tests* that reveal factor VIII activity is abnormally low.

Fifty years ago, most hemophiliacs did not survive to adulthood; today, bleeding episodes can be controlled by infusions of concentrates of factor VIII. Infusions must be given as soon as possible after the start of bleeding. Alternatively, the person can take regular doses of factor VIII as a preventive treatment. Patients can be trained to administer the treatment themselves. However, for more serious or unusual bleeding, the patient may require hospitalization.

Although the use of factor VIII concentrates has considerably improved the quality of life for many hemophiliacs, in recent years problems have arisen because of the AIDS virus. Factor VIII must be made from large pools of donor blood (2,000 to 5,000 individual donations). During the first few years of the AIDS epidemic (before its cause was recognized) large numbers of hemophiliacs became infected with HIV (the virus responsible for AIDS) through factor VIII infusions. Consequently, a percentage of hemophiliacs (and their sexual partners) have been exposed to the virus and some have died of AIDS.

Blood donations are now screened for evidence of the AIDS virus to prevent transmission of the virus by transfusion. Work is also under way to produce a genetically engineered factor VIII, which would prevent all problems of blood-borne transmission for hemophiliacs.

OUTLOOK

A child with hemophilia should avoid activities that expose him or her to a risk of injury, including contact sports such as judo and football; activities such as swimming and walking should be encouraged.

Hemophiliacs who test positive for the HIV antibody should take the usual precautions against transmitting the virus (see *AIDS*) and are advised not to have children.

Hemophiliacs who do not test positive for the HIV antibody (as well as the female relatives of hemophiliacs) should obtain *genetic counseling* before starting a family to discuss concerns about children or grandchildren being affected. Any female relative is a possible carrier of the condition; carrier status can now be ascertained with high accuracy by means of a blood test. The diagnosis can sometimes be determined prenatally.

Hemoptysis

The medical term for *coughing up blood*.

Hemorrhage

The medical term for *bleeding*.

Hemorrhoidectomy

The surgical removal of hemorrhoids.

WHY IT IS DONE

Hemorrhoidectomy is carried out if other, simpler methods of treatment (see *Hemorrhoids*) fail to resolve the problem. The procedure therefore tends to be reserved for people who have large, prolapsing, bleeding hemorrhoids.

HOW IT IS DONE

Stages in a hemorrhoidectomy are shown in the illustrated box.

RECOVERY PERIOD

Laxatives such as mineral oil are given after the operation to soften the stools and make them easier to pass. Non-narcotic analgesics (painkillers) and warm baths ease discomfort. Complete healing occurs after three to six weeks. Avoidance of constipation can frequently prevent recurrences.

COMPLICATIONS

Bleeding is a possible complication. There may be a slight loss of sensation in the anal area that may impair the ability to control release of gas.

Hemorrhoids

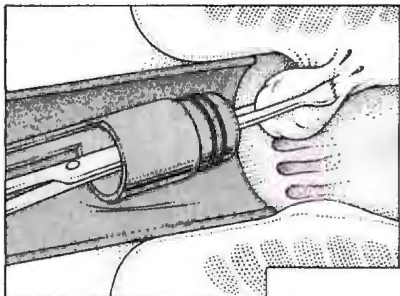
Distended veins in the lining of the anus. Hemorrhoids may be near the beginning of the anal canal (internal hemorrhoids) or at the anal opening (external hemorrhoids). Hemorrhoids sometimes protrude outside the anus (prolapsing hemorrhoids).

CAUSES AND INCIDENCE

Hemorrhoids are very common, particularly during pregnancy and immediately after childbirth. Some people have a congenital weakness of the veins in the anus that makes them more likely to develop hemorrhoids. Hemorrhoids occur because of increased pressure in the veins of the anus, usually due to straining during attempts to move hard feces that are difficult to pass. Modern diets consisting of too many highly refined foods fail to provide enough fiber and bulk, which is what produces normal stools.

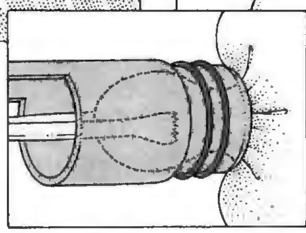
SYMPTOMS

Rectal bleeding and increasing discomfort, even pain, on defecation are the most common features. Prolapsed hemorrhoids often produce a mucous discharge and itching around the anal opening. A complication of prolapse is thrombosis and strangulation (in which a clot forms in the vein, the vein does not spring back into position in the anus, and its blood supply is reduced); this can cause extreme pain. Iron deficiency *anemia* may result from prolonged bleeding.



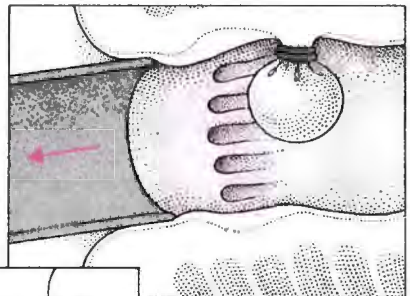
DIAGNOSIS AND TREATMENT

Proctoscopy (examination of the rectum through a viewing tube) is usually performed to exclude cancer.



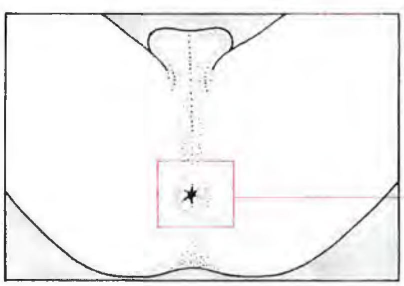
REMOVING HEMORRHOIDS

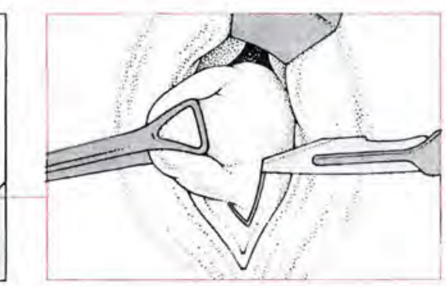
In both procedures shown below, the patient is first usually given a laxative so that the lower bowel is clear of feces. General or epidural anesthesia is given before a hemorrhoidectomy is performed.



BANDING HEMORRHOIDS

1 This common, simple, and effective procedure is usually painless (causing no more than a mild ache afterward) and no anesthesia is required. The patient lies on his or her side, the proctoscope is positioned and the hemorrhoid is grasped with the forceps.





2 Gentle traction is applied to draw the mass into the drum and the banding instrument is pressed into the anal wall.

3 The trigger mechanism of the banding instrument is fired and the bands are squeezed off onto the neck of the hemorrhoid. The proctoscope is withdrawn, leaving the hemorrhoid with its base tightly constricted by the bands. The hemorrhoid then withers and drops off painlessly.

HEMORRHOIDECTOMY

Using general or epidural anesthesia, the patient is examined with a proctosigmoidoscope to exclude a diagnosis of tumor. The patient is then placed in the *lithotomy position*. The hemorrhoid is clamped, placed under traction, secured with a suture, and then removed with a knife.

Mild cases are controlled by drinking fluids, eating a high-fiber diet, and having regular toilet habits. Rectal suppositories and creams containing *corticosteroid drugs* and local anesthetics help reduce swelling and pain.

Internal hemorrhoids can be treated during proctoscopy on an outpatient basis. If the hemorrhoids are very distended, tiny, tight rubber bands may be slipped onto the end of each vein, causing them to wither within a few days. Alternatively, *cryosurgery* may be used to shrink the veins.

Prolapsing hemorrhoids require a *hemorrhoidectomy*.

Hemosiderosis

A general increase in iron stores. It may occur after repeated blood transfusions or, more rarely, as a result of excessive ingestion of iron. Hemosiderosis does not usually cause organ dysfunction.

Hemospermia

The medical term for blood in the semen (see *Semen, blood in the*).

Hemostasis

The arrest of bleeding. There are three main natural mechanisms by which bleeding is stopped after injury. First, small blood vessels constrict when damaged, thus lessening the "gaps" through which blood can flow. Second, blood cells called platelets aggregate (clump) and plug the bleeding points. Third, the blood plasma coagulates, forming filaments of a substance called fibrin. These filaments enmesh blood cells at the bleeding points and contract to form a solid clot that seals the damaged blood vessel (see *Blood clotting*). Defects in any of the three natural mechanisms of hemostasis can cause a *bleeding disorder*. (See also *Bleeding, treatment of*.)

Hemostatic drugs

A group of drugs used in the treatment of *bleeding disorders*.

Preparations of coagulation factors are an important type of hemostatic drug. Coagulation factors are present naturally in the body to aid *blood clotting* but are deficient in certain disorders. Preparations of factor VIII, for example, are used to treat *hemophilia*; factor IX is used in the treatment of *Christmas disease*. The coagulation factor is injected after abnormal bleeding to allow clotting, or before surgery to reduce the risk of excessive bleeding.

Other commonly prescribed hemostatic drugs include *vitamin K* preparations (used to treat an overdose of certain *anticoagulant drugs*) and aminocaproic acid, which disrupts *fibrinolysis* (the body's mechanism for dissolving blood clots).

Hemostatic preparations of gelatin and cellulose may be applied to the skin or gums to stop bleeding (e.g., following tooth extraction).

Hemothorax

A collection of blood in the pleural cavity (the space between the chest wall and the lung). Hemothorax is most commonly caused by chest injury, but it may arise spontaneously in people with defects of blood coagulation or, occasionally, as the result of cancer.

Symptoms include pain in the affected side of the chest and the upper abdomen, breathlessness, and an increased pulse. If extensive, hemothorax may compress the lung and cause it to partially collapse. Blood in the pleural space tends to remain in a fluid state and can be drawn off by a needle.

Heparin

An *anticoagulant drug* used to prevent and treat abnormal *blood clotting*. Heparin is given by injection and is

particularly useful as an immediate treatment for deep-vein *thrombosis* or pulmonary *embolism*.

POSSIBLE ADVERSE EFFECTS

Bruising around the injection site is common. Other adverse effects include rash, aching bones, and abnormal bleeding in different parts of the body. Long-term use may cause *osteoporosis* (a bone disorder).

Hepatectomy, partial

Surgical removal of part of the liver. The liver has remarkable powers of regeneration; up to three quarters of the organ can be removed before it ceases to function.

WHY IT IS DONE

Severe injury to the liver sometimes occurs in automobile accidents, causing serious bleeding of and death to the damaged area. Treatment is to remove the dead tissue.

Benign liver tumors and sometimes *hydatid disease* require partial hepatectomy; rarely, *liver cancer* is also treated in this way.

Hepatectomy, total

Surgical removal of the liver. Hepatectomy is performed as the first stage in a *liver transplant* operation.

Hepatic

Related to the liver. For example, the hepatic vein is the vessel that drains blood from the liver.

Hepatitis

An inflammation of the liver, with accompanying liver cell damage or death, caused most frequently by viral infection, but also by certain drugs, chemicals, or poisons. Hepatitis may be either acute (of limited duration) or chronic (continuing).

ACUTE HEPATITIS

This form is a common condition, with about 20 to 30 cases per 100,000 population per year in the US. The most frequent cause is infection with a virus, such as viral hepatitis, type A or type B or non-A, non-B virus (see *Hepatitis, viral*). Other causes include overdose with drugs (such as acetaminophen), exposure to certain chemicals (such as dry-cleaning agents), or, rarely, a reaction to certain drugs in normal dosage. Acute hepatitis may also affect heavy drinkers who have progressive liver disease (see *Liver disease, alcoholic*).

SYMPTOMS

The most obvious sign of acute hepatitis is *jaundice*. In many cases, it is preceded by a flulike illness, accompanied by nausea, vomiting, loss of appetite, tenderness in the right upper abdomen, aching muscles, and sometimes joint pain.

In uncommon, severe cases, jaundice may be intense and *liver failure* may develop, with possible effects on other organs (including the brain), resulting in coma.

DIAGNOSIS AND TREATMENT

A physician may strongly suspect acute hepatitis from the symptoms alone, particularly if the patient is in a risk group for exposure to one of the causative viruses, chemicals, or drugs. *Ultrasound scanning* of the liver may help rule out bile duct obstruction (another cause of jaundice), and *liver function tests* can aid in diagnosis.

There is no specific treatment of acute hepatitis. However, if drug or chemical poisoning is suspected, the physician must determine the causative substance and stop the patient's exposure to it (for example, by withdrawing a drug). Sometimes, detoxification may be possible using an antidote to the substance. In all cases, rest and a nourishing diet are usually recommended; recovery usually occurs after a few weeks. Abstinence from alcohol after the illness aids in liver regeneration.

In severe cases leading to liver failure, intensive care is required. Acute hepatitis causes several hundred deaths in the US each year.

CHRONIC HEPATITIS

Occasionally, a person may fail to recover fully from an episode of acute hepatitis, leading to continued liver cell damage and inflammation. This occurs most commonly, but not exclusively, with certain types of viral hepatitis. Chronic hepatitis may also develop insidiously over a number of years without any acute episodes. Heavy alcohol consumption may again be responsible. In some cases the cause is an *autoimmune disorder* (in which the body's defenses attack its own tissues), a reaction to a medication, or a metabolic disorder affecting the liver.

Several types of chronic hepatitis are recognized, although generally they can be distinguished only by taking a *liver biopsy* (tissue sample) and looking at the liver cells under a microscope. In the type affecting heavy drinkers, damaged liver cells with areas of inflammation around them are scattered throughout the liver, and fat droplets can be seen within the cells. In another type, called chronic active hepatitis, there is obvious liver cell destruction and scarring that can lead to liver *cirrhosis* if untreated. In a third type, called chronic persistent hepatitis, there is a lesser degree of inflammation and little risk of progression to cirrhosis.

SYMPTOMS AND DIAGNOSIS

The symptoms of chronic hepatitis are usually no worse than a vague feeling of being sick. Often the disease remains undetected until the patient has a medical examination and the liver is found to be enlarged, a causative virus or specific antibody is found in the blood, or the results of *liver function tests* are abnormal. Liver biopsy helps the physician establish the type of chronic hepatitis.

TREATMENT

For hepatitis caused by alcohol consumption, total abstinence is the only cure. If strictly observed, it allows complete restoration of liver function. For chronic persistent hepatitis, treatment is not usually needed. For the chronic active form, therapy depends on the precise cause of the disease (see *Hepatitis, chronic active*).

Hepatitis A

See *Hepatitis, viral.*

Hepatitis B

See *Hepatitis, viral.*

Hepatitis, chronic active

A type of chronic *hepatitis* in which there is intense and progressive inflammation and destruction of cells surrounding certain structures within the liver. Scar tissue forms and leads to liver *cirrhosis*.

CAUSES

Chronic active hepatitis may be caused in any of four ways—as a result of an autoimmune reaction (immune system disturbance), a viral infection, a reaction to a medication (rare), or to a metabolic disorder (rare).

In the autoimmune type, antibodies (proteins with a defense role) that inappropriately attack liver cells are formed. This is the most common cause of hepatitis in Northern Europe and one of the most common causes in the US. Women are affected more often than men. Primary biliary cirrhosis may fall into this category.

Viral infection is the most common cause in the US, most often due to viral hepatitis, type B, or non-A, non-B virus (see *Hepatitis, viral*). Men are affected more often than women.

Medications are a rare cause of chronic active hepatitis. Drugs that have been implicated include

MAIN TYPES OF VIRAL HEPATITIS

	Viral hepatitis type A (infectious hepatitis)	Viral hepatitis type B (serum hepatitis)
Transmission of infection	Virus is present in feces of infected people and transmitted to others by fecal contamination of food (e.g., through infected people handling food). Feces are infective from two to three weeks before until eight days after onset of jaundice. Local epidemics can occur.	Virus is present in blood and other body fluids of infected people. In the US, virus is spread mainly sexually and by needle-sharing among drug abusers. Health workers are at risk from infected blood. In Africa and Asia, spread from mother to baby is common.
Incidence	Worldwide. In the US, about 40 percent of young adults have been exposed to the virus. In some parts of the world where hygiene is poor, almost everyone has been exposed to this type of hepatitis.	Worldwide. In parts of Africa and Asia, up to 20 percent of the population has been carrying the virus without symptoms for years. In the US, carrier rate is much lower (less than 1 percent).
Groups at particular risk	Travelers to areas where hygiene standards are poor and prevalence of the virus is high (i.e., parts of Asia, Africa, or South America).	Homosexuals, people with multiple sexual partners, intravenous drug abusers, health care personnel, or children born to carrier mothers.
Incubation period	Three to six weeks after virus has entered the body.	A few weeks to several months after infection.
Illness	In many cases there is no illness. Otherwise, typical acute hepatitis (flulike illness with jaundice), usually mild and never progressing to chronic hepatitis.	Typical acute hepatitis, often more severe than with type A virus. Progression to chronic hepatitis and other liver disease may occur. Sometimes, no illness.
Prevention	For nonimmune travelers at risk, passive immunization with immunoglobulin plus good hygiene and care in selection of food and drink. A vaccine has also recently been developed.	Observance of *"safe" sex* with possibly infected sexual partners and avoidance of blood exchange. Vaccine and/or passive immunization for groups at high risk.

oxyphenisatin, nitrofurantoin, and isoniazid. Metabolic disorders that may cause the disease include *hemochromatosis* and *Wilson's disease*.

SYMPTOMS, DIAGNOSIS, AND TREATMENT

The disease may cause vague feelings of tiredness, or no symptoms at all. It is diagnosed by *liver biopsy*.

The autoimmune type is treated with *corticosteroid drugs*, which usually bring some improvement. Antiviral agents have been tried unsuccessfully against viral infections. In the drug-induced type, withdrawal of the medication can lead to recovery. For metabolic disturbances, treatment depends on the underlying disorder.

Hepatitis, viral

Any type of *hepatitis* (inflammation of the liver) caused by a viral infection.

TYPES AND CAUSES

A number of viruses may secondarily infect the liver, but, for certain viruses, the liver is a primary target. These are called hepatotropic viruses and include hepatitis viruses type A, type B, and delta viruses. Tests are available for detecting any of these in the blood or tissues. Sometimes, a person has obvious symptoms of viral hepatitis, but the type A, type B, and delta viruses cannot be detected; in such cases the illness is called non-A, non-B hepatitis. A few viruses may cause this type, which is a common form among people who contract hepatitis from blood transfusions.

The different viruses have varying incidences in different parts of the world and different modes of transmission (see table).

Hepatitis, type A (formerly called infectious hepatitis), is thought to be spread by virus from an infected person's feces directly or indirectly contaminating food, drinking water, or someone else's fingers. In most parts of the world, a high proportion of the population has been infected with the virus, often without symptoms, and is immune to further attack. Many cases occur among travelers who have recently returned from an area where the virus is prevalent and standards of hygiene are low.

Viral hepatitis, type B, used to be spread mainly by blood transfusions and blood products (and was referred to as serum hepatitis), but the development of tests for the virus has removed this risk. Today hepatitis B is mainly sexually transmitted (being particularly common among male homosexuals) or spread by mechanisms in which an infected person's blood is inoculated into someone else (i.e., by needle sharing among drug abusers, razor sharing, or ear piercing). These are precisely the same mechanisms by which *HIV* (the virus responsible for *AIDS*) is spread.

Viral hepatitis, type B, is in many respects more serious than viral hepatitis, type A. In a proportion of cases, the virus persists for years after the initial infection and may lead to a chronic form of hepatitis (see *Hepatitis, chronic active*) and eventually to liver *cirrhosis* and/or *liver cancer*. Carriers of the virus may have few or no symptoms during this time, but can infect others. The non-A, non-B hepatitis virus is the cause of most transfusion-associated hepatitis cases.

Hepatitis delta virus can exist only in someone who is already carrying or has recently been infected with hepatitis, type B. In the US, it seems to be spread mainly by needle sharing among drug abusers.

SYMPTOMS, DIAGNOSIS, AND TREATMENT

Infection with any of the causative viruses may be symptomless or may cause a typical acute *hepatitis* with a flulike illness followed by jaundice. About 10 percent of patients infected with the hepatitis, type B; delta; or non-A, non-B viruses go on to acquire chronic hepatitis. This rarely, if ever, happens with hepatitis, type A.

H

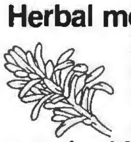
Diagnosis is made by identification of the virus (or by identification of antibodies to the virus) in the blood or, in the case of non-A, non-B hepatitis, by exclusion of the other types. Treatment is as for other causes of hepatitis.

PREVENTION

Vaccines are available against viral hepatitis, type B. However, vaccination is generally offered or recommended only to those who are at high risk of infection. For viral hepatitis, type B, it includes health care workers, children born to carrier mothers, male homosexuals, and drug addicts.

Passive immunization with immunoglobulins (antibodies) directed against viral hepatitis, type A and type B, is also available and can provide some protection. It is recommended for people who will be traveling to high incidence areas on vacation or on short business trips. Hepatitis, type B, immunoglobulin is also given immediately after birth to babies who had carrier mothers, to prevent infection while the vaccine (given at the same time) is beginning to build up.

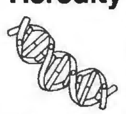
Avoidance of viral hepatitis, type A, is further helped by observing good hygiene, especially food hygiene, in parts of the world where sanitary standards are low (see *Food-borne infection*). The chances of getting viral hepatitis, type B, can be reduced through use of a condom, by not sharing needles, and by avoiding activities such as ear piercing or tattooing unless the equipment used is sterile. These precautions are broadly the same as for the avoidance of *AIDS*.



Hepatoma

The most common form of malignant tumor arising within the liver. (See *Liver cancer*.)

Hepatomegaly



Enlargement of the liver, which may occur as a result of virtually any type of liver disorder. Enlargement of the liver may cause tenderness just beneath the ribs and can be detected by a physician during the course of a physical examination. (See *Liver* disorders box.)

Herbal medicine

Systems of medicine in which various parts of different plants are used to treat symptoms and promote health. Herbal medicine was the most common medical treatment in most cultures for many centuries.

Heredity

The transmission of traits and/or disorders through genetic mechanisms. Each person inherits a combination of *genes* (units of inheritance)—half paternal, half maternal—via the sperm and egg cells from which he or she is derived. The interaction of these genes determines the person's inherited characteristics, including, in some cases, disorders or susceptibility to disorders. Half of an individual's genes are passed on, in turn, to each of his or her children. (See also *Genetic disorders; Inheritance*.)

Heritability

A measure of the extent to which a disease or disorder is the result of inherited (genetic) factors as opposed to environmental influences, such as diet and climate.

Certain disorders (such as *hemophilia* or *cystic fibrosis*) are known to be caused entirely by hereditary factors. Others (such as occupational disorders) are caused entirely by environmental factors. Between these two extremes lies a large number of disorders in which both inheritance and environment probably play a part.

Pinpointing hereditary factors is notoriously difficult. A rough estimate of heritability can be obtained from the known incidence of a disorder in the first-degree relatives (i.e., parents, siblings, and offspring) of affected people and by comparing it to the incidence in a population exposed to similar environmental influences. Other estimates of heritability are obtained from studies of identical twins who have been reared apart.

Such studies suggest a relatively high heritability for *schizophrenia*, *asthma*, *coronary heart disease*, non-insulin-dependent *diabetes mellitus*, *ankylosing spondylitis*, and some birth defects, such as *cleft lip and palate*, *pyloric stenosis*, and *talipes* (clubfoot). The heritability for congenital *heart disease* and *peptic ulcer* is low.

Estimates of heritability are useful in *genetic counseling*. (See also *Genetic disorders; Histocompatibility antigens*.)

Hermaphroditism

A congenital disorder in which both male and female gonads (testes and ovaries) are present and the external genitalia are not clearly male or female. True hermaphroditism is extremely rare and its cause unknown. The majority of affected children are raised as males because the external genitalia usually appear more male than female.

A more common condition is pseudohermaphroditism, in which the external genitalia may be ambiguous, but the gonads of only one sex are present. Pseudohermaphroditism is caused by a hormonal imbalance (such as in congenital *adrenal hyperplasia*) and can usually be treated by plastic surgery and hormone therapy.

Hernia

The protrusion of an organ or tissue through a weak area in the muscle or other tissue that normally contains it. The term is usually applied to a protrusion of the intestine through a weak area in the abdominal wall. In *hiatal hernia*, the stomach protrudes through the diaphragm into the chest. Very rarely, other organs or tissue (e.g., the brain) may herniate.

CAUSES

Abdominal hernias are usually caused by a *congenital* weakness in the abdominal wall. They may appear following surgery or after damage caused by lifting heavy objects, substantial weight gain, persistent coughing, or straining to defecate.

SYMPTOMS

The first symptom of a hernia is usually a bulge in the abdominal wall. There may also be abdominal discomfort. In some people, the protruding intestine can be pushed back through the abdominal wall.

Severe pain occurs when the hernia bulges out and cannot be replaced. If the blood supply to a twisted, trapped intestine becomes impaired (a condition known as a strangulated hernia), the bowel may become gangrenous. This requires urgent treatment.

DIAGNOSIS AND TREATMENT

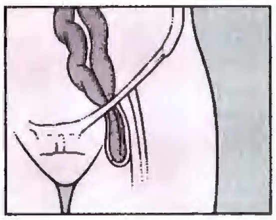
Hernias are diagnosed by physical examination. If the hernia is causing only slight discomfort and is readily pushed back, a supportive garment, or truss, may be recommended. Hernias that are painful or impossible to push back are usually treated surgically (see *Hernia repair*).

Hernia repair

Surgical correction of a *hernia*. The procedure is performed to treat a hernia of the abdominal wall that is painful or cannot be pushed back. A strangulated hernia requires an emergency operation.

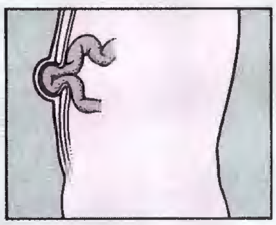
HOW IT IS DONE

Many hernias are repaired on an outpatient basis unless an underlying



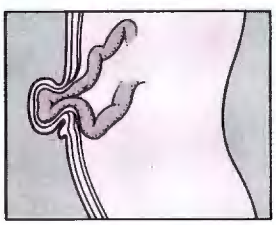
MAIN TYPES OF ABDOMINAL HERNIA

Inguinal hernia



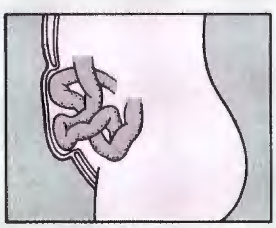
At least 2 percent of adult males in the US suffer from this kind of hernia, in which part of the intestine bulges through the inguinal canal (the passage through which the testes descend into the scrotum). The hernia is detected as a bulge in the groin or scrotum; untreated, the hernia may become stuck, so early surgery is generally recommended.

Femoral hernia



This type of hernia occurs most commonly in obese women; part of the intestine emerges where the femoral vein and artery pass from the abdomen to the thigh. A femoral hernia is noticed as a swelling of the top front of the thigh. Although the hernia itself may be large, its neck is narrow, and the condition can only be corrected by surgery.

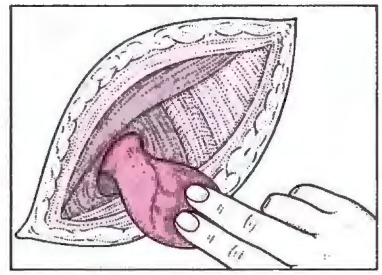
Epigastric hernia



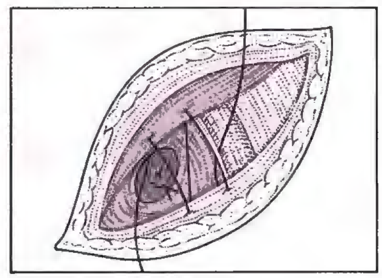
Also called a ventral hernia, an epigastric hernia is caused by a weakness in the muscles of the central upper abdomen; the intestine bulges out at a point between the navel and the breastbone. This form of hernia is three times more common in men than in women and is most likely to occur in people between 20 and 50 years old.

Umbilical hernia

This occurs when part of the intestine protrudes through the abdominal wall near the navel. Babies are the most common sufferers; the hernia can be repaired surgically or it may disappear naturally by about age 5. A similar problem, a parumbilical hernia, occurs mostly in obese, middle-aged women who have had several children.



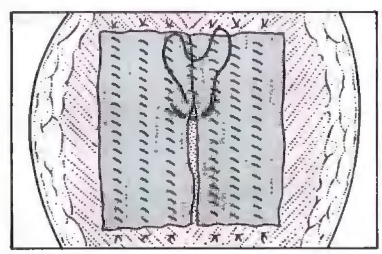
Incisional hernia



An area of weakness may occasionally develop following a surgical incision in the wall of the abdomen. This area may then develop into an incisional hernia. The defect may become so severe that a large amount of intestine bulges through the abdominal wall; if this happens, a repair using a piece of mesh may be necessary.

HERNIA REPAIR

During surgery the hernia is removed or repositioned and the weakened abdominal wall is reinforced with stitching or mesh.



1 The protruding sac of intestine is pushed back into the abdomen or, in some cases (e.g., strangulation), the sac is removed surgically.

2 The wall of the abdomen may then be repaired by overlapping the edges of the weakened area and securing with rows of stitching.

LARGE HERNIAS

For repair of some large hernias, two mesh leaves are secured by rows of stitching, then joined at the center.

medical condition necessitates hospitalization. A local, epidural, or general anesthetic may be used. The surgeon's aim is to push the protruding intestine back into place and then strengthen the weakened muscle wall (see illustrated box).

RECOVERY AND OUTLOOK

The speed of recovery depends on the patient's underlying medical condition and on the type of hernia repaired. Lifting heavy objects should be avoided for three to six months.

The risk of a recurrence of the condition varies with the type of hernia treated. Inguinal and incisional hernias both recur quite commonly; femoral and epigastric hernias recur only rarely.

Herniated disk

See *Disk prolapse*.

Herniorrhaphy

Surgical correction of a hernia. (See *Hernia repair*.)

Heroin

A *narcotic drug* derived from *morphine*, a substance extracted from the pods of the opium poppy. Heroin is a white or brownish powder that can be smoked, sniffed, or dissolved in water and injected. Its chemical name is diacetylmorphine.

Heroin abuse is a major health problem in many countries. It has many adverse effects on the user and is a sociological and economic problem of immense proportions.

H

EFFECTS

In addition to having an analgesic (painkilling) effect, heroin produces sensations of warmth, calmness, drowsiness, and a loss of concern for outside events.

Long-term use causes *tolerance* (the need for greater amounts of the drug to have the same effects) and psychological and physical dependence (see *Drug dependence*). Sudden withdrawal of the drug produces symptoms such as shivering, abdominal cramps, diarrhea, vomiting, sleeplessness, and restlessness.

Other common problems of heroin addiction include injection scars, skin abscesses, weight loss, and impotence. Infections, such as *hepatitis B* and *AIDS*, are spread by sharing needles. Death commonly occurs from accidental overdose.

Herpangina

A throat infection caused by a type of virus called coxsackievirus. Herpangina most commonly affects young children, although it occurs in adults. The virus is usually transmitted via infected droplets coughed or sneezed into the air. Many people harbor the virus but do not experience any symptoms.

SYMPTOMS

After an incubation period of two to seven days, there is a sudden onset of fever, loss of appetite, and sore throat. There may also be headache, abdominal discomfort, and vague muscular aches and pains. The throat becomes red and a few small blisters appear, which enlarge and burst, forming shallow ulcers. The condition usually clears up within a week.

TREATMENT

Usually no treatment is required other than simple *analgesics* (painkillers). There is no specific antiviral therapy available. Antibiotics are generally of no therapeutic value unless a bacterial infection develops as a secondary complication. Recurrent attacks of herpangina may result from infection with different strains of the virus.

Herpes

Any of a variety of conditions characterized by an eruption of small, usually painful, blisters on the skin.

When a person is said to be suffering from herpes, it usually refers to an infection with the *herpes simplex* virus. Forms of the virus are responsible for *cold sores* (painful blisters around the lips) and for the sexually transmitted infection genital herpes, which is characterized by blisters on the sex organs (see *Herpes, genital*). The virus can also cause a number of other conditions affecting the skin, mouth, eyes, brain, or, in rare cases, the whole body.

A closely related virus, the varicella-zoster virus, is responsible for two more conditions in which skin blisters are a feature—*chickenpox* (also known as varicella) and *herpes zoster* (also known as shingles). Like the herpes simplex virus, the varicella-zoster virus can affect the eyes or, rarely, may infect the brain or cause an infection throughout the body.

Herpes gestationis and *dermatitis herpetiformis* are among various other conditions in which "herpetiform" (herpeslike) groups of blisters may appear on the skin, but neither is related to herpes simplex or varicella-zoster virus infections.

Herpes, genital

A sexually transmitted disease that produces a painful rash on the genitals. Caused by the *herpes simplex* virus (*HERPESVIRUS HOMINIS*, type 2), genital herpes is transmitted by sexual intercourse with an infected person.

SYMPTOMS AND SIGNS

After an incubation period of about a week, the virus produces itching, burning, soreness, and small blisters in the genital area. The blisters burst to leave small, painful ulcers, which heal within 10 to 21 days. The lymph nodes in the groin may become enlarged and painful, and the affected person may feel sick, with headache and fever. Women with genital herpes may find urination very painful if the urine comes into contact with the sores. Occasionally, there may be cold sores around the mouth.

TREATMENT

Genital herpes cannot be cured, but the earlier treatment is given, the more likely the treatment will prevent or reduce the severity of an attack. An antiviral medication (such as acyclovir) helps make the ulcers less painful and encourages them to heal more quickly. Additional soothing measures include taking analgesics (painkillers) and warm baths with a tablespoon of salt added.

Subsequent attacks tend to occur after sexual intercourse, after sunbathing, or when the affected person is run down; these recurrent attacks often clear up quickly with or without treatment. Sexual activity should be avoided until the symptoms have disappeared. If a pregnant woman has an attack of genital herpes when the baby is due, a cesarean section is performed to prevent the baby from being infected during delivery.

OUTLOOK

Once the virus enters the body, it stays there for the rest of the person's life. About 40 percent of those affected never have another attack after the first. Others, however, suffer four or five attacks annually for several years. Gradually, the attacks become less severe and the intervals between recurrences become longer.

The herpes virus may have a role in the development of cervical cancer (see *Cervix, cancer of*); it is important for any woman who has had herpes to have a *cervical smear test* (Pap test) every one to two years.

Herpes gestationis

A rare skin disorder, characterized by crops of blisters on the legs and abdomen, that occurs only in pregnancy. The cause is not known and, despite its name, herpes gestationis is not related to any of the disorders caused by the *herpes simplex* viruses.

Severe herpes gestationis is treated with *corticosteroid drugs* in tablet form and may require hospital admission because of the risk of *miscarriage*. The disorder usually clears up completely after the birth of the baby, but tends to recur in subsequent pregnancies.

Herpes simplex

A common and troublesome viral disease. Although most herpes simplex infections are symptomless, mild, or merely irritating, others can be extremely distressing (notably infections affecting the genitals) and even life-threatening.

TYPES

The virus exists in two forms, known as HSV1 (herpes simplex virus, type 1) and HSV2 (type 2). HSV1 is usually associated with infections of the lips, mouth, and face. HSV2 is often associated with infections of the genitals and infections acquired by babies at birth. However, there is a considerable amount of overlap. Some conditions usually caused by HSV1 are sometimes caused by HSV2 and vice versa. Both virus types are contagious. Infection is spread by direct contact with the lesions themselves or by the fluid contained therein.

TYPE 1 VIRUS Most people have been infected with HSV1 by the time they reach adulthood; most of the remainder are infected during adulthood. The initial infection may cause

no symptoms or may cause a sometimes severe flulike illness with mouth ulcers. Thereafter, the virus remains in the nerve cells within the facial area. In many people, however, the virus is occasionally reactivated, causing recurrent *cold sores* that always erupt in the same site (usually around the lips), but are not serious. They often recur at times when there is an elevated temperature at the affected site (such as with fever or prolonged sun exposure).

Rarely, the virus may infect the fingers, causing an eruption of very painful blisters known as a herpetic *whitlow*. Sometimes it may cause an extensive rash of blisters (known as eczema herpeticum) in someone with a preexisting skin condition such as dermatitis.

If a person with an *immunodeficiency disorder* (such as *AIDS*) or someone who is taking *immunosuppressant drugs* is infected with the virus, it may cause a severe, generalized infection that is occasionally fatal.

If the virus gets into an eye, it may cause *conjunctivitis* (which usually lasts only a few days) or, more seriously, a *corneal ulcer*.

Very rarely, the type 1 virus may spread to the brain, leading to a serious *encephalitis*.

TYPE 2 VIRUS This form of the virus is the usual cause of sexually transmitted genital herpes, in which painful blisters erupt on the sex organs (see *Herpes, genital*). As with cold sores, the blisters recur in some people.

TREATMENT

Treatment of herpes simplex depends on its type, site, and severity. Antiviral drugs, such as acyclovir, are sometimes helpful. Lesions may also become infected with bacteria. If so, antibiotics (topical or oral) and tepid soaks may be helpful.

Herpes zoster

The medical term for shingles. Herpes zoster is an infection of the nerves that supply certain areas of the skin. It causes a painful rash of small, crusting blisters. After the rash heals, pain may persist for months or, rarely, years.

TYPES

Herpes zoster often affects a strip of skin over the ribs on one side or, less commonly, a strip on one side of the neck and arm or the lower part of the body. Sometimes it involves the upper half of the face on one side; in this case, the eye may also be affected. Shingles in this area is known as herpes zoster ophthalmicus.

CAUSES

Herpes zoster is caused by the varicella-zoster virus, which also causes *chickenpox*. During an attack of chickenpox, most of the viral organisms are destroyed, but some survive and lie dormant in certain sensory nerves, remaining there for many years. In some people, a decline in the efficiency of the *immune system* (the body's defenses against infection) allows the viruses to reemerge and cause shingles.

The competence of the immune system declines with age; this decline is probably accelerated by stress and by the use of *corticosteroid drugs*. Herpes zoster commonly follows a stressful episode.

INCIDENCE

Herpes zoster is a common disease. Every year in the US, a few hundred people per 100,000 suffer an attack. It mainly affects people over 50 and the incidence rises with age. Herpes zoster is very common in people whose immune systems have been weakened either by diseases such as *lymphoma* or *Hodgkin's disease*, or by treatment with *immunosuppressant* or *anticancer drugs*.

SYMPTOMS AND SIGNS

The first indication is excessive sensitivity in the area of skin to be affected; this is soon followed by pain, which is sometimes severe and which may, until the rash appears, be mistaken for pleurisy or appendicitis.

After about five days, the rash appears, starting as small, slightly raised, red spots that quickly turn to tense blisters, teeming with viruses. Within three days the blisters have turned yellowish and soon dry, flatten, and crust over. During the next two weeks or so these crusts drop off, often leaving small pitted scars.

Example of herpes zoster
An extensive rash of crusting blisters over one side of the neck that spreads over the shoulder and onto the front of the chest.

The most serious feature of herpes zoster is pain following the attack. The pain is a consequence of damage to the nerves, causing strong nerve impulses to be constantly produced and passed upward to the brain. The pain, which affects about one third of sufferers, may be severe and may last for months or years. The older the patient and the more pronounced the rash, the more likely the pain will be severe and persistent.

Ophthalmic herpes zoster may be confined to the skin of the lids and the forehead and need not affect the eye, but, if it does, it may cause a *corneal ulcer* or *uveitis*, both of which are potentially serious.

TREATMENT

Once the rash is fully established, little can be done to influence the course of the disease or the likelihood of postherpetic pain. Only palliative measures and *analgesics* (painkillers) are of value. It is, however, possible to reduce the severity of the active stage and to minimize nerve damage by the prompt use of *antiviral drugs* (such as acyclovir).

Many different measures have been advocated, in addition to analgesics, for the relief of postherpetic pain. They include skin stimulation by intermittent rubbing, the passage of alternating electric currents through the skin, local heat, cold spraying, injection of local anesthetics, and even surgical cutting of the nerves. None of these measures has been shown to be consistently effective.

Heterosexuality

Sexual attraction to members of the opposite sex. (See also *Bisexuality*; *Homosexuality, male*; *Lesbianism*.)

Heterozygote

A term used to describe a person whose cells contain two different *genes* controlling a specified inherited trait, in contrast to a *homozygote* who has identical genes controlling that trait. (See also *Inheritance*; *Genetic disorders*.)

Hiatal hernia

A condition in which part of the stomach protrudes upward into the chest through a hiatus (opening) in the diaphragm (the sheet of muscle involved in respiration that separates the chest from the abdomen).

CAUSES AND INCIDENCE
The underlying cause of this common condition is unknown, but it tends to occur more frequently in obese people (and especially in upper middle-aged women) and in those who smoke. In some cases it is present at birth.

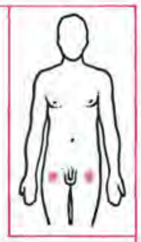
SYMPTOMS
Many people have no symptoms, but in some people hiatal hernia affects the efficiency of the muscle at the end of the esophagus (esophagogastric junction), permitting *acid reflux* (regurgitation of acidic juices from the stomach into the esophagus). This reflux may in turn cause *heartburn*, which is often made worse by bending over or lying down, and *peptic esophagitis* (inflammation of the esophagus). The pain of esophagitis or esophagospasm may mimic the pain of *coronary heart disease*.

DIAGNOSIS
Esophagoscopy (passage of a viewing tube down the throat into the esophagus) may be performed to determine the severity of esophagitis and to check for stricture (narrowing) of the esophagus (see *Esophageal stricture*). If there is any suspicion of esophageal cancer, a *biopsy* (removal of a small sample of tissue for examination) is carried out. Manometric studies (pressure measurements, see *Manometry*) can confirm the reduced pressure at the esophagogastric junction. A barium swallow (see *Barium X-ray examinations*) is performed with the patient tilted headdown. If the barium is seen on X ray to cause reflux into the esophagus, it indicates incompetence at the esophagogastric junction.

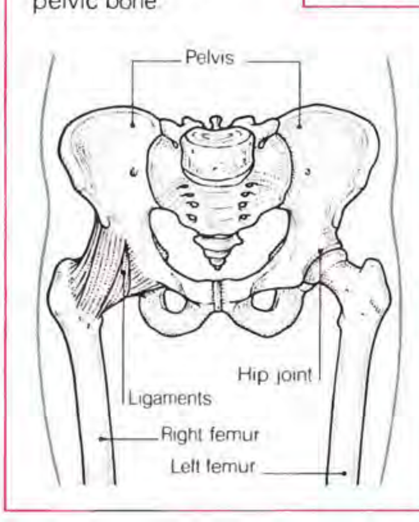
TREATMENT
To alleviate symptoms, the patient should avoid eating large, heavy meals and should never lie down or bend over immediately after a meal. The head of the bed should be raised to prevent reflux during the night. People who are obese need to lose weight and smokers should stop smoking. *Antacids* may be given to reduce stomach acidity and to protect the esophagus against acid juices.

In severe cases, an operation may be required to return the protruding part of the stomach to the abdomen and to prevent further reflux of acid gastric contents into the esophagus.

Hiccup
A sudden, involuntary contraction of the diaphragm followed by rapid closure of the vocal cords (which causes the characteristic sound); also called hiccough. Hiccups usually occur at brief intervals and attacks last for only a few minutes.



CAUSES AND TREATMENT
Attacks of hiccups are extremely common; in almost all cases, they occur without obvious cause and are not medically significant. Such minor attacks often stop of their own accord. There are also numerous popular remedies, the effectiveness of which varies from one person to another.



Rarely, hiccups may be due to a condition that causes irritation of the diaphragm or of the phrenic nerves that supply it. Known causes include pleurisy, pneumonia, certain disorders of the stomach or esophagus, pancreatitis, alcoholism, and hepatitis. Most bouts are of unknown cause.

Frequent, prolonged attacks of hiccups, which are extremely rare, may lead to severe exhaustion. In such cases, when medication has failed, surgery may be recommended. It may involve either crushing or injecting a drug around one of the phrenic nerves to paralyze half the diaphragm; this measure is sometimes unsuccessful.

Hip
The joint between the pelvis and the upper end of the femur (thigh bone). The hip is an extremely stable ball-and-socket joint; the smooth, rounded head of the femur fits securely into the acetabulum, a deep, cuplike cavity in the pelvis. Tough ligaments attach the femur to the pelvis, further stabilizing the joint and providing it with the necessary strength to support the weight of the upper body and to take the strain of running, jumping, and other vigorous leg movements. In addition, the ball-and-socket structure of the joint allows the leg a considerable range of movement that is available only because of the unique design of this joint.

LOCATION OF HIP
The hip is a ball-and-socket joint between the dome at the top of the femur (thigh bone) and the cup-shaped depression in the pelvic bone

DISORDERS

ARTHRITIS *Osteoarthritis* of the hip, one of the most common of all disorders, causes stiffness and pain in the joint, particularly during movement. Occasionally, *ankylosing spondylitis* and *rheumatoid arthritis* of the hip cause similar problems.

FRACTURE What is commonly called fracture of the hip (most common in elderly people as the result of a fall) is in fact fracture of the head or neck of the femur (see *Femur, fracture of*).

DISLOCATION Congenital dislocation of the hip usually clears up of its own accord or is remediable (see *Hip, congenital dislocation of*). Dislocation of the hip by injury is rare and usually results only from extreme force, such as that from an automobile accident. Such dislocation may cut off the blood supply to the head of the femur, causing the bone to die (aseptic necrosis), or may injure the sciatic nerve, leading to weakness in the leg.

Hip, congenital dislocation of
A disorder present at birth in which the ball-like head of the femur (thigh bone) fails to fit into the cuplike socket in the pelvis to form a joint but instead lies outside. One or both of the hips may be affected.

CAUSES AND INCIDENCE
The cause of congenital dislocation of the hip is not known, but it is more common in babies born by *breech delivery* and following pregnancies in which there was *oligohydramnios* (an abnormally small amount of amniotic fluid in the uterus).

About 400 in every 100,000 babies born are affected; in most cases the condition soon corrects itself. Only about 125 in 100,000 suffer from persistent dislocation. The disorder runs in families and affects many more girls than boys.

DIAGNOSIS
Shortly after birth and at intervals until walking starts, all babies are given a routine physical examination of the hip to check its stability and range of motion. If the condition is not

X ray showing congenital dislocation
The left femur (thigh bone) is displaced upward and backward from its socket

detected in infancy it may be diagnosed when a limp develops when the child is learning to walk.

TREATMENT

If the condition is found in early infancy, light splints are applied to the thigh to maneuver the ball of the joint into the socket and keep it in position. The splints are worn for two to four months and usually aid in correcting the problem.

If the condition is not discovered until later in infancy, traction is used. The head of the femur is moved into the correct position and kept there by a system of weights and pulleys attached to the leg.

If the dislocation is not detected until childhood, surgery using a general anesthetic may be required to correct it. The child usually must stay in the hospital for several weeks and wear a plaster cast for a few months.

OUTLOOK

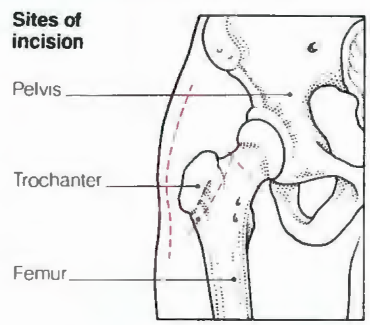
Provided the disorder is treated in infancy, the child usually walks normally and there are no aftereffects. When treatment is delayed until childhood, there may be lifelong problems with walking. If the condition remains untreated, the dislocation often leads to shortening of the leg, limping, and early *osteoarthritis* in the joint.

Hippocratic oath

A part of the writings attributed to Hippocrates, a fifth century BC Greek physician. The oath has served as a widely used ethical guide for the medical profession ever since. It pledges the physician to work for the good of the patient, to do him or her no harm, to prescribe no deadly drugs, to give no advice that could cause death, and to keep confidential medical information regarding the patient. The oath is often administered as a part of the graduation ceremonies at medical schools.

Hip replacement

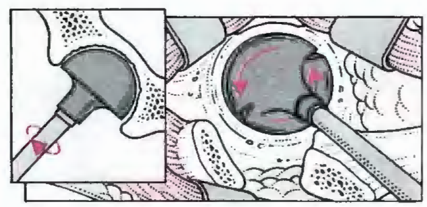
A surgical procedure to replace all or part of a diseased hip joint with an artificial substitute.



WHY IT IS DONE

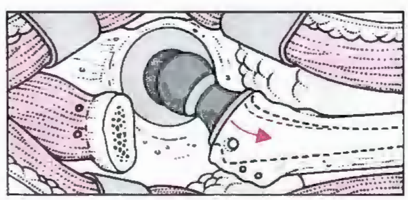
Hip replacement is most often carried out in older people whose joints are stiff and painful as a result of *osteoarthritis*. It may also be needed if *rheumatoid arthritis* has spread to the hip joint, making walking difficult, or if the top end of the femur is badly fractured (see *Femur, fracture of*).

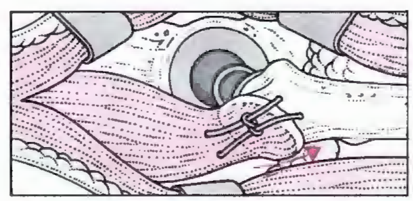
The operation is not usually advised for young patients, since their greater activity puts more strain on the joints and it is unknown how long any artificial replacement is likely to last.



PERFORMING A HIP REPLACEMENT

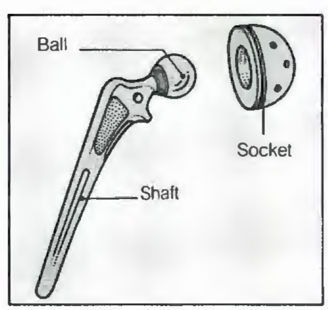
In this operation, the surgeon pushes aside or cuts through the surrounding muscles to expose the hip joint. The femur (thigh bone) is cut and the pelvis is drilled to make room for the two components of the artificial joint. These parts are secured in place, the femur is repaired, and the muscles and tendons are replaced and repaired.





1 The trochanter at the top of the femur is detached, and the hip joint is dislocated to separate the femur and the pelvis. The ball at the top of the femur is then cut away.

2 An instrument known as a reamer is used to make the hollow in the pelvis large enough to make room for the cup-shaped socket (one of the two components of the artificial hip joint).



3 A coarse file is used to cut a shaft in the femur, and the ball part of the artificial joint is inserted. The components are fixed in place with a special cement, which binds them to the bone.

4 The ball is placed in the socket and the trochanter is reattached to the femur with wires. The muscles and tendons are replaced and repaired, and the incision is then closed.

Before
This X ray shows a hip joint that has been badly damaged by arthritis.

Components
The ball and shaft are made of metal; the socket may be metal or plastic.

After
This X ray shows the artificial hip joint in position after surgery.

RECOVERY PERIOD

The joint remains unstable for a week or two after the operation, and patients must take care not to dislocate the new joint during this time. Patients are advised to sleep on their backs and not to cross their legs, and are taught how to get in and out of a bathtub without disturbing the joint.

OUTLOOK

Hip joint replacement is a remarkably successful operation that has transformed the lives of many people who suffered from severe pain and stiffness. However, with time, a substantial proportion of artificial joints show signs on X ray of loosening at the cemented union between bone and metal. Surgeons and engineers are continuing to develop newer joint designs that do not rely on cement to hold them in place.

H

Hip, snapping

A fairly common condition in adults in which a characteristic clicking is heard and felt during certain movements of the joint. Snapping hip is generally harmless and does not indicate disease of the hip joint.

The noise and sensation are caused by a tendon slipping over the bony prominence on the outside of the femur when the hip is bent upward.

Snapping hip should not be confused with a hip that clicks when a newborn baby is being examined, which is a sign that there may be congenital dislocation of the hip (see *Hip, congenital dislocation of*).

Hirschsprung's disease

Also known as congenital megacolon, a congenital disorder in which a segment of intestine (sometimes near the anus) lacks the ganglion cells that control the rhythmic motion of the bowel. This segment becomes narrowed and blocks the movement of fecal material. The bowel above becomes dilated and tortuous (twisted). Hirschsprung's disease is uncommon and tends to run in families. It occurs about four times more often in boys than girls.

SYMPTOMS

Symptoms usually appear in infancy or early childhood; they include marked constipation and bloating. The child usually has a poor appetite and may fail to grow properly.

DIAGNOSIS

A barium enema (see *Barium X-ray examinations*) can show the narrowed rectal segment of the intestine. A *biopsy* sample taken from the involved area during *proctoscopy* or surgical biopsy confirms the lack of ganglion cells and establishes the diagnosis.

TREATMENT

Treatment involves removing the narrowed intestinal segment and rejoining the normal colon to the normal colonic or rectal segments. Before surgery, a temporary *colostomy* (making an artificial outlet for the colon on the abdominal wall) may be necessary if the child is considerably underweight or to facilitate treatment for severe anemia.

Hirsutism

Excessive hairiness, particularly in women. The additional hair is coarse, like a man's, and grows in a male pattern on the face, trunk, and limbs.

CAUSES AND INCIDENCE

Hirsutism occurs in some conditions in which the level of male hormones in the blood is abnormally high (e.g., in *polycystic ovary* syndrome and congenital *adrenal hyperplasia*).

Much more commonly, hirsutism is not a sign of any underlying disorder; it occurs in many normal women, especially after the menopause. The condition tends to run in families. Dark-haired women, particularly those of Hispanic or Indian extraction, are particularly likely to be hirsute.

TREATMENT

Hair can be bleached or removed in various ways (see *Hair removal*); the only method of permanent removal is by *electrolysis* (destruction of hair roots by an electric current). See also *Hypertrichosis*.

Histamine

A chemical present in cells (mainly *mast cells*) throughout the body that is released during an allergic reaction (see *Allergy*); histamine is one of the substances responsible for the symptoms of *inflammation*. It also stimulates production of acid by the stomach and narrows the bronchi (airways) in the lungs.

The effects of histamine can be counteracted by *antihistamine drugs*; its action on the gastric acid-forming glands is blocked by *histamine-2 receptor antagonists*.

Histamine-2 receptor antagonists

A group of *ulcer-healing drugs* related to the *antihistamine drug* group. Histamine-2 (or H-2) receptor antagonists work by blocking the action of the chemical histamine at specific *receptors* (sites on a cell's surface), preventing release of acid in the stomach. Acid reduction promotes the healing of *peptic ulcers* and relieves symptoms of *esophagitis*. (See also *Cimetidine*; *Ranitidine*; *Famotidine*.)

Histiocytosis X

A rare childhood disease in which there is an overgrowth of a type of tissue cell called a histiocyte. The cause is unknown, but it probably results from a disturbance of the *immune system*.

In the mildest form of the disease, rapid cell growth occurs in one bone only, usually affecting the skull, clavicle, or a rib or vertebra, causing swelling and pain. The chances of recovery are good in these cases.

The most severe, and least common, form of the disease affects infants. This form of the disease behaves like advanced *leukemia*, leading rapidly to death.

Histocompatibility antigens

A group of proteins that is naturally present within tissues and has a role in the *immune system* (body's defenses against infection). The main group of histocompatibility antigens is known as the HLA (human leukocyte antigen) system. The particular set or types of HLAs in a person's tissues (called his or her tissue type) is inherited. These antigens have an influence on the outcome of organ transplantation (see *Transplant surgery*) and also seem to affect susceptibility to certain diseases. However, these are probably just side effects of the primary immunologic (defense) function of the antigens.

TYPES AND STRUCTURE

Like all proteins, histocompatibility antigens are synthesized in cells under the control of genes. The genes controlling their production are called the major histocompatibility complex; they give rise to several series of antigens called HLA-A, HLA-B, HLA-C, HLA-D, and HLA-DR.

Each histocompatibility antigen is composed of two parts, a constant region (which is the same for all people) and a variable region (which differs among people). The structure of this region is genetically determined (inherited from one of the parents) and can take any of several forms, which have been given numbers. Thus, a particular antigen has a letter (the series it belongs to) and a number corresponding to the form within the series—for example, HLA-A3, HLA-B13, or HLA-C5 types. The number of possible combinations of

antigens from the different series is vast, and, apart from identical twins, each person has a unique combination. By a technique called *tissue-typing*, every person can be immunologically "fingerprinted."

IMMUNOLOGICAL FUNCTION

Histocompatibility antigens within the series HLA-A, B, and C are present on virtually all living cells in the body. They are essential for the function of certain *lymphocytes* (white blood cells with an immunological function) called killer T cells. The antigens act as a guide for killer T cells to recognize and kill abnormal cells (i.e., virus-infected and tumor cells).

Histocompatibility antigens within the HLA-D series are present on the surfaces of various other cells with a defense role; they influence the interactions of these cells in fighting infection and tumors.

EFFECT IN TRANSPLANTATION

When an organ is transplanted from one person to another, the histocompatibility antigens in the donor organ are generally recognized as foreign and are attacked by the recipient's immune system, leading to rejection. However, if a donor can be found whose HLA types are very similar to those of the recipient (often a blood relative and ideally an identical twin), the chances of rejection occurring are minimized.

DISEASE ASSOCIATION

Certain HLA types occur more frequently in patients with particular diseases than in the rest of the population. For example, *multiple sclerosis* is associated with HLA-A3, *celiac sprue* with HLA-B8, and *ankylosing spondylitis* with HLA-B27.

It is suspected that susceptibility to these diseases is influenced by the HLA types, presumably as a result of their immunologic actions. The associations are of interest because they allow identification of individuals at risk and can help in the confirmation of disease.

LEGAL USES

An individual's HLA types are inherited (half from the father and half from the mother); blood relatives in general have similar types. Study of HLA types is thus sometimes of use in *paternity testing* and other situations in which there is a dispute as to whether two people are related. For example, if two people both have a highly unusual combination of HLA types, it may provide very strong evidence (although it can never be proven absolutely) that they are related.

Histologist

A specialist in *histology*, the study of the microscopic appearance of tissues.

Histology

The study of tissues, including their cellular structure and function. Its main practical use in medicine is in the diagnosis of disease. This often involves obtaining a tissue sample by *biopsy* and examining it for abnormalities. The histologist's skill lies in his or her familiarity with the range of normal appearances of tissues and the recognition of the abnormal appearances in different diseases.

Histopathology

The branch of *histology* (the study of tissues) concerned with the effects of disease on the microscopic structure of tissues.

Histoplasmosis

An infection caused by inhaling the spores of *HISTOPLASMA CAPSULATUM*, a fungus found in soil, particularly areas contaminated with droppings from birds or bats. Histoplasmosis occurs in the central and southern US and in parts of South America, the Far East, and Africa.

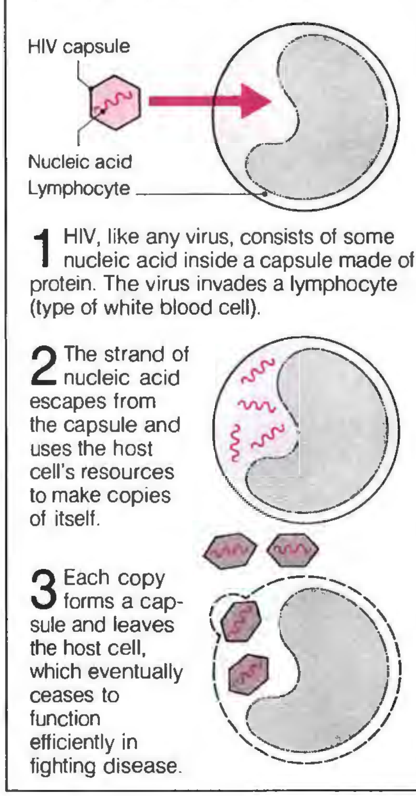
Most people who inhale the spores are not affected by them. The rare cases of infection occur either in people who are exposed to large quantities of the spores (such as pigeon handlers) or in people whose resistance to infection has been lowered—for example, by an *immunodeficiency disorder*, such as *AIDS*.

SYMPTOMS AND TREATMENT

The most common form of histoplasmosis is an acute illness (marked by breathlessness, cough, and joint pains) that usually clears up on its own. However, in some people (mainly in those with a low resistance to infection) the disease takes a chronic form and spreads throughout the body, resulting in fever, loss of weight, mouth ulcers, enlargement of the spleen, liver, and lymph nodes, failure of the adrenal glands, and anemia. Treatment with the antifungal drugs amphotericin B or ketoconazole is usually effective. In severe, untreated cases, the disease may be fatal (it causes about 50 to 100 deaths in the US each year).

History-taking

The process by which a physician learns from patients the symptoms of their illnesses and any previous disorders. (See *Diagnosis*.)



HIV

Human immunodeficiency virus. HIV belongs to the class of retroviruses (see *Virus*) and is the cause of *AIDS* and *AIDS-related complex*.

HIV gains access to the body by entering the bloodstream via blood transfusions, nonsterile needles, or sexual intercourse. A fetus can be infected by its mother. HIV has an affinity for the *T-lymphocytes* (part of the *immune system*), in which the virus multiplies and, in some cases, destroys function. HIV also attacks the brain and may cause severe damage with *dementia*; most infected people are likely to succumb to AIDS before this happens.

HIV is an organism of low infectivity; infected people present no threat to the health of their contacts at work or home, except for sexual partners and needle sharers.

HOW HUMAN IMMUNODEFICIENCY VIRUS (HIV) MULTIPLIES

1 HIV, like any virus, consists of some nucleic acid inside a capsule made of protein. The virus invades a lymphocyte (type of white blood cell).

2 The strand of nucleic acid escapes from the capsule and uses the host cell's resources to make copies of itself.

3 Each copy forms a capsule and leaves the host cell, which eventually ceases to function efficiently in fighting disease.

Hives

The popular name for *urticaria*.

HLA types

See *Histocompatibility antigens*.

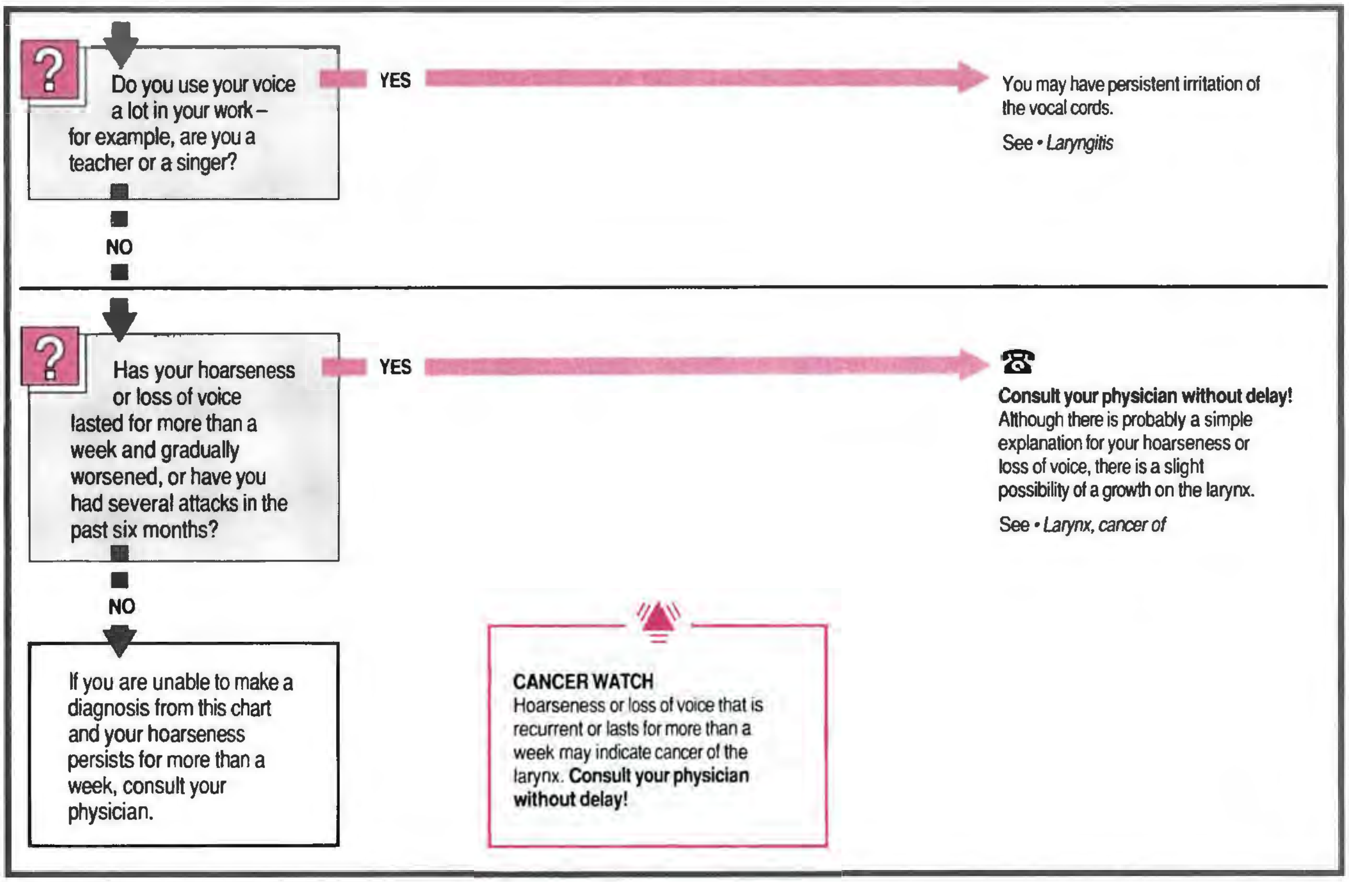
HMO

See *Health Maintenance Organization*.

HOARSENESS OR LOSS OF VOICE

Any abnormal huskiness in the voice that may be so severe that you can make little or no sound.

Has the hoarseness started within the past three days?
- YES → Do you have or have you just had a cold, cough, or sore throat?
  - YES → You probably have inflammation of the vocal cords. See • *Laryngitis*
  - NO → Had you been using your voice more than usual just before the hoarseness or loss of voice developed?
    - YES → Overuse can irritate the vocal cords. See • *Laryngitis*
    - NO → Have you recently become tense, nervous, or depressed?
      - YES → Anxiety can sometimes cause a sudden loss of voice. See • *Anxiety*
      - NO → go to next question
- NO → go to next question



Are you over 40 years old and has your voice deepened?
- YES → Have you noticed two or more of the following symptoms?
  - feeling the cold more than you used to
  - dry skin or hair
  - weight increase without overeating
  - unexplained tiredness
  - YES → An underactive thyroid gland is a possibility. This is an uncommon problem that is most likely to occur in middle-aged women. Consult your physician. See • *Hypothyroidism*
  - NO → go to next question
- NO → go to next question

Do you smoke?
- YES → Smoking can lead to inflammation of the vocal cords. See • *Laryngitis*
- NO → go to next question

Have you been drinking alcohol recently?
- YES → Drinking alcohol can lead to inflammation of the vocal cords. See • *Laryngitis*
- NO

Continued on next page

Self-help
Hoarseness usually clears up after a few days with simple measures such as resting the voice and abstaining from smoking and alcohol.

Hoarseness

A rough, husky, or croaking voice, usually caused by interference with the normal working of the vocal cords in the *larynx* (voice box). Most attacks do not last long and clear up of their own accord, but persistent hoarseness needs investigation to exclude the possibility of serious disease.

CAUSES

Hoarseness of limited duration is often due to overuse of the voice (for example, in teachers or singers), which strains small muscles in the larynx. It is also commonly caused by inflammation of the vocal cords as part of acute *laryngitis*, which is usually due to an upper respiratory tract infection such as a cold or sore throat.

Persistent hoarseness has many possible causes. It may be due to chronic irritation of the larynx (which can be caused by smoking or excessive consumption of alcohol) or chronic *bronchitis*. Irritation can also be caused by mucus constantly dripping on the larynx, as may occur in nasal *polyps* (harmless growths in the nose), allergic *rhinitis* (hay fever), *sinusitis*, or a deviated *nasal septum* (crookedness of the cartilage wall that separates the two nostrils).

Polyps on the vocal cords may also cause hoarseness, as may any accidental damage to them as the result of thyroid gland surgery. In *hypothyroidism* (underactivity of the thyroid gland), hoarseness can result from tissue forming on the vocal cords.

In young children, hoarseness is one of the symptoms of *croup* (inflammation and narrowing of the airways).

Occasionally, persistent hoarseness in adults has a more serious cause—including cancer of the larynx (see *Larynx, cancer of*). Less commonly, persistent hoarseness is caused by *thyroid cancer*.

SELF-HELP

Anyone suffering from hoarseness believed to be brought on by straining the voice should rest his or her voice until it has returned to normal; otherwise, permanent damage may eventually occur in the vocal cords. Voice training may reduce the chance of recurrence. Resting the voice, along with not smoking or drinking alcohol, also helps clear up laryngitis.

INVESTIGATION

If hoarseness persists for more than two weeks in anyone over the age of 40, it is essential to consult a physician. The physician will perform a *laryngoscopy* (examination of the larynx with a viewing tube) to exclude the possibility of cancer, which can be completely cured if diagnosed early.

Hodgkin's disease

Also known as Hodgkin's lymphoma, a malignant disorder of lymphoid tissue (found mainly in the *lymph nodes* and *spleen*) in which there is proliferation of its constituent cells and a resultant enlargement of the lymph nodes. The lymphoid tissues constitute an important part of the immune system and frequently do not function normally. The cause of Hodgkin's disease is unknown.

INCIDENCE

Hodgkin's disease is rare; about three new cases per 100,000 are diagnosed annually in the US. It is more common in men than women, and occurs with a peak incidence in people in their 20s and in people between 55 and 70 years of age.

SYMPTOMS AND SIGNS

The most common symptom is painless enlargement of a group of lymph nodes, typically those in the neck or armpits. Most other symptoms are caused by the presence of the enlarged nodes, invasion of other organs by

proliferating lymphoid tissue, or impairment of the body's immune system. Thus, there may be a general feeling of illness, with fever, loss of appetite, weight loss, and night sweats. There may also be generalized itching and, rarely, pain after drinking alcohol. Involvement of other organs may cause a diverse range of symptoms (such as breathlessness if the lungs are involved or paralysis if the spine is affected). As the disease progresses, the immune system becomes increasingly impaired and the patient may suffer life-threatening complications from an infection that would be trivial in a healthy person.

DIAGNOSIS

For a positive diagnosis of Hodgkin's disease, it is necessary to identify cells (called Reed-Sternberg cells) having a characteristic appearance in a sample of tissue (obtained by *biopsy*) from an enlarged lymph node or from another organ affected by the Hodgkin's disease. In addition, the relative proportions of other surrounding cells—including plasma cells, eosinophils, lymphocytes, and granulocytes (all types of white blood cell)—are usually determined. This enables the disease to be classified according to its histological type, which is one factor that affects the chances of a cure.

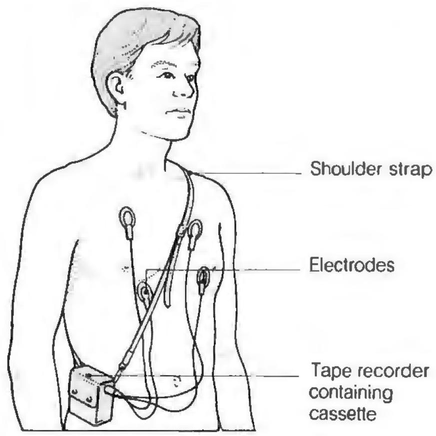
The extent of the disease (known as its *stage*) is also assessed in terms of the number of groups of lymph nodes affected and in terms of any other organs that are involved. This process, called staging, is important for the planning of treatment. Typically, this assessment includes a *chest X ray*, *CT scanning* of the abdomen, and a *bone marrow biopsy*. Other tests may include *laparotomy* (surgical exploration of the abdomen) sometimes with node biopsies, liver biopsy, *splenectomy*, or *lymphangiography* (X-ray imaging of the lymphatic system) of the abdomen.

TREATMENT AND OUTLOOK

Treatment varies according to the stage of the disease. In an early stage, *radiation therapy* is usually curative. If the disease has progressed to involve many organs, however, *chemotherapy* with *anticancer drugs* is usually recommended; this treatment may need to be continued for several months. In some cases, both radiation therapy and chemotherapy are used to increase the chances of a cure.

The outlook depends on the stage to which the disease has progressed and on the histological type. However, after treatment, some 70 to 80 percent of patients survive for at least five years. The condition is apparently cured in most people who receive treatment at an early stage. (See also *Lymphoma, non-Hodgkin's*.)

Hole in the heart



The common name for a *septal defect*.

Holistic medicine

A form of therapy aimed at treating the whole person—body and mind—not just the part or parts in which symptoms occur. A holistic approach is claimed to be emphasized by practitioners of *alternative medicine*, such as homeopathists, acupuncturists, and herbalists.

Holter monitor

A portable (worn by the patient), 24-hour electrocardiographic (see *ECG*) monitoring device used to detect paroxysmal *arrhythmias* (intermittent, irregular heart beats or palpitations). See also *Monitor*.

The Holter monitor
The patient wears the Holter monitor over one shoulder; electrodes attached to the chest transmit the heart rhythms to a slow-running cassette tape in the monitor.

Homatropine

An *anticholinergic drug* that is similar to, but less powerful than, *atropine*.

Homeopathy

A system of *alternative medicine* that seeks to treat patients by administering small doses of medicines that would bring on symptoms similar to those of the patient in a healthy person. For example, the homeopathic treatment for diarrhea would be a miniscule amount of a laxative.

Homeostasis

The dynamic processes by which an organism maintains a constant internal environment despite external changes. It is a major function of most organs. Examples of homeostatic mechanisms include the regulation of blood pressure, body temperature, and blood sugar levels.

Homeostasis plays a vital role in the body because tissues and organs can function efficiently only within a narrow range of conditions such as temperature and acidity. The homeostatic mechanisms regulate such conditions by negative feedback. When a certain factor varies from its optimum set point, automatic regulatory mechanisms act to counterbalance the disturbance and reestablish the internal equilibrium. For example, when the body overheats, sweating is stimulated until the temperature returns to normal. Similarly, when the level of oxygen in the blood is low, breathing is stimulated; when blood pressure falls, the heart rate increases.

Homeostatic mechanisms sometimes malfunction. For example, in malignant *hyperthermia*, the body's thermostat is somehow reset to a higher temperature than normal. In *diabetes mellitus*, blood sugar levels can no longer be regulated because of a malfunction of insulin production.

Homocystinuria

A rare, inherited condition caused by an *enzyme* deficiency. Homocystinuria is a type of inborn error of *metabolism* in which there is an abnormal presence of a particular *amino acid* (homocystine) in the blood and urine. Affected people resemble those with *Marfan's syndrome*—very tall and long-limbed with long, spindly fingers, and sometimes skeletal deformities (such as curvature of the spine).

The disease cannot be cured, but can be improved by vitamin B_6 and a special diet.

Homosexuality, female

See *Lesbianism*.

Homosexuality, male

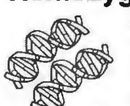
Sexual attraction to other men. According to Alfred Kinsey's studies of sexuality carried out in the 1940s, about 5 to 10 percent of men are completely homosexual; up to one third of men have had sexual contact with another man at some time.

CHARACTERISTICS

Homosexuals are no more effeminate than heterosexuals, despite the popular stereotype. Each partner may adopt a particular role in the relationship (either active or passive) that may

be reflected in styles of dress and behavior; more often, however, roles are interchangeable. Homosexuals achieve orgasm in various ways, including oral sex, mutual masturbation, and anal penetration.

Some male homosexuals have monogamous relationships. Others have multiple partners, high rates of sexual activity, and are consequently at high risk of venereal disease. It was in male homosexuals that the *AIDS* virus was first identified.



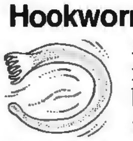
Homosexuality is more openly considered than it once was, but some homosexuals feel guilty about their sexual orientation. This may cause them to mask their feelings behind a cloak of apparent heterosexuality or to seek a medical cure.

CAUSES

Various theories have been put forward to explain homosexuality. Some studies have shown an increased incidence of homosexuality among men who had absent or weak fathers and who formed close emotional relationships with their mothers. Evidence for either a genetic tendency or a hormone imbalance is lacking.

The prevalence of homosexuality appears to be much the same in all cultures, with no change over thousands of years—suggesting that homosexuality is a consistent variation in behavior. (See also *Bisexuality*.)

Homozygote

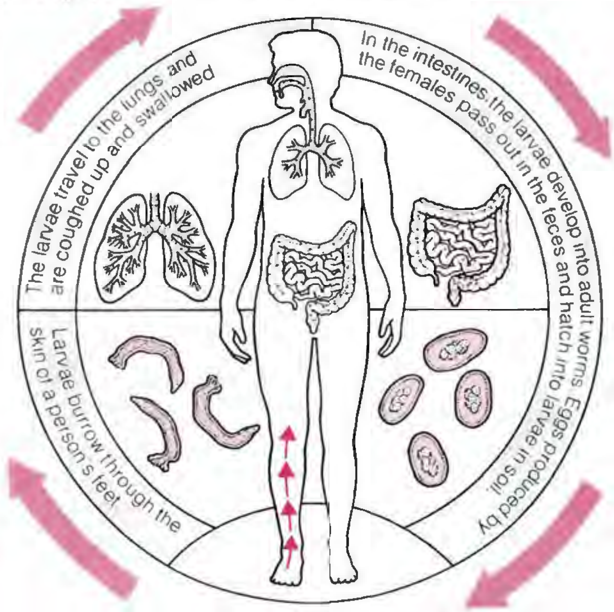


A term used to describe a person whose cells contain two identical *genes* controlling a specified inherited trait, in contrast to a *heterozygote*, whose cells contain two different genes controlling that trait. (See also *Inheritance*; *Genetic disorders*.)

Homunculus

From the Latin for "a little man." It may refer to a perfectly proportioned person of *short stature*; a fetus, by extension of the archaic theory that human germ cells contained minute human beings; a small model of a person, particularly one created by magic or alchemy; and, in psychiatry, a little man created by the imagination.

Hookworm infestation



An infestation of the small intestine by small, round, blood-sucking worms of the species *NECATOR AMERICANUS* or *ANCYLOSTOMA DUODENALE*. The worms are about half an inch long and have hooklike teeth.

HOOKWORM LIFE CYCLE

Infestation begins with larvae that penetrate the skin or are ingested and enter the bloodstream. They migrate throughout the body, particularly to the small intestine. Adult worms develop and lay eggs, which leave the body in feces and eventually hatch into larvae.

Head of hookworm
The hookworm uses its sharp, curved, toothlike structures to cling to the bowel

INCIDENCE AND CAUSES

Hookworms infest about 700 million people worldwide, mainly those living in poor countries in the tropics. There is very little risk of contracting a hookworm infestation in the US.

The illustration above shows how hookworms can enter and multiply in the body. In a heavy infestation, there may be several hundred worms in the intestine, consuming up to one tenth of a pint of blood every day.

SYMPTOMS AND COMPLICATIONS

When the larvae penetrate the skin, a red and intensely itchy rash may develop on the feet. This is called ground itch and may last for several days. In light infestations, no symptoms may be felt. In heavier infestations, migration of the larvae through the lungs may produce cough and pneumonia; the presence of adult worms in the intestines may cause vague abdominal discomfort.

By far the most important problem caused by a heavy infestation is iron-deficiency *anemia* due to loss of blood.

DIAGNOSIS AND TREATMENT

Diagnosis is made by microscopic examination of feces, which can reveal hookworm eggs. *Antihelmintic drugs*, such as mebendazole, kill the worms. Treatment also involves improving nutrition with a high-protein diet and correcting anemia with iron tablets or blood transfusion, if necessary. Elimination of the disease from a community depends on efficient sanitation. (See also *Larva migrans*.)

Hormonal disorders

See *Endocrine system*.

Hormonal methods of contraception

See *Contraception, hormonal methods*.

Hormone antagonist

A drug that blocks the action of a hormone. *Tamoxifen*, for example, blocks the effects of *estrogen hormones* and is used in the treatment of some types of breast cancer.

Hormone replacement therapy

The use of a synthetic or natural hormone to treat a hormone deficiency. In its broadest sense, the term describes the replacement of any deficient hormone, such as giving thyroxine to treat *hypothyroidism* or *insulin* to treat *diabetes mellitus*. More commonly, however, the term hormone replacement therapy refers to the use of *estrogen hormones* to treat symptoms accompanying the *menopause*.

WHY IT IS DONE

Estrogen replacement therapy is given to relieve menopausal symptoms such as hot flashes and excessive sweating

at night. Estrogen hormones help prevent atrophic *vaginitis* (dryness of the vagina) and shrinkage of the genitals, which may make sexual intercourse painful and difficult. Estrogen hormones also help prevent the development of *osteoporosis* (a bone disorder) and *atherosclerosis* (narrowing of the arteries causing impaired blood flow).

HOW IT IS DONE

In hormone replacement therapy, estrogen drugs are usually prescribed in combination with a *progesterone drug* (which can result in monthly spotting in place of menstruation) because estrogen drugs given alone may increase a woman's susceptibility to cancer of the uterus.

THE SOURCES AND MAIN EFFECTS OF SELECTED HORMONES

Section of body	Hormone secreted	Effects
Hypothalamus	Releasing hormones	Stimulate hormone secretion by pituitary gland
Pituitary gland	Growth hormone	Stimulates growth and metabolism
	Prolactin	Stimulates milk production after childbirth
	ACTH (adrenocorticotropic hormone)	Stimulates hormone production by adrenal glands.
	TSH (thyroid-stimulating hormone)	Stimulates hormone production by thyroid gland
	FSH (follicle-stimulating hormone); LH (luteinizing hormone)	Stimulate gonads (ovaries or testes)
	ADH (antidiuretic hormone)	Acts on kidneys to reduce urine production.
	Oxytocin	Stimulates contractions of uterus during labor and ejection of milk during breast-feeding
	MSH (melanocyte-stimulating hormone)	Acts on the skin to promote production of skin pigment (melanin)
Brain	Endorphins; enkephalins	Alleviate pain
Thyroid gland	Thyroid hormone	Increases metabolic rate; affects growth
	Calcitonin	Controls level of calcium in blood
Parathyroid glands	Parathyroid hormone	Controls level of calcium in blood
Thymus	Thymic hormone	Stimulates lymphocyte development
Adrenal glands	Epinephrine; norepinephrine	Prepare body for stress
	Hydrocortisone	Affects metabolism
	Aldosterone	Regulates sodium and potassium excretion by kidneys
	Androgens	Affect growth and, in women, sex drive
Kidneys	Renin	Regulates blood pressure
	Erythropoietin	Stimulates erythrocyte production
	Vitamin D	Controls calcium and phosphorus metabolism
Pancreas	Insulin; glucagon	Regulate blood sugar level
Placenta	Chorionic gonadotropin; estrogens; progesterone	Maintain pregnancy
Gastrointestinal tract	Gastrin; secretin; cholecystokinin	Regulate secretion of some digestive enzymes
Testes	Testosterone	Affects development of male secondary sexual characteristics and genital organs
Ovaries	Estrogens; progesterone	Affect development of female secondary sexual characteristics and genital organs; control menstrual cycle; maintain pregnancy

The various glands that make up the hormonal system constitute a control and communications network that is complementary to the nervous system. However, instead of using nerve impulses, the glands secrete chemical messengers (hormones) to affect other glands and tissues in various parts of the body. Hormones are carried in the bloodstream to their targets, where they exert their specific effects. This table lists the hormones secreted by different parts of the body and gives a description of their wide-ranging actions.

The drugs are usually taken orally in a three-stage cycle repeated each month—estrogen for the first 11 to 14 days, estrogen and progesterone for the next seven to 10 days, and no drugs for the last seven days.

Alternatively, an implant containing estrogen is placed under the skin of the abdomen. The estrogen is released slowly and progesterone is taken in tablet form.

Therapy is usually continued for between two and five years. Regular tests, including weight and blood pressure checks, breast and pelvic examinations, and cervical smears, are carried out to monitor the effects of the therapy. Occasionally, a *biopsy* of the lining of the uterus may be carried out to test for cancer.

POSSIBLE ADVERSE EFFECTS

Minor adverse effects include nausea, breast tenderness, fluid retention, and leg cramps. In some women, estrogen replacement therapy may increase the risk of abnormal blood clotting. It is therefore not usually given to women who smoke heavily or have suffered from *thrombosis*, *stroke*, liver disease, or severe *hypertension* (raised blood pressure). Women who have had cancer of the breast or uterus are also not usually given hormone replacement therapy because estrogen may increase the risk of recurrence.

Hormones

A group of chemicals (such as *cortisol*, *estrogen*, *insulin*, and *epinephrine*), each of which is released into the bloodstream by a particular gland or tissue to have a specific effect on tissues elsewhere in the body. Hormones control numerous body functions, including the *metabolism* (chemical activity) of cells, growth, sexual development, and the body's response to stress or illness.

Glands that primarily produce hormones make up the *endocrine system*, which comprises the *adrenal glands*, gonads (*ovaries* or *testes*), *pancreas*, *parathyroid glands*, *pituitary gland*, *placenta* (in pregnant women), and *thyroid gland*. Hormones are also secreted by other organs, including the kidneys, intestines, and brain.

Horn, cutaneous

A hard, noncancerous protrusion occasionally found on the skin (usually the face) of elderly people. Horns are slow growing and vary in color from yellow to brown to black. They may develop where there was previously a wart on normal skin.

Appearance of cutaneous horn
The horny protuberance that has developed under the arm results from an overgrowth of keratin (a skin protein).

Left untreated, they can grow to a considerable size and may protrude as much as 0.75 inch (2 cm). Surgical removal is usually recommended.

Horner's syndrome

A group of physical signs that affects one side of the face and indicates damage to part of the sympathetic nervous system (see *Autonomic nervous system*). The signs are narrowing of the pupil of the eye (miosis), drooping of the lid (ptosis), and absence of sweating (anhidrosis). They are caused by damage to or destruction of sympathetic nerve fibers, usually in the lower part of the neck, and may be the first sign of disease in the area.

Hornet stings

See *Insect stings*.

Horseshoe kidney

A congenital abnormality in which the two kidneys are joined at the base, forming a horseshoe shape, rather than being separate. Horseshoe kidney affects about one person in 600; it is twice as common in men.

The joined kidneys usually function normally and cause no problems.

Hospice

A hospital or part of a hospital devoted to the care of patients who are dying, often from one specified cause. One hospice may thus care only for AIDS patients, another for cancer patients, and another for those dying of old age (see *Dying, care of the*).

Hospitals, types of

The roughly 7,000 hospitals in the US, which maintain about 1.3 million beds, can be classified in many ways. There are government hospitals—federal, state, county, and municipal. Many hospitals are owned and run by religious orders. Though graduate medical education is conducted in many hospitals, teaching hospitals generally have a close affiliation with universities and medical schools. A growing number of hospitals are owned by for-profit corporations. Far more are community hospitals that depend on community-generated contributions. By far the largest number of hospitals are classified as short-term acute care general hospitals.

Hot flashes

Reddening of the face, neck, and upper trunk usually facilitated by decreased *estrogen hormone* production by the ovaries during or after the *menopause*. A hot flash typically lasts one to two minutes and is accompanied by a sensation of heat; it is often followed by sweating. Hot flashes are aggravated when the sufferer is under stress.

Hot flashes may also occur after a total *hysterectomy*, in which the uterus and the ovaries are removed. Occasionally, men experience hot flashes after *orchiectomy* (removal of a testis), which causes a reduction in testosterone levels. If hot flashes are severe, they can usually be alleviated by *hormone replacement therapy*.

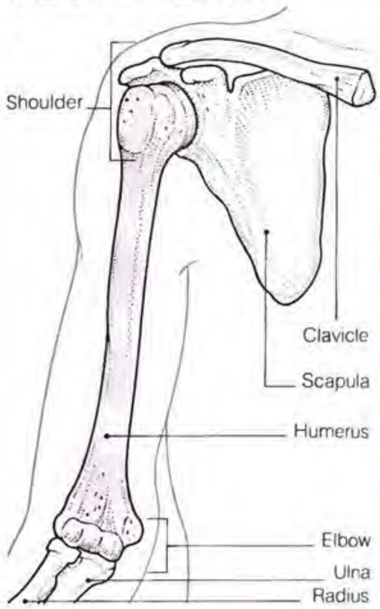
Housemaid's knee

Inflammation of the *bursa* that acts as a cushion over the kneecap. The inflammation is usually caused by prolonged kneeling, but may develop after a sharp blow to the front of the knee. (See also *Bursitis*.)

HTLV III

Human T-cell lymphotropic virus, strain III, a name once used for the virus that causes *AIDS*. The organism is now called *HIV*.

Human chorionic gonadotropin



See *Gonadotropin, human chorionic*.

Humerus

The bone of the upper arm. The smooth, dome-shaped head of the bone lies at an angle to the shaft and fits into a shallow socket in the scapula (shoulder blade) to form the shoulder joint. Below the head, the bone narrows to form a cylindrical shaft. It flattens and widens at its lower end, forming a prominence on each side called an epicondyle. At its base, the humerus articulates with the ulna and radius (the bones of the lower arm) to form the elbow.

H

LOCATION OF HUMERUS
The humerus is the bone of the upper arm, located between the shoulder and elbow joints.

A spiral groove in the shaft of the humerus carries the *radial nerve*, the major nerve of the arm.

Humerus, fracture of

The most usual site of fracture of the humerus (the bone of the upper arm), especially in the elderly, is at the neck of the bone, just below the head. Fracture of the lower end of the bone (a supracondylar fracture) occurs most commonly in children. The fracture may be accompanied by damage to the brachial artery. If injury to this artery goes undetected, it may impair circulation to the arm, resulting in *Volkmann's contracture*, a deformity of the forearm and hand due to muscle damage caused by *ischemia* (insufficient blood supply).

Any suspected fracture of the humerus is first X rayed. If the neck of the bone is found to be fractured, it usually requires only a sling to keep the bone immobilized; a supracondylar fracture usually needs to be put in a plaster cast.

A fractured humerus normally takes six to eight weeks to heal. However, supracondylar fractures sometimes fail to mend properly, resulting in deformity of the elbow.

Humors

Liquid or jellylike substances in the body. The term usually refers to the aqueous humor (the watery fluid in the front chamber of the *eye*) and vitreous humor (the jellylike substance in the rear chamber of the eye).

According to early medical theory, there were four humors—blood, phlegm, black bile, and yellow bile—that permeated the entire body and determined its state of health. This theory was generally discarded in the 17th century.

Hump back

See *Kyphosis*.

Hunch back

See *Kyphosis*.

Hunger

A disagreeable feeling caused by the need for food (as opposed to *appetite*, a pleasant sensation felt in anticipation of a meal).

Hunger occurs when the stomach is empty and when the blood sugar level is low. In response to these stimuli, the hypothalamus in the brain indirectly causes the muscular wall of the stomach to contract rhythmically, signaling the need for food; if pronounced, these contractions produce hunger pains.

Hunger caused by a low blood sugar level is usually the result of strenuous exercise. However, it can also occur in certain diseases (notably *thyrotoxicosis*, which is marked by a speeding-up of body processes) and insulin-dependent *diabetes mellitus* if an incorrect balance between insulin and carbohydrate intake causes *hypoglycemia*.

Huntington's chorea

An uncommon disease in which degeneration of the basal ganglia (paired nerve cell clusters in the brain) results in *chorea* (rapid, jerky, involuntary movements) and *dementia* (progressive mental impairment). Symptoms do not usually appear until the age of 35 to 50; in rare cases the condition is apparent in childhood.

Huntington's chorea is a *genetic disorder* with an autosomal pattern of inheritance. Because the age of onset of symptoms is generally so late, an affected person may bear children before realizing that he or she has the disease. Each child has a 50 percent chance of the condition developing. The disease develops in about 5 persons per 100,000 in the US.

SYMPTOMS

The chorea usually affects the face, arms, and trunk, resulting in random grimaces and twitches and general clumsiness. Dementia takes the form of personality and behavior changes, irritability, difficulty making decisions, memory loss, and apathy.

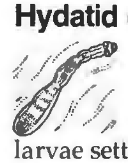
When the disease starts in childhood, it may be marked by loss of movement and muscle rigidity.

DIAGNOSIS

Until recently there was no way of detecting whether a child of a person with Huntington's chorea had inherited the abnormal gene responsible for the condition. As a result of recent advances in genetics, young adults with parents who have the condition can now learn, with 95 percent accuracy, whether or not they have the abnormal gene and thus have the disorder. This may affect their decisions on whether to have children themselves (see *Genetic counseling*).

TREATMENT AND OUTLOOK

There is no known cure. Treatment is aimed at lessening the chorea with drugs, such as chlorpromazine (which was investigational in 1987), and alleviating the effects of dementia with good nursing care.



Most sufferers survive for about 15 years after the onset of symptoms; some live for up to 30 years afterward.

Hurler's syndrome

A rare, inherited condition caused by an *enzyme* defect. Hurler's syndrome is a type of inborn error of *metabolism* in which there is an abnormal accumulation of substances called mucopolysaccharides in the tissues.

Affected children may appear normal at birth, but, between 6 and 12 months of age, cardiac abnormalities, umbilical hernia, skeletal deformities, and enlargement of the tongue, liver, and spleen develop. Physical growth is limited and mental development slows, leaving the child mentally retarded. The strange features of affected children gave the condition its former name of gargoylism.

Hydatid disease

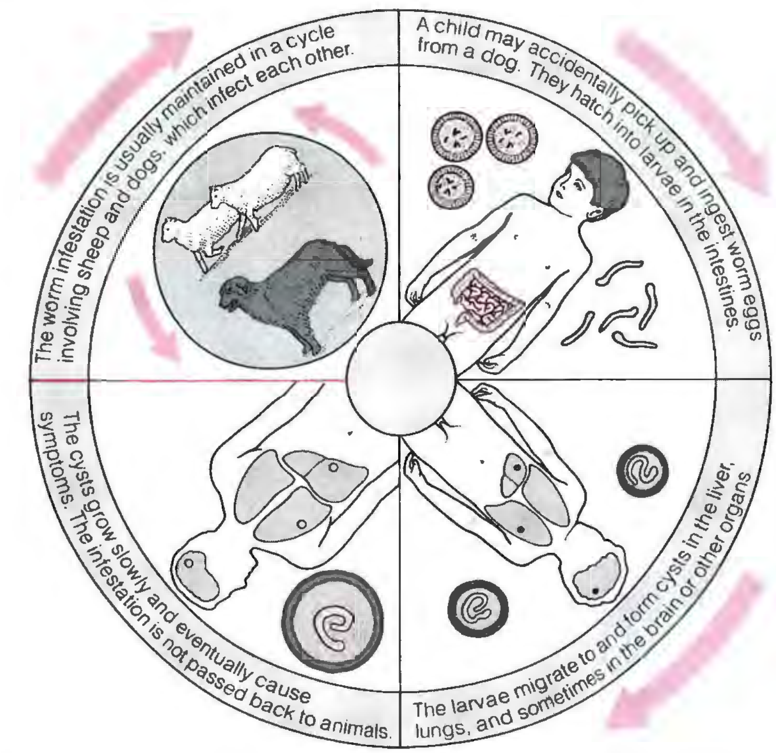
A rare infestation caused by the larval stage of the small tapeworm *ECHINOCOCCUS GRANULOSUS*. The larvae settle in the liver, lungs, or the brain or other organs and cause the development of slowly growing cysts.

CAUSE AND INCIDENCE

The illustration on the next page shows how eggs or larvae can enter the body.

Hydatid disease is prevalent only in areas of the world where sheep are reared with the aid of dogs, including

some parts of California and Utah. About 200 cases of hydatid disease are diagnosed in the US each year.



SYMPTOMS AND TREATMENT

Although the infestation is usually acquired in childhood, the cysts grow very slowly, so symptoms, if any, occur mainly in adults. In many cases there are no symptoms. However, a cyst in the liver may cause a tender, localized lump or lead to *bile duct obstruction* and jaundice. In the lungs, a cyst may press on an airway, causing *bronchitis*. Rupture of a cyst can cause chest pain, hemoptysis (coughing up blood), wheezing (if present in the lung), or *anaphylactic shock* (a severe allergic reaction). Cysts in the brain can cause seizures or other symptoms similar to those of a brain tumor.

Hydatid cysts are diagnosed by *CT scanning*. Treatment of cysts that are causing symptoms consists of surgical removal, or sterilization followed by drainage. Newer antiparasite drugs are under investigation.

ORIGINS OF HYDATID DISEASE

The infestation is generally confined to dogs and sheep, but occasionally a child swallows eggs from dog feces. These hatch into larvae, which migrate through the body, especially to the liver or lungs, to form slow-growing cysts. Symptoms may not appear until years later.

Hydatidiform mole

An uncommon benign tumor that develops from placental tissue during an early pregnancy in which the embryo has failed to develop normally. A hydatidiform mole, which resembles a bunch of small grapes, is caused by degeneration of the chorionic villi, minute fingerlike projections in the placenta. The cause of the degeneration is unknown.

INCIDENCE

A hydatidiform mole is the most common form of *trophoblastic* disease. It occurs in about one in 2,000 pregnancies in developed countries; the incidence is much higher in developing areas. In about 3 percent of affected pregnancies the growth develops into a *choriocarcinoma*, a malignant tumor that can invade the walls of the uterus if left untreated.

SYMPTOMS AND DIAGNOSIS

There is usually vaginal bleeding and excessive morning sickness. The diagnosis is made by *ultrasound scanning* and from urine and blood tests. The mole produces excessive amounts of the hormone human chorionic *gonadotropin* (HCG), which can be detected in urine and blood.

TREATMENT

The tumor can be removed either by suctioning out the contents of the uterus or by a *D and C*. A *hysterectomy* may be considered.

OUTLOOK

There is a small risk that a malignant tumor may develop later; for this reason, tests are performed regularly for several years to determine the levels of HCG in the blood and urine.

A woman should not become pregnant again until her HCG levels have returned to normal for at least a year. There is a one in 75 risk of the growth recurring in a future pregnancy.

Hydralazine

An *antihypertensive drug* that is particularly useful as an emergency treatment for *hypertension*. Hydralazine is often also used when the combination of *diuretic* and *beta-blocker drugs* fails to control high blood pressure.

Hydralazine may cause nausea, vomiting, headache, dizziness, and irregular heart beat. Less common adverse effects include loss of appetite, rash, and joint pain. When prescribed in high doses over a prolonged period, hydralazine may cause *lupus erythematosus*.

Hydramnios

Excess *amniotic fluid* in the uterus during pregnancy. Hydramnios occurs in about one in 250 pregnancies.

CAUSES

In many cases, there is no known cause for hydramnios. It sometimes occurs if the fetus has a malformation (particularly *anencephaly* or *esophageal atresia*) that makes normal swallowing impossible. Hydramnios may also occur if the pregnant woman has *diabetes mellitus*. It occurs in about 10 percent of multiple pregnancies.

SYMPTOMS AND SIGNS

An excess of amniotic fluid usually accumulates slowly during the second half of the pregnancy, producing symptoms from about week 32. The main symptom is abdominal discomfort. Other possible symptoms are breathlessness and edema of the legs. The uterus is larger than usual for the duration of the pregnancy.

Less commonly, the fluid accumulates rapidly, causing abdominal pain, breathlessness, nausea, and vomiting. The abdomen becomes tense, the overlying skin is stretched and shiny, and the legs swell. Hydramnios may cause premature labor and the baby may not be in the usual delivery position (see *Malpresentation*).

DIAGNOSIS

Hydramnios is usually evident from the patient's history and a physical examination. *Ultrasound scanning* is needed to detect fetal abnormality or multiple pregnancy.

TREATMENT

In the case of severe fetal abnormality, a therapeutic *abortion* may be performed. Mild cases without fetal abnormality require no treatment other than extra rest. Withdrawal of amniotic fluid via a needle inserted through the abdominal wall can provide relief in severe cases although the procedure may cause premature labor. If the pregnant woman has diabetes mellitus, careful attention must be paid to her diabetic control. If symptoms occur in late pregnancy, *induction of labor* may be performed to deliver the baby early.

Hydrocele

A soft, painless swelling in the scrotum caused by the space around the testis filling with fluid. A hydrocele is sometimes caused by inflammation, infection, or injury to the testis. Occasionally, a tumor may cause fluid to accumulate, but in most cases there is no apparent cause. Hydroceles occur very commonly in middle-aged men.

Treatment is rarely necessary. If the swelling is large enough to be uncomfortable or painful, the fluid may be aspirated (drawn off through a hollow needle) using local anesthetic. The most common surgical method of dealing with recurrent swelling is to remove the lining around the testis.

Hydrocephalus

An excessive amount of *cerebrospinal fluid*, usually under increased pressure, within the skull. The term "water on the brain" is sometimes used to describe the condition. Hydrocephalus is often associated with other congenital abnormalities, particularly *spina bifida*.

CAUSES

The condition may be *congenital* (present at birth) or may develop as a result of major head injury, brain hemorrhage, infection (*meningitis*, for example), or a tumor.

Hydrocephalus is caused by excessive formation of cerebrospinal fluid, by a block in the circulation of this fluid, or both.

SYMPTOMS

When the condition is congenital, the main feature is an enlarged head that continues to grow at an abnormally fast rate because the bones are not rigid and expand to accommodate the fluid. Other features are rigidity of the legs, *epilepsy*, irritability, lethargy, vomiting, and the absence of normal reflex actions. If the condition is not treated, it progresses to extreme drowsiness, severe brain damage, and seizures, which may lead to the baby's death within a matter of weeks.

Infant with hydrocephalus
Skull enlargement is due to pressure from excess fluid within the cavities of the brain. To prevent brain damage, the fluid must be drained by means of a tube inserted through a hole made in the skull.

When the condition occurs later in childhood or in adulthood, the skull is no longer flexible and symptoms are caused by raised pressure within the skull. Symptoms include headache, vomiting, loss of coordination, and deterioration of mental function.

DIAGNOSIS AND TREATMENT

CT scanning or *MRI* show the location and nature of any obstruction.

In most cases, treatment aims to drain excess fluid away from the brain to another part of the body, such as the lining of the abdomen or chest wall, where it can be absorbed. Drainage is achieved by means of a *shunt* (tube), which is inserted into the brain through a hole made in the skull. In some cases, the shunt must be left in position indefinitely. In older children and adults, treatment is sometimes for the underlying cause only.

Hydrochloric acid

A strong acid released by the stomach lining. It forms part of the stomach juices and is important in the digestion of proteins. Excessive acid production, which may be stimulated by stress or tobacco smoking, is an important factor in the development of *peptic ulcers*. *Acid reflux* (regurgitation of stomach acid into the esophagus) resulting in *esophagitis* and heartburn is another problem created by hydrochloric acid secretion. (See also *Digestive system*.)

Hydrochlorothiazide

A thiazide *diuretic drug* used to reduce *edema* (fluid retention) in people with *heart failure* (reduced pumping efficiency), *nephrotic syndrome* (a kidney disorder), *cirrhosis* of the liver, and breast tenderness before menstruation. Hydrochlorothiazide is also given to treat *hypertension* (high blood pressure), and is occasionally used to prevent the recurrence of certain types of kidney stones.

POSSIBLE ADVERSE EFFECTS

Adverse effects include leg cramps, lethargy, dizziness, rash, and impotence. Hydrochlorothiazide may (rarely) cause *gout* and may aggravate *diabetes mellitus*.

Hydrocortisone

CORTICOSTEROID

Tablet Injection Rectal suppository
Cream Eye drops

Prescription sometimes needed

Available as generic

A *corticosteroid drug* sometimes used to treat inflammatory and allergic disorders, such as *dermatitis*, *uveitis*, *ulcerative colitis*, types of *arthritis*, and *asthma*. Hydrocortisone is chemically identical to *cortisol*, a hormone produced by the adrenal glands. Hydrocortisone is therefore given to replace this hormone when the amount produced by the body is insufficient, as in *Addison's disease*.

POSSIBLE ADVERSE EFFECTS

Hydrocortisone creams used in excess may cause thinning of the skin. Taken by mouth over a prolonged period, high doses of hydrocortisone may cause *diabetes mellitus*, *glaucoma*, *osteoporosis*, *peptic ulcer*, fluid retention, weight gain, acne, muscle weakness, mood changes, and retarded growth in children.

Hydrogen peroxide

An *antiseptic* solution used to treat infections of the skin or mouth and to bleach hair. Hydrogen peroxide combines with catalase, an enzyme present in the skin and mouth, to release oxygen. This effect kills bacteria and cleanses infected areas. Hydrogen peroxide occasionally causes soreness and irritation.

Hydronephrosis

A condition in which the kidney becomes distended with urine due to a blockage or narrowing of the *ureter*. If

left untreated, hydronephrosis can severely damage the kidney and, if bilateral, cause *renal failure*.

CAUSES

Obstruction of a ureter is usually caused by a stone (see *Calculus, urinary tract*), a *kidney tumor*, or sometimes by a blood clot. Alternatively, the urine in the bladder may be under pressure caused by obstruction of its outflow from an enlarged prostate gland. In some cases, constriction of the ureter is present from birth.

SYMPTOMS AND SIGNS

Acute hydronephrosis, with sudden blockage of the ureter, results in severe pain in the small of the back. Chronic hydronephrosis, in which the obstruction develops slowly, may, however, cause no symptoms until the ureter has become completely blocked and renal failure occurs. There is also a risk that the kidney may become infected, resulting in pyonephrosis (pus-filled kidney).

DIAGNOSIS AND TREATMENT

Ultrasound scanning can provide an image of the kidneys and ureter. If it reveals obstruction and the kidney is still relatively healthy, the blockage is removed or relieved by surgery; the kidney soon resumes normal functioning. Occasionally, however, the kidney is so badly damaged that it requires removal (see *Nephrectomy*). In this case, the remaining kidney compensates for the loss of the other.

Hydrophobia

A popular term—now almost obsolete—for *rabies*. Meaning "fear of water," hydrophobia refers to the inability to drink that is one of the characteristic symptoms of rabies.

Hydrops

An abnormal accumulation of fluid in the body tissues or in a sac (such as the gallbladder). Hydrops fetalis is marked generalized *edema* (fluid collection causing tissue swelling) affecting the fetus. It may occur in pregnancy as a result of severe *hemolytic disease of the newborn*.

Hydrotherapy

The external use of water to treat patients recovering from injury or suffering from lack of mobility. It includes the use of exercise pools, whirlpool baths, and showers.

People who are unable to bear full weight on a limb (because of arthritis or after a fracture, for example) often can exercise more fully and effectively in a hydrotherapy pool. The buoyant effect of the water allows a greater range of movement and permits fuller use of the limb with little discomfort.

Warm whirlpool baths provide a gentle massage to stimulate areas of the body and relieve stiffness. Cold baths or showers can reduce blood flow, swelling, and bruising after injury and minimize tissue damage. (See also *Heat treatment*; *Ice packs*.)

Hydroxocobalamin

A long-acting synthetic preparation of *vitamin B_{12}*.

Hydroxyprogesterone

A *progesterone drug* given by injection to treat cancer of the uterus (see *Uterus, cancer of*) and certain types of *breast cancer*.

Hydroxyzine

An *antihistamine drug* commonly used in the treatment of *urticaria* (hives) and other allergic rashes. Hydroxyzine is also used as a *premedication* before surgery, in the management of alcohol withdrawal, and, occasionally, in the short-term treatment of mild anxiety. It is also used to relieve nausea and vomiting in *motion sickness*, *vertigo*, and following a general anesthetic.

Possible adverse effects include drowsiness, dry mouth, and tremor.

Hygiene

The science and practice of preserving health. Today the word is commonly equated with cleanliness. However, in the early years of this century the term hygiene was widely used as an equivalent to *public health*—the scientific study of environmental influences on health (especially the provision of pure water supplies, safe sanitation, good housing, and safe conditions in the workplace).

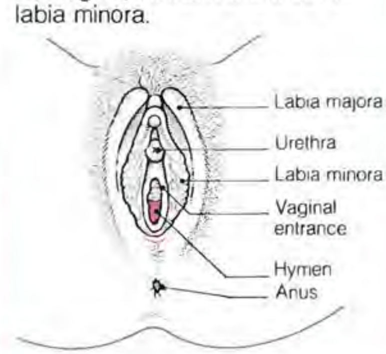
Hygiene, oral

See *Oral hygiene*.

Hygienist, dental

A licensed professional who is qualified to carry out *scaling* (the removal of calculus from the teeth) and to demonstrate methods of keeping the teeth and gums healthy (see *Oral hygiene*). Keeping the teeth and gums healthy is especially important in preventing or controlling gum disorders occurring in middle life, such as *gingivitis* and *periodontitis*.

Hygroma, cystic



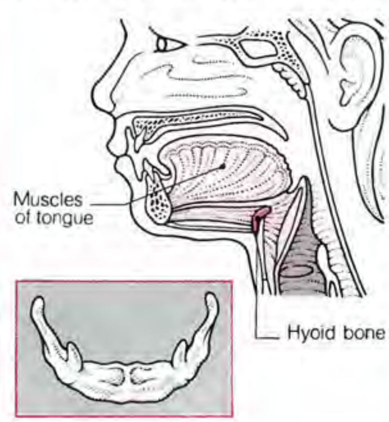
A type of *lymphangioma*.

Hymen

The thin fold of membrane surrounding the vaginal opening. The hymen has a central perforation that is usually stretched or torn by the use of tampons or during first sexual intercourse. Once torn, the hymen becomes an irregular ring of tissue around the vaginal opening.

LOCATION OF HYMEN

The membrane that forms the hymen surrounds the opening to the vagina, inside the woman's labia minora.



Imperforate hymen is a rare condition in which the hymen has no perforation; at the onset of menstruation, menstrual blood collects in the vagina, causing lower abdominal pain. It is corrected by minor surgery.

Hyoid

A small, U-shaped bone situated deep in the muscles at the back of the tongue. It is not joined to any other bone but is suspended by ligaments

LOCATION OF HYOID BONE

The U-shaped hyoid bone provides an anchor for the muscles at the back of the tongue.

from the base of the skull. Its function is to provide an anchor point for the muscles of the tongue and for those in the upper part of the front of the neck.

The hyoid is commonly fractured in homicidal strangulation.

Hyoscyamine

An *anticholinergic drug* used to treat the spasm of the bladder muscle that occurs with an *irritable bladder* and the spasm of the intestinal wall that accompanies *irritable bowel syndrome*.

Hyper-

A prefix meaning above, excessive, or greater than normal, as in *hypertension* (raised blood pressure) and *hyperthyroidism* (overactivity of the thyroid gland).

H

Hyperacidity

A condition in which an excessive amount of acid is produced by the stomach. Hyperacidity is commonly confused with *acid reflux* (which causes a burning sensation in the upper abdomen or lower chest) or a sudden filling of the person's mouth with a fluid (water brash). Most people with a duodenal ulcer (see *Peptic ulcer*) produce more acid than normal, and those with *Zollinger-Ellison syndrome* produce vast amounts.

Hyperactivity

A behavior pattern of certain children who are constantly overactive and have difficulty concentrating on one activity. Also known as hyperkinetic syndrome, the condition may affect as many as 5 to 10 percent of children in the US. It is four to five times more common in boys than girls.

CAUSES

It has been suggested that some hyperactive children, especially those who are clumsy, may have a subtle form of "minimal" brain damage. However, there is no definite, conclusive evidence. Hyperactive children seem more likely to have fathers who were hyperactive, so the condition may be partly inherited. Children with *mental retardation, cerebral palsy*, or *temporal lobe epilepsy* are also more likely to be hyperactive.

SYMPTOMS

The main feature of hyperactivity is continual overactivity, which is often worse in the classroom or in a group situation; it may not be evident during an interview by a physician. Hyperactive children are always on the go, full of energy, fidgety, and seem to sleep less than their peers. In addition, they tend to be impulsive and reckless, with no sense of danger, and are usually irritable, emotionally immature, and aggressive. Their attention span is short and, as a result, they do not conform to orderly routine.

Hyperactivity often leads to antisocial acts and difficulty learning, although IQ is normal. It is uncertain whether this behavior is a part of the disorder or simply a result of an affected child's poor attention span and disruptive activity.

DIAGNOSIS

Overactivity in itself does not indicate that hyperactivity is present, since overactivity can be caused by a stressful home environment or physical illness. In addition, many of the behavioral problems mentioned are, to some degree, common to all young children. However, when other causes have been eliminated and the behavior continues past the age of 4 years, is intense, and is different from that of "normal" children, then it is reasonable to regard the child as being hyperactive.

TREATMENT

Paradoxically, *stimulant drugs* (amphetamine or methylphenidate) seem to be the most effective treatment. This suggests that hyperactivity results from "underarousal" of the midbrain, which causes no damping down or control of movements and sensations. Stimulant drugs seem to work by stimulating the midbrain enough to suppress the extra activity. Behavior therapy and counseling of the child and parents are also useful.

Diets that exclude certain artificial food colorings, additives, or foods are popular and heavily promoted, but research has shown that these diets benefit very few children.

Hyperactive children should have formal educational and psychological assessment; many need help at school with reading and spelling.

OUTLOOK

In many cases, hyperactivity disappears completely at puberty. In others, the overactivity subsides and is replaced by sluggishness, depression, and moodiness; these teenagers often fail at school and resort to antisocial and criminal behavior. Sometimes all the symptoms of hyperactivity continue into adult life.

Hyperacusis

An exceptionally developed sense of hearing. It may cause the sensation of pain or discomfort in the ears on exposure to loud noises.

Hyperaldosteronism

An alternative name for *aldosteronism*, or Conn's syndrome, a metabolic disorder caused by overproduction of the hormone aldosterone (secreted by the cortex of the adrenal gland).

Hyperalimentation

Administration of nutrients to patients unable to take food by mouth. (See *Feeding, artificial*.)

Hyperbaric oxygen treatment

A method of increasing the amount of oxygen in the tissues by exposing a person to oxygen at a much higher than normal atmospheric pressure.

WHY IT IS DONE

The technique is occasionally used to treat poisoning from *carbon monoxide*, in which the tissues are starved of oxygen because *hemoglobin* (the oxygen-carrying component of red blood cells) is prevented from taking up oxygen. Hyperbaric oxygen treatment is also used in cases of gas *gangrene*; the bacteria that infect gangrenous tissue cannot survive if they are oxygenated.

HOW IT IS DONE

The patient is placed in a chamber into which oxygen is pumped at up to three times normal atmospheric pressure for no more than three hours. The oxygen is inhaled and dissolves in the blood.

Hyperbilirubinemia

A raised blood level of bilirubin (a waste product formed from the destruction of red blood cells). Hyperbilirubinemia may be undetectable except by a blood test, but *jaundice* becomes apparent if the blood bilirubin level rises to two times the normal level. Both have similar causes and implications.

Hypercalcemia

An abnormally high level of calcium in the blood. Normally the blood carries (in the plasma) less than 0.1 percent of the body's total amount of calcium—the optimum amount for the efficient functioning of cells throughout the body. A raised level or a lowered one (hypocalcemia) may seriously disrupt cell function, particularly in muscles and nerves.

CAUSES

The most common cause of hypercalcemia is secondary *bone cancer*, which releases calcium from an affected bone into the blood. Other causes include *hyperparathyroidism* (overproduction of parathyroid hor-

mone, which helps control the blood calcium level); certain inflammatory disorders, such as *sarcoidosis;* taking too much vitamin D, which helps regulate the absorption of calcium from the diet; a diet too rich in foods containing calcium; or, infrequently, taking large amounts of calcium-containing antacids.

SYMPTOMS

Mild hypercalcemia causes nausea, vomiting, lethargy, and excessive urination. Higher levels of calcium in the blood produce confusion, extreme fatigue, and muscle weakness. If the disorder is untreated and the blood calcium level continues to increase, arrhythmia (irregular heart beat), coma, and even death may result. Long-standing mild hypercalcemia may cause kidney calcifications, or stones, to form.

DIAGNOSIS

The condition is diagnosed by tests that measure the blood calcium level. If the diagnosis is confirmed, more tests are performed to discover and treat the underlying cause.

Hypercapnia

Excessive carbon dioxide in the blood. Carbon dioxide is a waste product of the metabolic processes that produce energy in body cells; dissolved in body fluids, it forms carbonic acid. The blood circulation carries the acid to the lungs, where it is eliminated from the body as carbon dioxide during exhalation. The amount of carbonic acid in the blood is normally maintained within narrow limits by mechanisms such as the breathing rate. However, if these mechanisms fail to remove enough carbon dioxide from the body (which may occur as a result of impaired breathing), carbonic acid accumulates and the blood becomes too acidic, a condition called *acidosis.*

Hyperemesis

The medical term for excessive *vomiting,* as in hyperemesis gravidarum (vomiting during pregnancy that causes dehydration and weight loss).

Hyperglycemia

An abnormally high level of glucose (sugar) in the blood. The condition occurs in people suffering from untreated or inadequately controlled *diabetes mellitus;* it may also occur in diabetics as a result of an infection, stress, or surgery.

The symptoms of hyperglycemia are the same as those of diabetes: thirst, the passing of large amounts of urine, *glycosuria* (glucose in the urine), and *ketosis* (an accumulation of ketones in the body). In severe cases, hyperglycemia may lead to confusion and coma, which require emergency medical treatment with insulin and an intravenous infusion of fluids.

Hypergonadism

Overproduction of estrogen or androgen *hormones* by the *ovaries* or *testes,* causing precocious sexual development and excessive growth.

Hyperhidrosis

A disorder marked by excessive sweating that occurs at times other than in hot conditions or during or just after exercise. It usually begins at puberty and worsens in the summer, affecting the palms, soles, armpits, or all three. Hyperhidrosis may cause the sufferer distress. The constantly moist hands that result may rule out certain occupations and activities, and excessively sweaty armpits or feet may produce an unpleasant *body odor,* which can cause social embarrassment. In many sufferers, the condition improves on its own in the middle 20s or early 30s.

TREATMENT

Treatment includes taking *anticholinergic drugs* and applying aluminum chloride paint to the affected areas to block the sweat pores. Wearing clothing and shoes made of natural, absorbent materials (such as cotton and leather) can be helpful.

Hyperkeratosis

Thickening of the outer layer of the skin due to an increased amount of *keratin* (a tough protein that is the major component of the outer layer of skin). The most common forms of hyperkeratosis are *corns* and *calluses,* caused by prolonged pressure or friction, and *plantar warts.* Hyperkeratosis also occurs in *lichen planus.*

The term is also used to describe thickening of the nails in people with a fungal nail infection or in people with *psoriasis* (a skin condition).

Hyperkinetic syndrome

Another name for *hyperactivity.*

Hyperlipidemias

A group of metabolic disorders characterized by high levels of lipids in the blood. Hyperlipidemias are the most common of the lipid disorders and are an important factor in the health disorders of middle-aged, sedentary people.

TYPES

There are six types of hyperlipidemia, differentiated principally by the extent to which the blood levels of various fatty substances are higher than normal. The characteristics of each type of hyperlipidemia, along with their symptoms and treatment, are given in the table on the next page. Many of the types produce similar symptoms; diagnosis usually depends on blood tests to measure the levels of lipids.

Lipids are carried in the blood in several forms, chiefly cholesterol, triglycerides, and lipoproteins. Lipoproteins consist of fat and cholesterol molecules linked to protein molecules. There are different types: very low-density lipoproteins (VLDLs), low-density lipoproteins (LDLs), and intermediate-density lipoproteins (IDLs). There are also high-density lipoproteins (HDLs), but they are not involved in the hyperlipidemias. Lipoproteins are differentiated according to their relative proportions of cholesterol and protein. The higher the proportion of cholesterol, the lower the density of the lipoprotein. Chylomicrons (microscopic droplets in the blood containing triglycerides, cholesterol, and protein) are usually also classed as lipoproteins.

CAUSES

Each type of hyperlipidemia may be inherited or may be secondary to another disorder. The main secondary causes for each type are: Type I—systemic lupus erythematosus (SLE); Types IIa and IIb—hypothyroidism, nephrotic syndrome, Cushing's syndrome, and corticosteroid therapy; Type III—hypothyroidism and SLE; Types IV and V—diabetes mellitus, obesity, alcoholism, nephrotic syndrome, renal failure, and corticosteroid therapy or estrogen therapy.

RISKS

There is some evidence that the hyperlipidemias are associated with a number of serious disorders, notably *atherosclerosis* and *coronary heart disease.* For this reason, if a close relative has or had either of these disorders, particularly if he or she has had a heart attack at an early age (under 50), other members of the family should be tested. Treatment is given to reduce the blood lipid levels and thus lower the risk of atherosclerosis.

Hypermetropia

See *Hyperopia.*

TYPES OF HYPERLIPIDEMIA

Type	Lipoprotein elevated	Blood cholesterol level	Blood triglyceride level	Symptoms and signs in addition to risk of heart disease	Treatment
I	Chylomicrons	Small elevation	Large elevation	Fatty nodules in skin; abdominal pain; inflammation of pancreas	Diet very low in fats
IIa	Low-density lipoproteins	Small to medium elevation	Normal	Fatty nodules around tendons (especially Achilles tendon and hand tendons) and over joints; white line around rim of cornea	Diet low in saturated fats and cholesterol; cholestyramine, colestipol, lovastatin, or clofibrate may be prescribed
IIb	Low-density and very low-density lipoproteins	Small to medium elevation	Small elevation	Fatty nodules on eyelids; white line around rim of cornea	Diet low in saturated fats, cholesterol, and carbohydrates; cholestyramine, lovastatin, or colestipol may be prescribed
III	Intermediate-density lipoproteins	Small to medium elevation	Small to medium elevation	Fat deposits in palms and sometimes over joints	Diet low in fats and carbohydrates; clofibrate, niacin, gemfibrozil, or lovastatin may be prescribed
IV	Very low-density lipoproteins	Normal	Small to medium elevation	Fatty nodules in skin; patient is often obese	Diet low in carbohydrates; weight reduction; clofibrate and sometimes niacin and gemfibrozil may be prescribed
V	Chylomicrons and very low-density lipoproteins	Small elevation	Small to medium elevation	Fatty nodules in skin; abdominal pain; inflammation of pancreas; patient may be obese	Diet low in fats and carbohydrates; weight reduction; gemfibrozil and niacin may be prescribed

Hypernephroma

An alternative name for renal cell carcinoma, a type of *kidney cancer*.

Hyperopia

Commonly called farsightedness, an error of *refraction* that initially causes difficulty in seeing near objects and then affects distance vision. Hyperopia tends to run in families.

Hyperopia is caused by the eye being too short from front to back, so that images are not clearly focused on the retina. Mild or moderate hyperopia in the young is overcome by *accommodation* (the action of the ciliary muscles to change the shape of the lens), which brings the point of focus forward to produce a clear image.

SYMPTOMS AND SIGNS

The error is present from early childhood, but symptoms generally do not appear until later life. The more severe the hyperopia, the lower the age at which the problem appears. People with hyperopia experience varying degrees of difficulty viewing close objects because the power of accommodation declines with age. In time, distant objects are also blurred. Hyperopia may lead to *eyestrain*. Neither blurred images nor eyestrain permanently affects vision.

TREATMENT

When blurred vision occurs, an ophthalmologist may prescribe *glasses* or *contact lenses* with convex lenses to reinforce focusing power.

Hyperparathyroidism

Overactivity of the *parathyroid glands*. These pea-sized glands are embedded in the thyroid gland in the neck and produce parathyroid hormone. This hormone, together with vitamin D and calcitonin (a hormone produced by the thyroid gland), controls the level of calcium in the body. Overproduction of parathyroid hormone raises the level of calcium in the blood (a condition called *hypercalcemia*) by removing the mineral from bones, leading to *osteoporosis* and *osteomalacia* (weakening of the bones).

In an attempt to normalize the high blood calcium level, the kidneys excrete large amounts of calcium in the urine, which can result in the formation of kidney stones (see *Calculus, urinary tract*).

CAUSES AND INCIDENCE

Hyperparathyroidism is most often caused by a small benign tumor of one or more of the parathyroid glands. However, sometimes it is due to an enlargement of the glands, the cause of which is unknown.

About 40 persons per 100,000 suffer from the disorder. It usually develops after the age of 40 and is twice as common in women as men.

SYMPTOMS

Hyperparathyroidism may cause generalized aches and pains, depression, and abdominal pain. Often, the only symptoms are those of kidney stones, but if the hypercalcemia is severe, it may cause nausea, vomiting, tiredness, excessive urination, confusion, and muscle weakness.

DIAGNOSIS AND TREATMENT

The condition is diagnosed by X rays of certain bones and by tests to measure the level of calcium, phosphorus, and parathyroid hormone in the blood.

Surgical removal of all abnormal parathyroid tissue usually cures the condition; sometimes all but part of one gland requires removal. In this

case, the remaining parathyroid tissue may not produce enough hormone. The affected person may then require treatment for *hypoparathyroidism* (underactivity of the glands).

Hyperplasia

Enlargement of an organ or tissue due to an increase in the number of its constituent cells. The new cells are normal, unlike those of a tumor.

Hyperplasia is usually the result of hormonal stimulation. It may be a normal occurrence (such as in the enlargement of breast tissue and uterine muscle that occurs during pregnancy) or it may indicate a disorder (such as in hyperplasia of the thyroid or adrenal glands, which may be due to oversecretion of certain pituitary hormones). See also *Hypertrophy*.

Hyperplasia, gingival

Swelling of the gums. The condition may be a feature of *gingivitis* (inflammation of the gums), especially when it occurs during pregnancy; it can also develop around the front teeth as a result of persistent breathing through the mouth. Hyperplasia can also be caused by phenytoin, the anticonvulsant drug used to treat *epilepsy*.

Ill-fitting dentures can cause rolls of fibrous tissue to form beyond the edges of the dentures. This can be irritating and may require surgical treatment. Whatever the cause, gingival hyperplasia should be checked by a dentist.

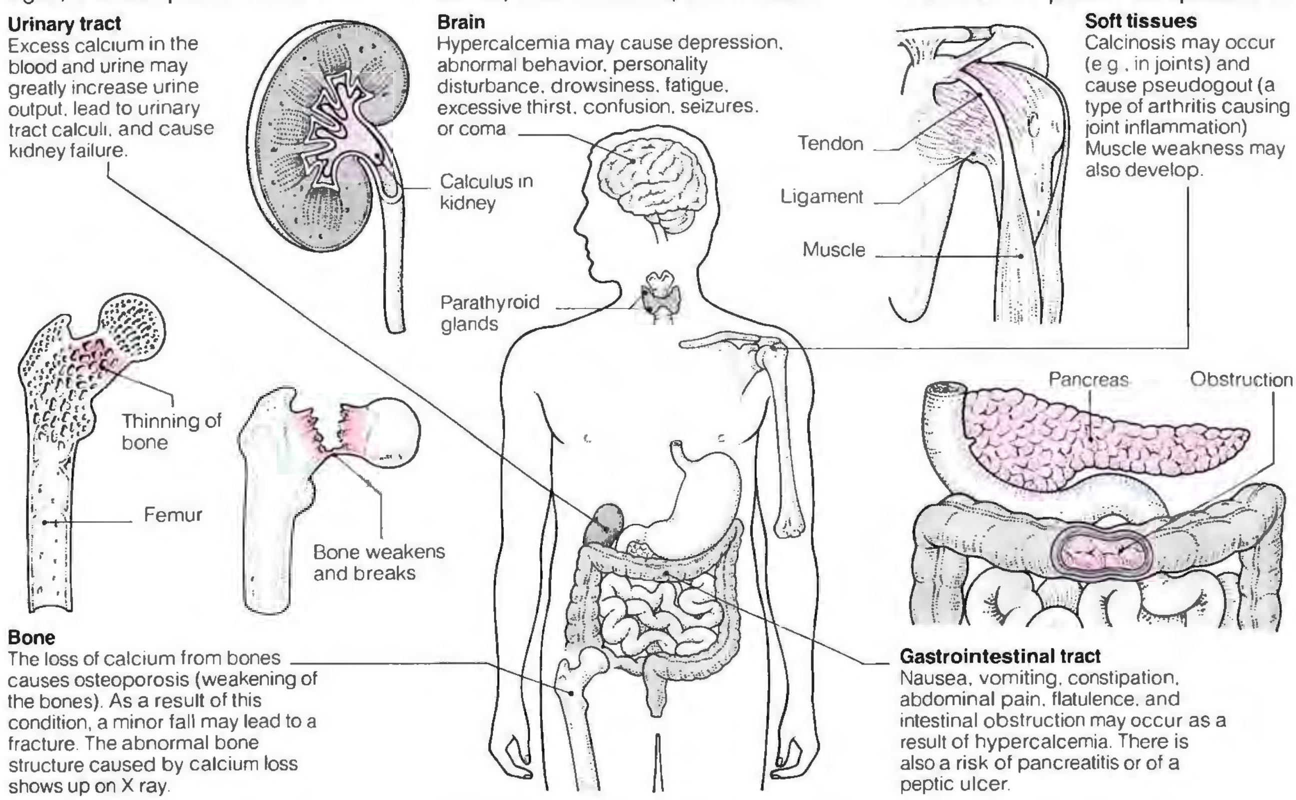
Hyperpyrexia

A medical term for extremely high body temperature; it is synonymous with hyperthermia. Heat hyperpyrexia is a term for *heat stroke*.

Hypersensitivity

An overreaction of the *immune system* (defense against infection) to an *antigen* (protein recognized as foreign). Hypersensitivity reactions occur only on second or subsequent exposures to particular antigens, after the first exposure has sensitized the immune system. Such reactions have the same mechanisms as those of protective *immunity*. However, while the latter protect against disease, hypersensitivity reactions lead to tissue damage and disease.

Hypersensitivity is closely related to *allergy*, except that only one of the four main types of hypersensitivity reaction (type I) is closely associated with allergic illnesses.

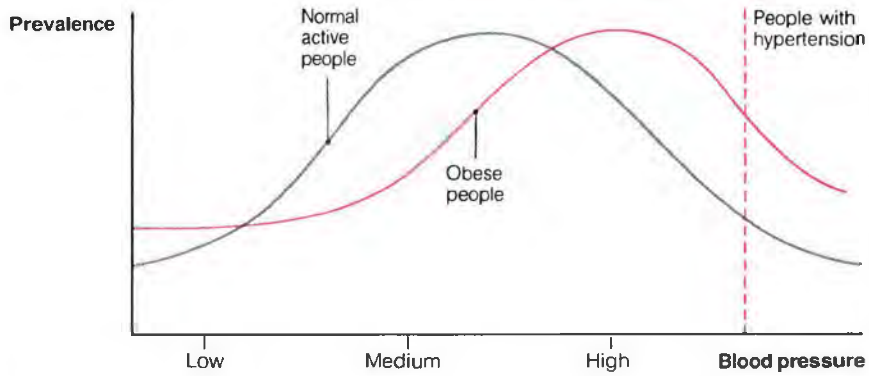


TYPES

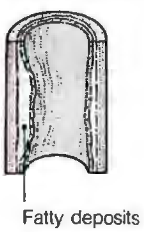
The four main types of hypersensitivity reaction are as follows.

TYPE I This type is also called immediate or anaphylactic hypersensitivity. After a first exposure to an antigen (which may be a harmless substance such as grass pollen), *antibodies* (substances that can recognize and bind to the antigen) are formed; these antibodies coat cells called mast cells in various tissues. On second exposure, the antigen and antibodies combine, causing the mast cells to disintegrate and release various chemicals that cause the symptoms of *asthma*, allergic *rhinitis* (hay fever), *urticaria* (hives), *anaphylactic shock*, or other illnesses of an allergic nature.

HYPERPARATHYROIDISM

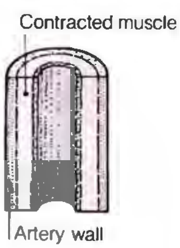


In this disorder, the parathyroid glands produce too much parathyroid hormone. Symptoms, signs, and complications of the disorder occur as a result of an increased calcium level in the blood and urine, the loss of calcium from bones, and calcinosis, the formation of calcium deposits in different tissues. Surgical removal of abnormal parathyroid tissue is carried out to prevent complications.

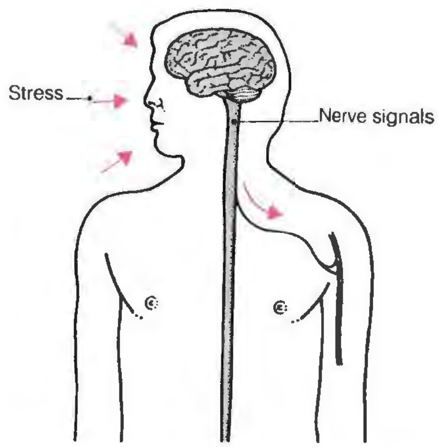


HYPERTENSION

Hypertension is a common condition, affecting up to 10 percent of adults in the US. It is diagnosed if a person's resting blood pressure is persistently raised. Blood pressure is expressed by two values—the systolic and diastolic pressures (see bottom right) and measured in millimeters of mercury.



Although hypertension rarely causes symptoms, it is an important condition. Left untreated, it increases the risk of stroke and other disorders. In many cases, there is no obvious cause, but, in some, there is a specific cause, such as a kidney disorder, pregnancy, or use of oral contraceptives. Hypertension is linked to obesity and, in some people, to a high salt intake. Smoking appears to aggravate the effects of hypertension.



Variation in blood pressure
In any population, blood pressure varies over a wide range in the same way as height. Many people are considered to be hypertensive because they are at the top end of this range (see above). In obese people, the range is similarly wide but shifted toward the top end; hence, more obese people are hypertensive.

Atheroma
Hypertension and atherosclerosis, in which arteries are narrowed (left), are closely linked both to each other and to obesity.

Constriction
Factors such as nicotine in tobacco cause artery constriction (left) and a short-term rise in blood pressure that may worsen hypertension.

Stress and hypertension
Stress acts on the nervous system, causing blood vessels to constrict and the heart to work harder. Both lead to a temporary rise in blood pressure. Hence, pressure should be measured when a person is relaxed. It is possible (but unproven) that frequent stress may eventually cause hypertension.

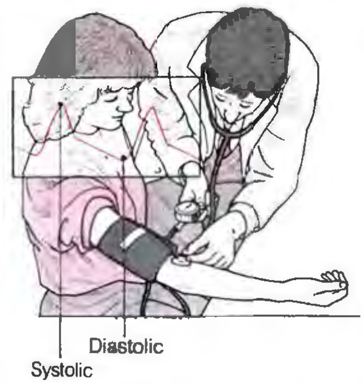
COMMON FACTORS AND PREVENTIVE MEASURES

Factors associated with essential hypertension	Age (incidence higher in the elderly)		Family history	Race (incidence higher in blacks than in whites)	
Factors that may aggravate hypertension	Smoking	Obesity	Excess alcohol intake	Diabetes mellitus	Stress

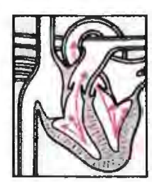
Self-help and treatment

1. Regular screening of blood pressure is important for early diagnosis and can help prevent complications.

2. Sufferers from essential hypertension should:



Reduce weight Not smoke Reduce or stop alcohol intake



Reduce salt intake Learn relaxation methods to combat stress

3. Antihypertensive drugs, prescribed by a physician, can usually keep high blood pressure under control.

MEASURING BLOOD PRESSURE

During one heart beat, pressure varies between the (higher) systolic and the (lower) diastolic pressures.

Systolic pressure
The systolic pressure is the maximum pressure attained as blood surges into the arteries.

Diastolic pressure
The diastolic pressure is the lowest value to which the pressure drops.

TYPE II In this type, antibodies are formed that bind to antigens bound to cell surfaces, leading to possible destruction of the cells. Type II reactions may be responsible for certain *autoimmune disorders* (in which antibodies attack the body's own tissues) and for some cases of red blood cell destruction (*hemolysis*) triggered by certain drugs.
TYPE III Antibodies combine with antigens to form particles called immunocomplexes, which can lodge in various tissues and activate further immune system responses, leading to tissue damage. This type of hypersensitivity reaction is responsible for *serum sickness*, for allergic *alveolitis* (a lung disease caused by exposure to the spores of certain fungi), and for the large swellings that sometimes form after booster vaccinations.
TYPE IV This type is also called delayed hypersensitivity. In type IV, sensitized T-*lymphocytes* (a class of white blood cell and an important component of the immune system) bind to antigens and subsequently release chemicals called lymphokines, which promote an inflammatory reaction. Type IV reactions are responsible for contact *dermatitis* and the rash of *measles*; they are important in the body's defense against *tuberculosis* and may also play a part in some "allergic" reactions to drugs.

TREATMENT
Effective treatment of a hypersensitivity reaction depends on its type, cause, and severity. When possible, exposure to the offending antigen should be avoided.

Hypersplenism
Overactivity of the spleen, resulting in and associated with blood disease. One of the functions of the spleen is to break down blood cells as they age and wear out. An overactive spleen may begin to destroy cells indiscriminately, causing a deficiency of any of the types of blood cell. In most cases of hypersplenism, the spleen is also enlarged.

Hypersplenism may be primary, occurring for no known reason, but more commonly it is secondary to another disorder in which the spleen has become enlarged, such as *Hodgkin's disease* or *malaria*.

SYMPTOMS AND TREATMENT
A person with hypersplenism is likely to have the symptoms of *anemia* (due to destruction of red blood cells) or of *thrombocytopenia* (platelet deficiency), and there is sometimes a decrease in resistance to infection due to lack of white cells. There may also be symptoms of an underlying disorder, such as malaria.

Treatment of secondary hypersplenism aims to control the underlying cause. Primary hypersplenism requires *splenectomy*.

Hypertension
Abnormally high *blood pressure* (the pressure of blood in the main arteries). Blood pressure goes up as a normal response to stress and physical activity. However, a person with hypertension has a high blood pressure at rest.

Hypertension is usually defined as a resting blood pressure greater than 140 mm Hg (systolic)/90 mm Hg (diastolic). However, an elderly person normally has blood pressure readings above these values because blood pressure increases with age. Young children usually have blood pressure readings well below these values.

CAUSES
The majority of people have no obvious cause for their elevated blood pressure; in such cases it is called essential hypertension. However, in about 10 percent of patients, a definite cause can be found, including various disorders of the *kidney*, certain disorders of the *adrenal glands*, and *coarctation of the aorta*.

Tobacco smoking and *obesity* significantly increase the risk of hypertension. Hypertension sometimes develops in women who are taking the birth-control pill.

SYMPTOMS AND COMPLICATIONS
Hypertension usually causes no symptoms and generally goes undiscovered until detected by a physician during the course of a routine physical examination.

Possible complications of untreated hypertension include *stroke*, *heart failure*, kidney damage, and *retinopathy* (damage to the retina at the back of the eye). Severe hypertension may cause confusion and seizures.

TREATMENT
Mild hypertension may respond to weight reduction and a reduction in personal stress. Smokers should stop smoking and heavy drinkers should drastically reduce their consumption of alcohol. Restriction of salt intake is sometimes recommended.

If these measures have no effect, *antihypertensive drugs* may be prescribed. Occasionally, in severe cases, admission to the hospital for investigation of the cause, emergency treatment, and bed rest are required.

Hyperthermia
A medical term for extremely high body temperature. Hyperthermia has been used to treat advanced cancer. (See also *Heat stroke*.)

Hyperthermia, malignant
A rapid rise in body temperature to a dangerously high level brought on by general anesthesia. The condition is rare, occurring in only about one in 50,000 operations, and, in most cases, susceptibility to it is inherited. People suffering from certain muscle disorders may also be at risk.

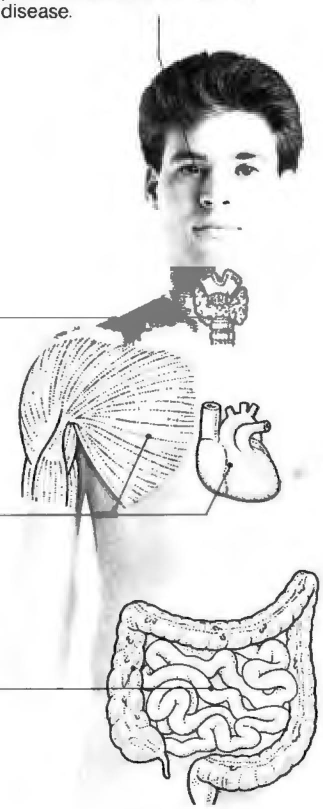
The patient's temperature rises soon after the anesthetic is given. At the same time, large amounts of *lactic acid* pass from the muscles into the blood, causing *acidosis*. The muscles then stiffen and the patient turns blue; this may be followed rapidly by seizures and death if emergency treatment is not delivered.

Malignant hyperthermia may be suspected if the patient does not relax normally during the early, induction stage of anesthesia, or if he or she shows signs of abnormal muscle contractions after being given succinylcholine (a chemical used to relax muscles during operations).

TREATMENT
If malignant hyperthermia occurs, the anesthetic is stopped immediately and the patient is cooled with ice packs. Pure oxygen and intravenous injections of bicarbonate may also be given to counteract acidosis.

Hyperthyroidism
Overactivity of the *thyroid gland* and, therefore, simultaneous overproduction of thyroid hormones.

CAUSES AND INCIDENCE
The most common form of hyperthyroidism is *Graves' disease*, an *autoimmune disorder* in which the body develops antibodies that stimulate the production of excessive amounts of thyroid hormones. This condition affects about 1 percent of the adult population and is most common in young to middle-aged women. More rarely, hyperthyroidism may be associated with the development of enlarged nodules on the thyroid.



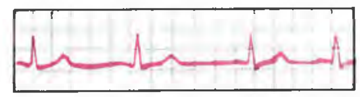
SYMPTOMS AND SIGNS
See illustration, next page.

DIAGNOSIS AND TREATMENT
The diagnosis of hyperthyroidism is confirmed by tests to measure the level of thyroid hormones in the blood. The condition may be treated with drugs that inhibit the production of thyroid hormones or by surgical

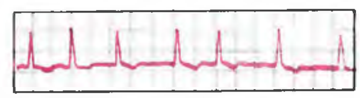
SYMPTOMS AND SIGNS OF HYPERTHYROIDISM

Oversecretion of thyroid hormones produces symptoms associated with overactivity of the body's metabolism. Weight loss, increased appetite, intolerance to heat, and increased sweating are early signs; there may also be tremors and a rapid heart rate. In more severe cases, the thyroid gland is often enlarged and there tends to be physical and mental hyperactivity and wasting of the muscles.

Protruding eyes
This symptom (known as exophthalmos) affects some 30 to 50 percent of people with Graves' disease.



Thyroid gland enlargement
This symptom (known as goiter) may be due to hyperthyroidism. However, it may also be associated with hypothyroidism (underactivity of the thyroid).



Muscle wasting
Severe hyperthyroidism may cause wasting of both skeletal and heart muscle; the latter may lead to irregularities of heart rhythm.

Increased appetite
This symptom is a result of the metabolic overactivity that hyperthyroidism causes. Despite increased appetite, there is often weight loss.

Hyperthyroid heart rate
Excessive thyroid hormones may result in the heart beating too rapidly or irregularly.

Healthy rhythm
A healthy hear beat, as shown in this ECG tracing, has a regular rhythm and a normal rate of beating.

Hyperthyroid rhythm
The hyperthyroid heart beat shown in this tracing is irregular and adnormally rapid.

Appearance of exophthalmos
Hyperthyroidism can cause swelling of tissues around the eyes, resulting in a staring appearance.

removal of part of the thyroid gland. In older patients, an alternative is a single dose of radioactive iodine, which is taken up by the thyroid and destroys some of its tissue.

Hypertonia

Increased rigidity in a muscle. It may be caused by damage to its nerve supply or by cell changes within the muscle itself. Hypertonia causes episodes of continuous muscle spasm (e.g., in the bladder wall when the outflow of urine is being obstructed by an enlarged prostate gland).

Persistent hypertonia in limb muscles following a *stroke* or major *head injury* causes *spasticity*.

A variable increase in muscle tension associated with abnormal patterns of movement and posture is referred to as *dystonia*.

Hypertrichosis

Growth of excessive hair, often in places not normally covered with hair. Hypertrichosis is often a result of taking certain drugs (including cyclosporine, minoxidil, and diazoxide). The disorder is not the same as *hirsutism*, which is excessive hairiness in women due to abnormal levels of male hormones.

Hypertrichosis is also the term used to describe hair growth in a colored, fleshy mole.

Hypertrophy

Enlargement of an organ or tissue due to an increase in the size, rather than number, of its constituent cells. For example, skeletal muscles increase in size in response to increased physical demands. (See also *Hyperplasia*.)

Hyperuricemia

An abnormally high level of *uric acid* in the blood. Hyperuricemia may lead to the development of *gout* due to the deposit of crystals of uric acid in the joints; it may also cause kidney stones (see *Calculus, urinary tract*) and tophi (crystals in the tissues).

CAUSES

Hyperuricemia may be caused by an inborn error of *metabolism*, by rapid destruction of cells as part of a disease such as *leukemia*, or by medication (such as *diuretic drugs*) that reduces the excretion of uric acid by the kidneys. Increased amounts of purine in the diet may raise the level of uric acid in the blood, precipitating gout.

TREATMENT

Drugs such as allopurinol (which reduces uric acid production in cells) and probenecid or sulfinpyrazone (which increase the excretion of uric acid by the kidneys) may be prescribed for life to prevent complications. Foods high in purine (e.g., liver, poultry, and dried peas and beans) need to be avoided.

Hyperventilation

Abnormally deep or rapid breathing, usually caused by *anxiety*. Hyperventilation may also occur as a result of uncontrolled *diabetes mellitus*, oxygen deficiency, *renal failure*, and some lung disorders (such as pulmonary *edema* and *emphysema*).

Hyperventilation causes an abnormal loss of carbon dioxide from the blood, which can lead to *alkalosis* (increase in blood alkalinity). Symptoms include numbness of the

extremities, faintness, and *tetany* (painful spasms and twitches of the muscles in the hands and feet), and a sense of an inability to take a full breath. The effects of alkalosis often add to the already existing feelings of anxiety, and may give rise to the "hyperventilation syndrome," in which the sufferer experiences a feeling of impending doom.

Breathing into a plastic or paper bag during an attack may help reduce the loss of carbon dioxide and avoid the risk of alkalosis.

Hyperventilation associated with uncontrolled diabetes or uremia represents a compensatory effort by the body to eliminate excess carbon dioxide in dealing with *acidosis*. In this case, the hyperventilation syndrome does not develop.

Hyphema

Blood in the front chamber of the eye, almost always caused by an injury that ruptures a small blood vessel in the iris or the ciliary body.

Vision is markedly affected while the blood remains mixed with the aqueous humor, but it clears as the red cells sink. Usually the blood disappears completely within a few days and vision is fully restored, but there is a risk of delayed bleeding three to five days after the injury. Drug treatment or surgical evacuation of the blood is sometimes necessary.

Appearance of hyphema
Blood that has collected in the front chamber of the eye is clearly visible in front of the iris; hyphema is usually caused by an injury.

Hypnosis

A trancelike state of altered awareness that is characterized by extreme suggestibility. Hypnosis was once believed to be a form of sleep. However, the *EEG* (electrical tracing of brain-wave activity) of a hypnotized person does not show any of the normal sleep patterns.

HISTORY

A form of hypnotism was first practiced by the Austrian physician Franz Mesmer in the eighteenth century. Mesmerism (renamed hypnotism after the Greek god of sleep) began to receive attention from many leading members of the medical community in the nineteenth century. The celebrated Parisian physician Charcot gave public demonstrations, and Freud used hypnosis in his early treatment of hysteria. Hypnotism continues to attract much popular interest, both theoretical and medical, but its clinical use is still much debated. Likewise, its use to stimulate the memory of witnesses for courtroom testimony is controversial. Hypnosis for this purpose is acceptable in some jurisdictions and not in others.

HOW IT IS DONE

For hypnosis to succeed, the subject must first want to be hypnotized. The second requirement is relaxation, so a comfortable chair and a quiet, dimly lit room are usually necessary. The subject is usually asked to fix his or her attention on a particular object while the therapist quietly repeats phrases such as "Be still and listen to my voice" or "Empty your mind of all thoughts." The person gradually becomes more and more relaxed, eventually losing touch with the environment and hearing only the therapist's voice. At the end of the session, the subject "wakes up" when told to do so.

With training, it is possible for people to practice autohypnosis (self-hypnosis) by repeating certain phrases to themselves or imagining relaxing scenes.

Some people are more easily hypnotized than others, usually those with an intense imaginative life. The ability seems to be related to early childhood experiences and may be partly inherited.

CHARACTERISTICS

Hypnotized subjects wait passively to be told what to do by the therapist and are very suggestible—they touch or hold imaginary objects and act out suggested roles. They do not, however, obey commands to behave in a manner they would normally regard as dangerous or improper.

Attention usually becomes highly selective, so that only one person at a time is heard. Subjects frequently will obey orders to forget everything that has happened during hypnosis, or, alternatively, to remember or repeat behavior learned while hypnotized (posthypnotic suggestion).

THERAPEUTIC USES

Some psychoanalysts use hypnosis as a means of helping patients remember and come to terms with disturbing events or feelings that have been repressed from consciousness. More often, hypnosis is used as a means of helping patients relax. It may be useful in people suffering from *anxiety*, *panic attacks*, or *phobias*, and is sometimes successful in treating addictive habits, such as smoking. Scientific studies are lacking, however, and claims of fantastic cures should be treated with skepticism.

Hypnotic drugs

Drugs that induce sleep, such as *antianxiety* and *barbiturate drugs*.

Hypo-

A prefix meaning under, below, or less than normal, as in hypodermic (under the skin), hypoglycemia (abnormally low blood sugar level), and hypotension (lower than normal blood pressure).

Hypoaldosteronism

A deficiency of *aldosterone* in the body. This hormone, along with other *corticosteroid hormones* (notably hydrocortisone), is produced by the adrenal cortex (outer part of the adrenal glands). Removal of, or damage to, the cortex results in a deficiency of these hormones, which, in turn, causes *Addison's disease*.

Hypochondriasis

The unrealistic belief or fear that one is suffering from a serious illness, despite medical reassurance.

SYMPTOMS

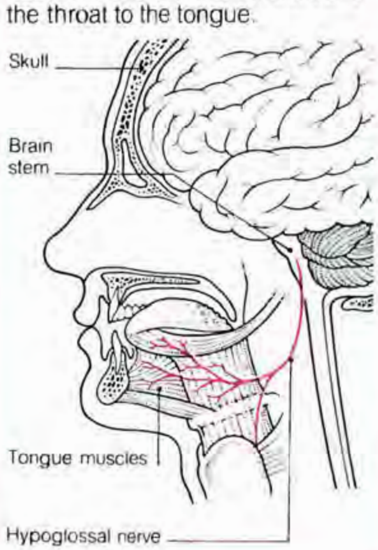
Hypochondriacs worry constantly about their bodily health and interpret any physical symptom, however trivial, as evidence of a serious disorder. The feared disease may involve many parts of the body or may center on a particular organ and a single disease, as in *cardiac neurosis* (fear of heart disease). Hypochondriacs constantly seek medical advice and undergo numerous tests and treatments. Rarely, an obscure physical disorder is discovered, but it does not justify the symptoms described.

CAUSES

Hypochondriasis is usually a complication of other psychological disorders, including *obsessive-compulsive behavior*, *phobia*, *generalized anxiety disorder*, *schizophrenia*, *depression*, and brain diseases, such as *dementia* and *brain tumors*.

The cause of hypochondriasis in the absence of an underlying disorder is uncertain. However, it seems to be more common in people who suffered from a true organic illness during childhood or were constantly exposed to sick relatives. The reason for this may be that the hypochondriac becomes programmed to overreact to every bodily feeling, though there may also be an inherited sensitivity to pain. Other factors that may predispose a person to hypochondriasis include social stresses and personality type (usually obstinate).

TREATMENT



When there is an underlying mental disorder, it is treated as required. Hypochondriasis alone is more difficult to treat. An understanding and patient physician can often help relieve distress.

Hypoglossal nerve

The nerve that controls movements of the tongue. The hypoglossal nerve is rarely damaged. If damage does occur (e.g., as a result of a stroke), one side of the tongue becomes paralyzed.

LOCATION OF HYPOGLOSSAL NERVE

The hypoglossal nerve arises in the medulla oblongata (part of the brain stem), passes through the base of the skull, and runs around the throat to the tongue.

Hypoglycemia

An abnormally low level of glucose (sugar) in the blood. Almost all cases occur in sufferers from insulin-dependent *diabetes mellitus*. In this disease, the pancreas fails to produce enough *insulin* (a hormone that regulates the level of glucose in the blood), resulting in an abnormally high level of glucose. To lower it, diabetics take either *hypoglycemic* drugs by mouth or insulin by injection. Too high a dose of either can reduce the blood sugar to too low a level, thus starving the body cells of energy. Hypoglycemia can also occur if a diabetic person misses a meal, fails to eat enough carbohydrates, or exercises too much.

Rarely, hypoglycemia can result from drinking a large amount of alcohol or from an *insulinoma* (an insulin-producing tumor of the pancreas); it also occurs for no known reason in some children, but is usually only temporary.

Hypoglycemia is a serious condition. The brain needs glucose for its metabolism and to function properly, and prolonged lack of it may lead to permanent intellectual impairment in an affected person.

SYMPTOMS

The principal symptoms include sweating, weakness, hunger, dizziness, trembling, headache, palpitations, confusion, and sometimes double vision. Behavior is often irrational and aggressive and movements are uncoordinated; this state may be mistaken for drunkenness. The victim may lapse into a coma due to extremely low blood sugar.

TREATMENT

Insulin-dependent diabetics should always carry sugar with them (in a convenient form such as sugar lumps or glucose tablets) to take at the first sign of an attack of hypoglycemia. If it is suspected that an unconscious person has suffered a hypoglycemic attack, medical help should be summoned immediately. The physician will give an injection of either glucose solution or the hormone glucagon; the latter counteracts the effects of insulin and raises the blood sugar level by stimulating the conversion of glycogen to glucose.

Hypoglycemics, oral

COMMON DRUGS

Acetohexamide Chlorpropamide Glipizide Glyburide Tolazamide Tolbutamide

WARNING

Consult your physician if you regularly experience symptoms, such as dizziness, nausea, and sweating, that are relieved only by food or a sugary drink.

A group of drugs that are used to treat non-insulin-dependent *diabetes mellitus* when *hyperglycemia* (raised blood glucose level) cannot be controlled simply by diet.

HOW THEY WORK

Oral hypoglycemics lower blood glucose levels by increasing the production by the pancreas of *insulin*, a hormone that increases the amount of glucose that is absorbed from the bloodstream into body cells. Insulin rather than oral hypoglycemics may need to be prescribed temporarily to control the blood glucose level (e.g., during surgery, pregnancy, or a severe illness). Oral hypoglycemics are of no use in treating insulin-dependent diabetes because in these cases the pancreas is unable to produce any insulin.

POSSIBLE ADVERSE EFFECTS

Oral hypoglycemic drugs may cause *hypoglycemia* (abnormally low blood glucose) if the dosage is too high or if the person has not had enough to eat.

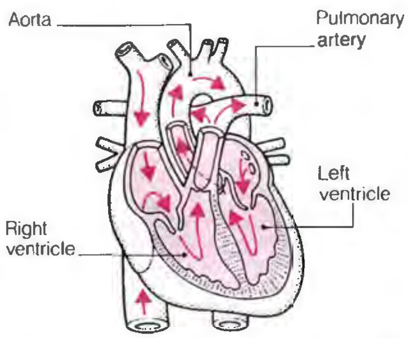
Hypogonadism

Underactivity of the gonads (testes or ovaries). Hypogonadism may be caused by disorders of the *testis* or *ovary* or by a *pituitary gland* disorder resulting in deficient production of *gonadotropin hormone*. In affected males, hypogonadism causes the symptoms and signs of *androgen hormone* deficiency. In females, it causes the symptoms and signs of *estrogen hormone* deficiency.

Hypohidrosis

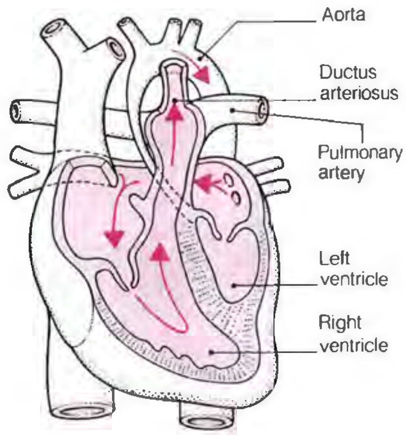
Reduced activity of the sweat glands. It is a feature of hypohidrotic ectodermal dysplasia, a rare, inherited, incurable condition characterized by reduced production of sweat usually accompanied by dry, wrinkled skin, sparse, dry hair, small, brittle nails, and conical teeth. Other causes include exfoliative *dermatitis* and some *anticholinergic drugs*.

Hypomania



A moderate form of *mania*.

Hypoparathyroidism



Insufficient production of parathyroid hormone produced by the *parathyroid glands*, which lie behind the thyroid gland in the neck. Parathyroid hormone, along with vitamin D and calcitonin (a hormone produced by the thyroid gland), regulates the level of calcium in the body. A deficiency of the hormone results in low levels of calcium in the blood and tissue fluids.

HYPOPLASTIC LEFT HEART SYNDROME

The heart defects associated with this syndrome are shown (at right) and compared with those of the normal heart (at left). Neither the left ventricle (pumping chamber) nor the aorta is properly formed.

In a normal heart, blood is pumped by the left ventricle to the body via the aorta. If the left ventricle is poorly formed, blood can reach the body only via the ductus arteriosus, which closes soon after birth.

CAUSES

The most common cause of hypoparathyroidism is the accidental removal of the parathyroid glands during surgery on the thyroid gland. It may also result from surgery to remove a portion of the parathyroid glands themselves in the treatment of *hyperparathyroidism* (overproduction of parathyroid hormone). Occasionally, the parathyroid glands are absent from birth, or they may cease to function for no apparent reason.

SYMPTOMS

The main effect of a low level of calcium in the body is *tetany*, an increased excitability of the nerves that causes uncontrollable, painful, cramplike spasms of the face, hands, arms, and sometimes the feet. Rarely, general seizures similar to those of an epileptic attack may occur.

DIAGNOSIS AND TREATMENT

The condition is diagnosed by tests to measure the level of parathyroid hormone in the blood.

If the patient is suffering from an attack of tetany, calcium may be injected slowly into a vein to provide quick relief. To maintain the blood calcium at a normal level, a lifelong course of calcium and vitamin D tablets is necessary (the vitamin D is needed to increase absorption of calcium from the diet). Regular checkups are also necessary.

Hypophysectomy

Surgical removal of the pituitary gland or destruction of the gland by radioactive *implants*.

WHY IT IS DONE

Hypophysectomy is sometimes performed to remove a *pituitary tumor* that may be the cause of a number of endocrine diseases, such as *acromegaly* and *Cushing's syndrome*.

The operation may also be performed to treat some types of breast, ovary, or prostate gland cancer, the growth of which is stimulated by hormones secreted by the pituitary gland.

HOW IT IS DONE

A general anesthetic is given. Usually the gland is removed via the nose. However, if the tumor is very large, a *craniotomy* (incision into the skull) is performed just above the hairline, and a flap of bone temporarily removed to give access to the gland.

Hypoplasia

Failure of an organ or tissue to develop fully and reach its normal adult size.

Hypoplasia, enamel

A defect in tooth enamel. It is usually due to *amelogenesis imperfecta* (a hereditary condition), but may also be caused by vitamin deficiency, injury, or infection of a primary tooth that interferes with maturation of enamel.

Hypoplastic left heart syndrome

A serious and usually fatal form of congenital *heart disease* that affects about one to two newborn babies in every 10,000 live births. The baby is born with a poorly formed ventricle (pumping chamber) on the left side of the heart and other heart defects. The aorta (main artery carrying blood from the heart to the body) is malformed and blood can reach it only via a duct (the ductus arteriosus) that links the aorta to the pulmonary artery (blood vessel that transports blood to the lungs).

At birth the baby may seem healthy, but within a day or two the ductus arteriosus closes off and the baby collapses, becoming pallid and breathless. There is no effective surgical treatment for the condition and most affected babies die within a week. The risk of parents having another affected child is small.

Hypospadias

A congenital defect, occurring in about one in 300 male babies, in which the opening of the *urethra* is situated on the underside of the glans (head) or shaft of the penis. Sometimes the penis curves downward, a condition known as *chordee*.

In an extreme form of hypospadias the urethral opening lies between the genitals and the anus, the scrotum is small, and the testes are undescended. In such cases the genitals may resemble those of a female and the true sex of the child may be in doubt.

TREATMENT

Single-stage operations to correct hypospadias are available today. The penis is straightened and a tube of skin (or occasionally bladder lining) is used to create a new urethra that extends to the tip of the penis. The operation is usually performed before the boy is two years old. Surgery is usually successful, allowing the boy to pass urine normally and, later, to have satisfactory sexual intercourse.

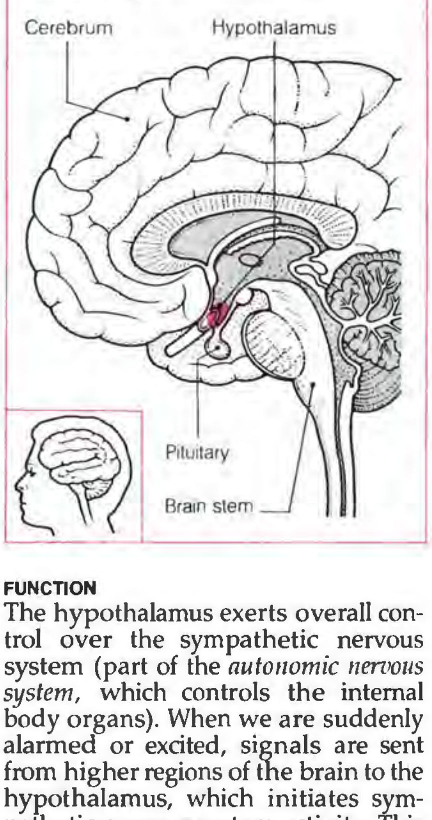
Hypotension

The proper medical term for low blood pressure.

Some healthy people with a normal heart and blood vessels have blood pressure well below average for their age. The term hypotension is usually used only when blood pressure has fallen to the extent that blood flow to the brain is reduced, causing dizziness and fainting.

In postural hypotension (the most common type), symptoms occur after abruptly standing or sitting up. Usually, blood pressure increases slightly with these changes in posture; in people with postural hypotension, this increase fails to occur. Postural hypotension may be an adverse effect of *antidepressant drugs* or *antihypertensive drugs* (drugs used to treat high

blood pressure). It also occurs in diabetics because of nerve damage disrupting the reflexes that control blood pressure.



Acute hypotension (of sudden onset) may be caused by injuries involving heavy blood loss or serious burns leading to *hypovolemia* (reduced blood volume) and physiological *shock*, or by any crisis, such as *myocardial infarction* (heart attack) or *adrenal failure*, that leads to shock.

Treatment of hypotension depends on the underlying cause (diabetes mellitus, for example). For many people with postural hypotension, adjustment of medication may resolve the condition.

Hypothalamus

A region of the brain, roughly the size of a cherry, situated behind the eyes and beneath another brain region called the thalamus. It has nerve connections to most other regions of the nervous system.

LOCATION OF HYPOTHALAMUS
This small area of the forebrain lies under the thalamus and above the pituitary gland.

FUNCTION

The hypothalamus exerts overall control over the sympathetic nervous system (part of the *autonomic nervous system*, which controls the internal body organs). When we are suddenly alarmed or excited, signals are sent from higher regions of the brain to the hypothalamus, which initiates sympathetic nervous system activity. This causes a faster heart beat, increased breathing, widening of the pupils of the eyes, and increased blood flow to muscles (known as the "fight or flight" response).

Other groups of nerve cells in the hypothalamus are concerned with the control of body temperature. Some are sensitive to heat and cold so that, when blood flowing to the brain is hotter or cooler than normal, the hypothalamus switches on temperature-regulating mechanisms (among them sweating or shivering). The hypothalamus receives information from internal sense organs regarding the level of glucose in the blood and the body's water content; if they are too low, it stimulates appetite for food and drink. The hypothalamus is also involved in regulating sleep, in motivating sexual behavior, and in determining mood and the experience of emotions.

Another role of the hypothalmus is coordination of the function of the nervous and endocrine (hormonal) systems of the entire body. The hypothalamus connects with the pituitary gland through a short stalk of nerve fibers and controls hormonal secretions from this gland. It does this in two ways—through direct nerve connections and through specialized nerve cells, which secrete hormones called releasing factors into the blood to flow directly to the pituitary. In this way, the hypothalamus can convert nerve signals into hormonal signals. Thus, the hypothalamus indirectly controls many of the endocrine organs, including the pituitary, thyroid, adrenal cortex, and gonads.

DISORDERS

Disorders of the hypothalamus are usually caused by a brain hemorrhage within the hypothalamic region (see *Intracerebral hemorrhage*) or by an expanding pituitary tumor. Loss of hypothalamic function can have diverse effects, ranging from hormonal disorders (see *Endocrine system*) to disturbed temperature regulation, and increased or decreased appetite for food, sex, and sleep.

Hypothermia

A fall in body temperature to below 95°F (35°C). It causes drowsiness, lowers breathing and heart rates, and may lead to unconsciousness or death. Most victims are elderly people who are unable to keep sufficiently warm in winter.

The term hypothermia is also used to describe the deliberate lowering of body temperature during some forms of surgery (see *Hypothermia, surgical*).

CAUSES

Hypothermia can be caused by prolonged exposure to extremely cold weather, swimming in the sea, or wearing damp clothing in cold conditions. However, most cases occur in elderly people living in poorly heated homes. As the body ages, it gradually loses its sensitivity to cold; an elderly person's body temperature may drop without the individual being aware of it. In addition, the aging body also becomes increasingly less able to reverse a fall in temperature. This reduced ability is also present in the very young; aside from the elderly, babies are the most common victims of hypothermia.

The risk of hypothermia is increased if an elderly person is also suffering from a disorder that reduces the body's heat production (such as *hypothyroidism*), impairs mental function (such as senile *dementia*), or reduces mobility (such as *arthritis*).

Certain drugs may also contribute to the onset of hypothermia. For example, *tranquilizers* (such as chlorpromazine) may lower the level of consciousness and reduce the ability to shiver (shivering has a protective function against cold).

SIGNS

A person suffering from hypothermia is usually pale, puffy-faced, and listless. The heart rate is slow and the victim is often drowsy and confused. Areas of the body that are normally warm (such as the armpits and the groin) are cold.

In severe hypothermia, breathing becomes slow and shallow, the muscles are often stiff, the victim may become unconscious, and the heart may beat only faintly and irregularly or—especially if the body temperature falls below 90°F (32.2°C)—it may stop beating altogether.

DIAGNOSIS

The condition is usually obvious from the above signs and the victim's circumstances. To determine how cold the body has become, the physician takes a rectal temperature with a special low-reading thermometer. Alternatively, the temperature of the urine may be measured.

TREATMENT

Hypothermia is a medical emergency and anyone suspected of suffering from it requires immediate medical attention. Mild hypothermia usually responds to giving the victim warm drinks and covering the head (from which as much as 20 percent of the body's heat loss takes place).

FIRST AID: HYPOTHERMIA

DO NOT
- let the victim walk
- warm the victim by rubbing his or her skin
- give the victim any alcohol
- warm the victim by applying direct heat

IN BABIES

Medical help should be sought immediately. Hypothermia is often difficult to detect. The baby may look pink and healthy, but he or she may be unusually limp and drowsy. Rewarm the baby by keeping him or her well wrapped.

IN ADULTS

1 Seek medical help. If the victim is unconscious and breathing, place in the *recovery position*. If not breathing, begin *artificial respiration*.

2 Move the victim to a warm place. Take off wet clothing and replace with dry, or dry off and cover with waterproof material.

3 If the victim is conscious, give a warm (not hot) drink. Hold the mug if necessary.

4 If the victim is otherwise healthy, place in a warm (not hot) bath.

When the condition is more severe, treatment varies according to the age of the victim. A young person is usually warmed in a hot bath. However, this causes a rush of blood to the surface of the body, reducing the supply to the heart and brain, which could be fatal to an elderly person. For this reason, warming is carried out gradually in the elderly (at a rate of about 1°F (0.6°C per hour) by placing the person in a room with a temperature of 78°F (25°C) and covering him or her with layers of heat-reflecting material known as space blankets. Rectal temperature is monitored every half hour until the temperature and vital signs show improvement.

When hypothermia is severe enough to be life-threatening, the victim is admitted to an intensive-care unit and warmed rapidly by safe means; part of the circulating blood is bypassed outside the body, where it is warmed, or warm fluid is run into the abdominal cavity.

PREVENTION

It is recommended that an elderly person's living quarters be heated at a temperature of at least 65°F (18°C). Relatives or neighbors of elderly people living by themselves should check regularly throughout winter that these people have additional means of keeping warm, including suitable clothing, warm blankets, and nutritious food.

Elderly people should also be made aware of the need to eat hot food and drink warm fluids several times a day and wear a warm hat at all times.

People walking or climbing in cold weather should carry survival bags, lined with space blankets, which they can crawl into while waiting for help in the event of an accident.

Hypothermia, surgical

The deliberate reduction of body temperature to prolong the period for which the vital organs can safely be deprived (partially or totally) of their normal blood supply during *open heart surgery*. Cold reduces the rate of metabolism in cells and tissues; hence, lack of oxygen is better tolerated as the temperature is lowered.

In the early days of heart surgery, induced hypothermia allowed surgeons to perform quick (eight to 10 minutes) operations on the heart while blood circulation throughout the body was completely stopped.

Today, open heart surgery is usually performed with the general blood circulation maintained by means of a *heart-lung machine*. Nevertheless, mild hypothermia—with the body temperature reduced from 98.6°F (37°C) to about 82 to 88°F (28 to 31°C)—is still generally induced as a safety measure. It can allow heart operations to proceed for several hours. A heat exchanger, installed into the machine circuit, can be used to cool the blood before return to the body, thus inducing hypothermia.

The blood supply to the heart muscle itself is interrupted during open heart surgery, so the heart also must be vigorously cooled by continuously instilling cold saline into the open chest cavity at a temperature of about 40°F (4°C). By this method, damage to the heart muscle from lack of oxygen is minimal, even after an operation lasting several hours.

At the end of the operation, rewarming of the patient is carefully synchronized with restarting the heart and the switch back from use of the heart-lung machine.

Hypothyroidism

Underactivity of the *thyroid gland* and, therefore, underproduction of thyroid hormones.

CAUSES AND INCIDENCE

Most cases of hypothyroidism are caused by the body developing antibodies against its own thyroid gland (an example of an *autoimmune disorder*) with a resultant reduction in thyroid hormone production. *Hashimoto's thyroiditis* is an example of this phenomenon. More rarely, hypothyroidism may result from surgery to remove part of the thyroid gland as a treatment for *hyperthyroidism* (overactivity of the thyroid).

Hypothyroidism affects about 1 percent of the adult population. It is most common in elderly women, though it occurs at all ages and in both sexes.

SYMPTOMS AND SIGNS

Thyroid hormones stimulate energy production, so a deficiency of them causes generalized tiredness and lethargy. There may also be muscle weakness, cramps, a slow heart rate, dry and flaky skin, hair loss, and a deep and husky voice. In addition, the skin and other body tissues may thicken and there may be weight gain—a syndrome known as *myx-*

edema. In some cases, a goiter (enlargement of the thyroid gland) develops, although not all goiters are due to hypothyroidism.

The severity of the symptoms depends on the degree of thyroid deficiency. Mild deficiency may cause no symptoms; severe deficiency may produce all of the above symptoms.

If hypothyroidism occurs in childhood and remains untreated, it may retard growth, delay sexual maturation, and inhibit normal development of the brain.

DIAGNOSIS AND TREATMENT

The disorder is diagnosed by tests to measure the level of thyroid hormones in the blood.

Treatment consists of replacement therapy with the thyroid hormone thyroxine; in most cases, hormone therapy must be continued for life. Such treatment may not cure a goiter, which may require surgery.

Hypotonia

Abnormal muscle slackness. Normally, a muscle that is not being used has a certain built-in tension. In a number of disorders affecting the nervous system (such as *Huntington's chorea*) this natural tension or tone is moderately or markedly reduced.

Hypotonia in infants

Excessive limpness in infants, also called floppy infant syndrome.

FEATURES

Hypotonic babies cannot hold their limbs up against gravity and thus tend to lie flat with their arms and legs splayed. Their limbs and joints seem slack when moved by someone else. Floppy babies move around less than normal babies and their mothers may report that they did not feel the baby move much during pregnancy. When held horizontally by the trunk, face downward, they hang limply.

CAUSES

Premature infants are naturally more floppy than full-term infants, but, as they mature, their muscles attain the normal tension.

Hypotonia is often a feature of chromosomal disorders, such as *Down's syndrome*. Illnesses that affect general health (e.g., malnutrition, congenital *heart disease*, and *hypothyroidism*) may also cause hypotonia. More specifically, disorders of the brain (particularly *cerebral palsy*) and of the spinal cord (such as *Werdnig-Hoffmann disease*) are characterized by hypotonia. Treatment depends on the cause.

Hypovolemia

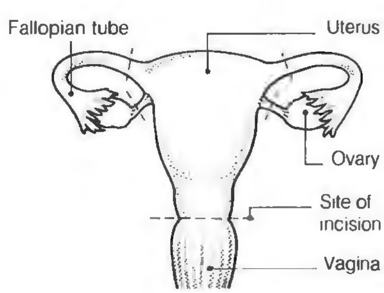
An abnormally low volume of blood circulating in the body. It usually follows severe blood loss, which may occur as a result of injury, internal bleeding, or surgery. Hypovolemia also occurs in various other conditions, such as serious burns, severe dehydration, or, rarely, adrenal crisis (see *Addison's disease*).

Hypovolemia is a dangerous condition because, untreated, it can lead to *shock*, which is potentially fatal.

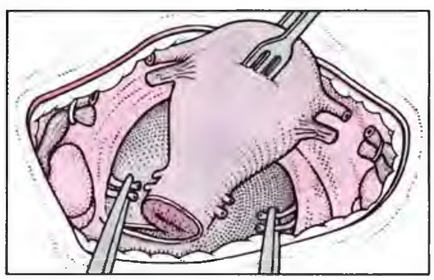
Hypoxia

An inadequate supply of oxygen to the tissues.

CAUSES

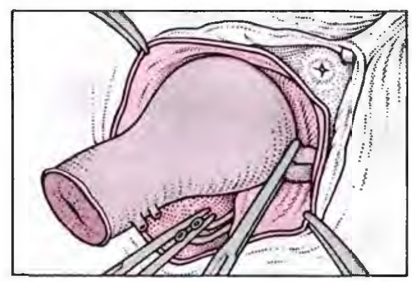


Temporary hypoxia may occur as a result of strenuous exercise in which the normal supply of oxygen cannot meet the additional requirements of the tissues. In such cases, the condi-



PERFORMING A HYSTERECTOMY

Hysterectomy may be performed through the abdomen or the vagina. For an abdominal hysterectomy, the incision is made in the lower abdomen (see below). In vaginal hysterectomy, the uterus is removed through an incision at the top of the vagina.



Site of incision for abdominal hysterectomy
The incision is made in the lower abdomen (in this case horizontally) level with the top of the pubic hair.

Abdominal hysterectomy
The uterine vessels are clamped. Traction is placed on the top of the uterus and the vessels are tied and then divided. In some cases, the fallopian tubes are cut and the tubes and ovaries left in place.

Vaginal hysterectomy
After a vaginal incision is made, the uterus and cervix are removed (the ovaries cannot be removed in a vaginal hysterectomy). The upper end of the vagina is repaired by stitching.

POSTOPERATIVE PROBLEMS

Many women worry that their sex lives will be affected by hysterectomy. Physically, there should be no noticeable change in the woman's sex life. Counseling before the procedure can help dispel any misconceptions or fears. Depression is not uncommon in women who are inadequately counseled.

tion disappears once exercise has stopped and breathing has reoxygenated the tissues.

More serious causes include impaired breathing (see *Respiratory failure*), usually as a result of a lung disorder; *ischemia* (reduced blood flow to a tissue), which may be due to an artery disorder or a heart disorder; and severe *anemia*, in which the oxygen-carrying capacity of the blood is reduced. Another, rare, cause is *carbon monoxide* poisoning, which prevents the blood from being adequately oxygenated. In severe cases, any of these more serious causes may lead to *anoxia* (complete absence of oxygen in a tissue), which, if prolonged, may cause tissue death.

SYMPTOMS AND SIGNS

Hypoxia in muscles forces the muscle cells to produce energy by *anaerobic* metabolism, which produces lactic acid as a by-product. The accumulation of lactic acid causes cramps. Hypoxia in heart muscle may cause the chest pain of *angina pectoris*. Hypoxia of the brain initially causes confusion, dizziness, and incoordination, progressing to unconsciousness and death if the condition persists.

TREATMENT

Severe, potentially life-threatening hypoxia may require treatment by *oxygen therapy* or artificial *ventilation*. Otherwise, the treatment depends on the underlying cause.

Hysterectomy

Removal of the uterus. Hysterectomy is one of the most frequently performed operations in the US.

WHY IT IS DONE

Hysterectomy is most often performed to treat *fibroids* (benign tumors of the uterus) that are causing symptoms. It is also performed to treat cancer of the uterus or cervix (see *Uterus, cancer of*; *Cervix, cancer of*). Occasionally, a hysterectomy is performed to relieve *menorrhagia* (heavy menstrual bleeding) or *endometriosis* (a condition in which fragments of the uterine lining occur elsewhere in the pelvis) that has not responded to a *D and C* or hormone treatment. A hysterectomy may also be performed to remove a severely prolapsed uterus (see *Uterus, prolapse of*).

TYPES

The most common type of hysterectomy is a simple hysterectomy, in which the uterus and cervix only are removed. In a total hysterectomy, the fallopian tubes and ovaries are removed as well. If cancer is advanced, a radical hysterectomy (in which the pelvic lymph nodes are also removed) is necessary.

RECOVERY PERIOD

After the operation a drainage tube may be inserted at the site of the incision. For a few days there may be some vaginal bleeding and discharge and considerable tenderness and pain. The stay in the hospital depends on the age and health of the woman and whether there are postoperative problems. Full recovery requires another three to six weeks; sexual intercourse can be resumed about a month after the surgery.

OUTLOOK

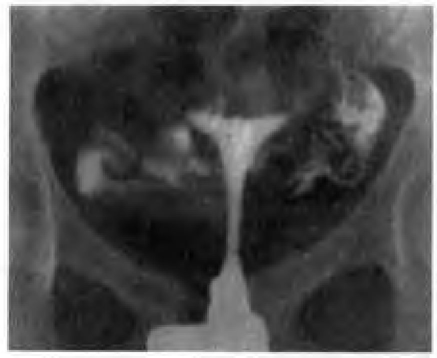
After hysterectomy the woman is unable to bear children; she does not menstruate and needs no contraception. If the ovaries have also been removed from a woman before or around the *menopause*, *hormone replacement therapy* should be considered.

Hysteria

A term encompassing a wide range of physical or mental symptoms that are attributed to mental stress in someone who is not psychotic.

Derived from the Greek word for uterus, hysteria was originally thought to be a physical disorder confined to women. By the nineteenth century, hysteria was believed to have a psychological origin and was used to describe many seemingly bizarre states (including hallucination, sleepwalking, and trances).

Today, many psychiatrists feel that the term hysteria is no longer helpful in diagnosis. In modern classifications, therefore, the symptoms formerly grouped under this term are now included in the more specific diagnostic categories of *conversion disorder*; *dissociative disorders*; *somatization disorder*; and *factitious disorders*.



Physicians still sometimes use the term loosely to describe any difficult, unusual, or exotic behavior that does not seem consistent with the symptoms or situation of the patient. Mass hysteria describes the spread of psychologically produced symptoms (such as fainting) from person to person. It usually occurs in schools or institutions of young women in response to group tensions or worries and is often triggered by a person with a charismatic personality.

Hysterosalpingography

An X-ray procedure performed to examine the inside of the uterus and fallopian tubes.

WHY IT IS DONE

The examination is performed as part of the investigation of *infertility*. Dye injected during *laparoscopy* indicates whether the tubes are blocked, but hysterosalpingography is needed to determine the site of the blockage, which is most often due to scar tissue caused by a previous infection. Hysterosalpingography also outlines any distortion in the uterus, such as a congenital abnormality or a *fibroid*.

A normal hysterosalpingogram
The X-ray image shows radiopaque dye filling the uterus and passing through the fallopian tubes into the pelvic cavity.

HOW IT IS DONE

The test is an outpatient procedure performed by a radiologist and/or a gynecologist. Because the procedure may be uncomfortable (often producing a cramplike pain), the patient is usually mildly sedated.

A plastic or metal *cannula* is inserted into the cervix (neck of the uterus), a radiopaque dye (one that shows up on X-ray film) is passed through it into the uterus and the fallopian tubes, and X-ray pictures are taken to reveal any abnormalities. The procedure takes 10 to 30 minutes.

RISKS

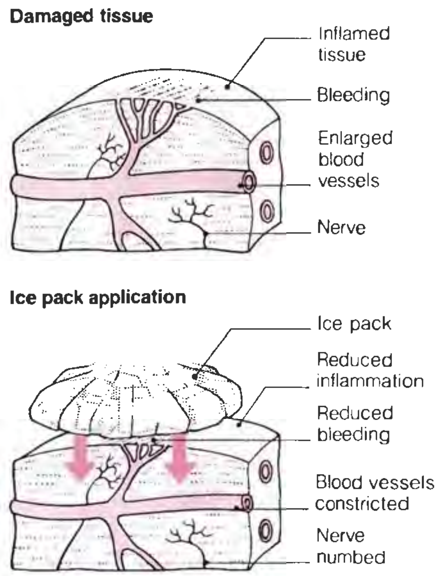
In a woman who has just become pregnant, the dye may wash the fertilized egg out of the fallopian tube; if this does not happen, the embryo may be damaged by radiation from the X rays. To avoid these risks, the test is carried out only in the second half of the menstrual cycle, when it is certain the woman is not pregnant.

Hysterotomy

A method of late *abortion* in which the abdomen and uterus are surgically opened to remove the fetus. Hysterotomy is the most complicated method of abortion and carries the highest risk. It is rarely used today; instead, *prostaglandin drugs* are used to terminate pregnancy by inducing labor.

H

Iatrogenic
Meaning literally "physician produced," the term iatrogenic can be applied to any medical condition, disease, or other adverse occurrence that results from medical treatment. The development of an iatrogenic condition does not necessarily imply a lack of care or knowledge on the part of the physician. Effective forms of treatment are seldom, if ever, entirely free of possible unwanted effects. The drowsiness produced by some groups of antiallergy drugs is one example.



Ibuprofen
A *nonsteroidal anti-inflammatory drug* (NSAID) used as an *analgesic* (painkiller) in the treatment of headache, menstrual pain, and painful injury to soft tissues (such as muscles and ligaments). The anti-inflammatory effect of ibuprofen helps reduce joint pain and stiffness occurring in some types of arthritis, such as *rheumatoid arthritis* and *osteoarthritis*.

Ibuprofen may cause abdominal pain, diarrhea, nausea, heartburn, and, rarely, dizziness. It may also cause a *peptic ulcer*, but is less likely to do so than some other NSAIDs.

Ice packs
Means of applying ice (in a towel or other material) to the skin to relieve pain, stem bleeding, or reduce inflammation. Cold causes the blood vessels to contract, reducing blood flow.

WHY IT IS DONE

Ice treatment is used to relieve pain in a variety of disorders, including severe *headache*, *hemorrhoids*, and pain in the throat after a *tonsillectomy*. Another common use is after sports injuries to minimize swelling, bruising, and further tissue damage. In sports injuries, ice is usually combined with the application of a pressure bandage and the raising of the injured part. Ice may also be used to stop bleeding from small vessels, as in a nosebleed.

Use of an ice pack
Applying an ice pack to an area of damaged tissue helps relieve pain, reduce inflammation and further tissue damage, and minimize bleeding and swelling.

HOW IT IS DONE

Ice is wrapped in a wet cloth (to prevent it from burning the skin) and applied to the skin's surface. Chemical packs are also available; striking or shaking the pack mixes the chemicals within, producing a liquid with a very low temperature.

Ichthyosis
A rare, inherited condition in which the skin is dry, thickened, scaly, and darker than normal due to an abnormality in the production of *keratin* (a protein that is the main component of skin). The name ichthyosis is taken from the Greek word "ichthus" (meaning fish); the condition is commonly called fish skin disease.

Ichthyosis usually appears at or shortly after birth and generally improves during childhood. The areas most commonly affected are the thighs, arms, and backs of the hands.

There is no special treatment, although lubricants and emulsifying ointments help the dryness and bath oils moisten the skin. Washing with soap makes ichthyosis worse and should be avoided. The condition improves in a warm, humid atmosphere. Ichthyosis is at its worst in cold weather (when the sufferer should wear additional layers of protective, warm clothing).

Icterus
Another term for *jaundice*.

Id
One of the three parts of the personality (with the *ego* and *superego*) described by Sigmund Freud. The id is the primitive, unconscious store of energy from which come the instincts for food, love, sex, and other basic needs. The id seeks simply to gain pleasure and to avoid pain. (See also *Psychoanalytic theory*.)

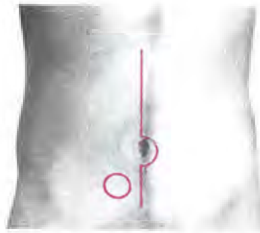
Idiocy
An outdated term for severe *mental retardation*. Idiots were defined as having an IQ of under 35.

Idiopathic
Of unknown cause. For example, epilepsy in which no specific cause can be found is referred to as idiopathic epilepsy. The word idiopathic comes from the Greek "idio-" meaning "one's own" and "pathos" meaning disease.

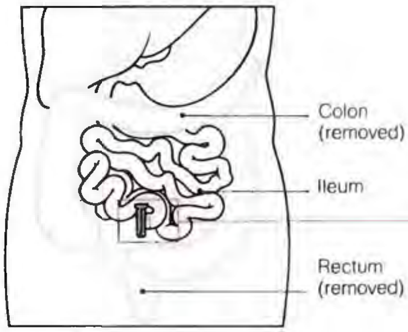
Idoxuridine
An *antiviral drug*. Idoxuridine is used to treat *herpes simplex* infections affecting the eyelids or cornea of the eye. It is occasionally given to prevent a recurrence of herpes simplex infection in people receiving *corticosteroid drug* treatment for a different eye disorder.

Idoxuridine may cause irritation of the eye and, in rare cases, photophobia (abnormal sensitivity to light), swollen eyelids, or blurred vision.

Ileostomy
An operation in which the ileum (lower part of the small intestine) is brought through an incision in the abdominal wall and formed into an artificial outlet for the bowel to allow the discharge of feces into a bag attached to the skin. An ileostomy is usually permanent.

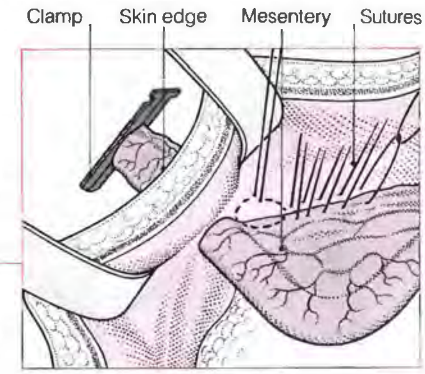


WHY IT IS DONE



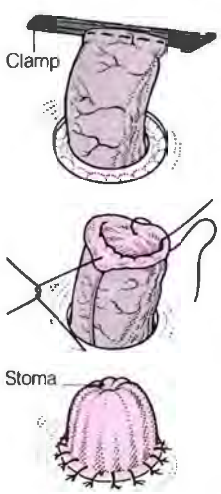
Permanent ileostomy is usually performed for people with *ulcerative colitis* or *Crohn's disease* whose health, despite drug treatment, continues to deteriorate because of chronic inflammation of the colon. For these people, the only means of restoring health is to perform a *colectomy* (an operation to remove the colon and rectum) followed by an ileostomy.

Temporary ileostomy is sometimes required at the time of partial colectomy (removal of part of the colon) to allow the repair of the colon to heal before waste material passes through it. Temporary ileostomy may also be carried out as an emergency measure in a person who is very ill due to an



PROCEDURE FOR ILEOSTOMY

Two incisions are made in the abdominal wall (usually on the right side)—a small circular cut for the stoma (most often located about 2 inches below the waist and away from the hipbone and groin crease) and a vertical cut to give access to the intestine and *mesentery*.



1 After removal of the colon, the cut end of the ileum is clamped and part of the mesentery is cut to free a short length of ileum for the stoma.

2 The free end of the ileum is pushed out through the circular incision in the abdomen; the mesentery is then stitched to the inner abdominal wall.

3 The main vertical incision is closed, and the clamp is removed from the protruding end of the ileum (top). The end of the ileum is then turned back and attached to the abdomen with sutures (middle). When completed, this creates a small protruding stoma (bottom). A temporary ileostomy appliance is usually fitted immediately.

4 After the intestine begins to function normally, an ileostomy bag is fitted around the stoma. The bag attaches closely to the skin with adhesive seals.

obstruction high in the large intestine that is preventing the normal passage of feces. The ileostomy is made above the obstruction and, by allowing waste material to discharge, enables the patient to recover sufficiently to undergo a partial colectomy to remove the obstruction. Temporary ileostomies are closed when the rejoined colon has healed.

HOW IT IS DONE

When the whole of the colon and rectum has been removed, the cut end of the ileum is brought to the surface of the skin through an incision in the abdominal wall. In the case of a temporary ileostomy, a loop of bowel is brought to the surface and opened so that waste material can pass through. The edges of this opening are then stitched to the skin at the edge of the abdominal incision to create a stoma (an artificial opening). The stoma is usually located on the right side about 2 inches (5 cm) below the natural waist and away from the hipbone.

POSTOPERATIVE CARE

For a few days, patients may need to be fed by *intravenous infusion*. After that, the intestine starts to function normally again; liquid waste is discharged through the stoma into a bag that is closely attached to the skin by adhesive seals.

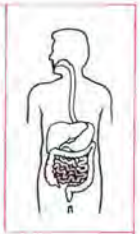
During the convalescent period, patients with permanent ileostomies are given counseling to help them come to terms with an altered body image and the appearance of the stoma. They are also taught the practical aspects of stoma care. There is no muscle control over evacuation of body wastes through the stoma. These wastes are semiliquid and contain enzymes that can damage the skin around the stoma. For these reasons, it is usually necessary for the bag to be worn at all times. The nursing staff (ideally a stoma-care nurse clinician) teaches the patient how to empty, change, and dispose of the bag, and how to maintain a good seal between bag and body to protect the skin and prevent leaks.

Full recovery from the operation takes about six weeks, during which time patients should avoid vigorous physical activity.

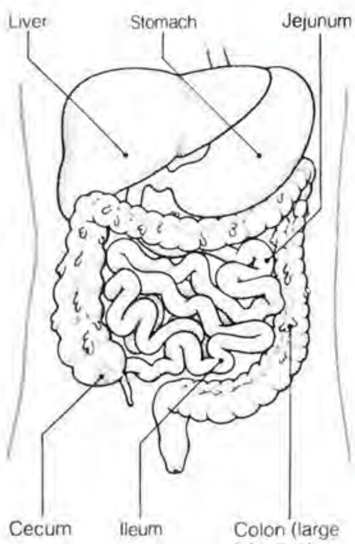
OUTLOOK

The condition of patients who are given ileostomies after removal of a chronically inflamed colon usually improves dramatically. Because their ability to be active is enhanced, many of these people say they wish they had had the operation years earlier.

Following convalescence, patients should be able to return to their usual employment, life-style, and family and social activities. After an ileostomy it is necessary to drink increased amounts of water and to ensure that the intake of salt is adequate, thus compensating for the lack of a colon (the main functions of which are the absorption of water and salt). Apart from this recommendation, it is generally possible to eat a normal diet.



Only an occasional medical checkup is needed to make sure that the stoma is in good condition, although the physician should always be informed of any change in the function or appearance of the stoma. Occasionally, the channel of the stoma becomes narrowed or prolapses (protrudes too far from the abdomen), requiring surgical correction.



Various attempts have been made to devise ileostomies that require emptying only once or twice a day at fixed times and do not require an external appliance. These devices include internal reservoirs made from loops of small intestine, magnetic closures, and carbon filter systems for gas. However, none has yet proved consistently reliable, and most patients are still offered a conventional ileostomy.

Ileum
The final, longest, and narrowest section of the small intestine. It is joined at its upper end to the *jejunum* and at its lower end to the large intestine.

The function of the ileum is to absorb nutrients from food that has been digested in the stomach and first two sections of the small intestine. The millions of *villi* (minute fingerlike projections) that line the ileum considerably increase its surface area and thus its powers of absorption.

LOCATION OF THE ILEUM
The ileum (the final part of the small intestine) joins the jejunum and cecum (the first part of the large intestine).

DISORDERS
Occasionally, the ileum becomes obstructed—by pushing through a weakness in the abdominal wall (see *Hernia*) or by becoming caught up with scar tissue following abdominal surgery, for example.

Other disorders of the ileum include *Meckel's diverticulum* (a pouch in the ileum wall that may become ulcerated), *Crohn's disease*, and diseases in which absorption of nutrients is impaired, such as *celiac sprue*, tropical *sprue*, and *lymphoma*.

Ileus, paralytic
A failure, usually temporary, of the normal contractility of the muscles of the intestine. As a result, intestinal contents can no longer pass out of the body and the bowel becomes obstructed. This condition commonly follows abdominal surgery and may also be induced by severe abdominal injury, *peritonitis* (inflammation of the membrane lining the abdomen), internal extraintestinal bleeding, acute *pancreatitis* (inflammation of the pancreas), or interference with the blood or nerve supply to the intestine.

Symptoms include a distended abdomen, vomiting, and failure to pass stools. The condition is usually successfully treated by sucking out the intestinal contents through a tube passed through the nose or mouth into the stomach or intestine and by maintaining body fluid levels by *intravenous infusion* (drip).

Illness
Perception by a person that he or she is not well. Illness is a subjective sensation and may have physical or psychological causes; illness is not synonymous with disease or disorder.

Illusion
A distorted sensation. An illusion is based on misinterpretation of a real stimulus (for example, a pen is seen as a dagger or the sound of a screeching brake is heard as a scream). This is not the same as a *hallucination*, in which a perception occurs with no stimulus.

Usually, illusions are brief and can be understood when explained. They may be due to tiredness or anxiety, to drugs of many sorts, or to certain forms of brain damage. *Delirium tremens* is a classic inducer of illusions.

Imaging techniques
Techniques that produce images of structures within the body that cannot otherwise be seen. Imaging techniques are an invaluable aid in diagnosing abnormalities and disease.

X RAYS
In 1895 the discovery of *X rays* revolutionized medical diagnosis by making it possible for the first time to visualize bone, organs, and other internal tissue without opening up the body. The rays are electromagnetic waves of short wavelength. Some are absorbed and others pass through tissues; the shadow that is cast is projected onto a fluorescent screen or a film.

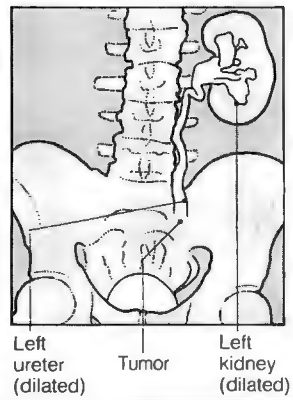
CONTRAST MEDIA X-ray images of bones are distinct, but soft tissues show up less clearly. To overcome this, radiologists from the 1920s onward began using substances opaque to radiation as part of certain X-ray procedures. When such substances (known as contrast media) are introduced into internal organs, blood vessels, or ducts, they produce (on the X-ray screen or film) an outline of the cavities they fill.

A contrast medium can be introduced into the body in various ways. In *cholecystography* (carried out to examine the gallbladder and common bile duct) and in some *barium X-ray examinations* of the esophagus, the stomach, and the small bowel, the medium is swallowed in tablet or liquid form. In *bronchography* (used to diagnose various chest disorders) the contrast medium is placed into the airways (bronchi) connecting the windpipe to the lungs. In *angiography* and *venography*, it is injected into an artery or vein, respectively, to provide images of the blood vessels. In intravenous *pyelography*, contrast medium injected into a vein in the arm travels to the kidneys and urinary tract. In *ERCP* (by which the pancreatic duct and biliary system are examined), the medium is passed into the ducts by means of a catheter (tube) passed through a channel in an endoscope (a flexible viewing instrument).

SCANNING TECHNIQUES
Since the 1970s many X-ray imaging techniques have been superseded by newer procedures that are simpler to perform and are safer and more comfortable for the patient. *Ultrasound scanning* consists of passing high-frequency sound waves through the body with a transducer placed against the skin. The waves are reflected to varying degrees by structures of different density, and the pattern of the echoes is electronically recorded on a screen. Ultrasound scanning is the first choice for diagnostic imaging of the gallbladder, female genital tract, and fetus. It also provides remarkably clear pictures of the kidney.

COMPUTERS Many scanning techniques use a computer to provide images. In *CT scanning* (computerized tomography scanning), X rays are passed through the body at different angles. The computer produces cross-sectional images ("slices") of the tissues being examined. In *MRI* (magnetic resonance imaging), the patient is placed in a strong magnetic field and radio-frequency waves are passed through the body. A computer analyzes changes in the magnetic alignment of the hydrogen protons of the cells to give an image of the tissues.

CT scanning and MRI are particularly valuable in the diagnosis of brain disorders. So, too, is a more recent

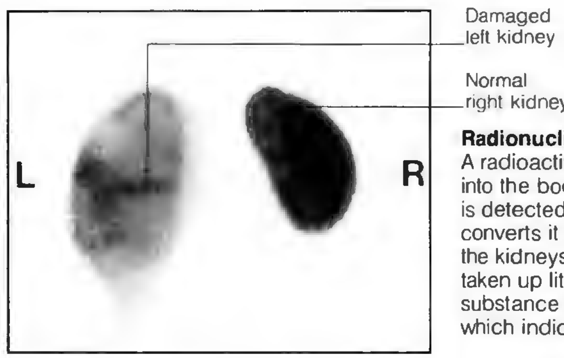


IMAGING THE BODY

Over the past decade, many new methods of imaging the body have been developed. These new imaging techniques have made it possible to visualize internal structures in a variety of different ways. Today, in addition to conventional X rays (which show primarily bones), techniques such as CT scanning, radionuclide scanning, ultrasound scanning, MRI, and PET scanning are used to provide detailed diagnostic pictures of soft tissues and organs. The examples given here show some of the different ways in which the kidneys can be imaged. Annotated diagrams and explanatory text will help you interpret the images.

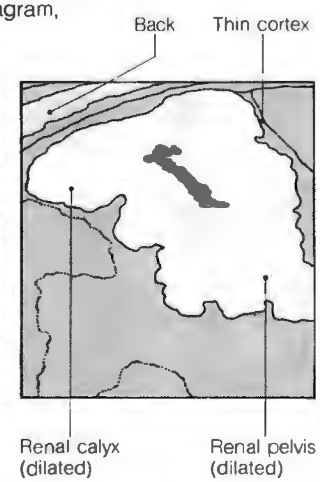
X RAYS

Radiopaque contrast media may be utilized to give distinct X-ray images of soft tissues, as in intravenous pyelography, which is used to clearly visualize the kidneys and urinary tracts.

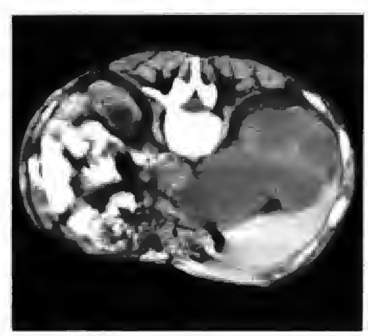


Intravenous pyelogram
The intravenous pyelogram (far left) shows the left kidney and ureter, which are visible because they are filled with contrast medium that has been retained due to a tumor obstructing the ureter (see left).

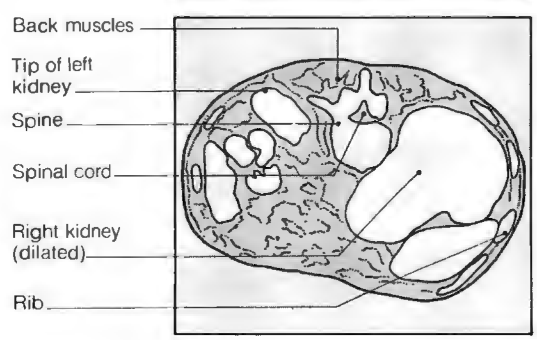
SCANNING TECHNIQUES



Many new techniques have been developed for imaging the body, particularly the soft tissues. Some of these techniques, such as CT scanning, rely on computers to process the raw imaging data and produce the actual image. Others, such as ultrasound scanning and radionuclide scanning, can produce images without a computer, although one may be used for image enhancement.



Radionuclide scanning
A radioactive substance is introduced into the body, and the radiation emitted is detected by a gamma camera, which converts it into an image. In the scan of the kidneys (left), the left one has taken up little of the radioactive substance (and thus appears faint), which indicates that it is damaged.



Ultrasound scanning
Ultrahigh frequency sound waves reflected from tissues in the body are converted into an image by special electronic equipment. The scan (below left) shows a section through a diseased kidney; the inner tissues (calyx and pelvis) are greatly dilated, and the outer cortex is abnormally thin (see diagram, below right).

CT scanning
A CT scanner produces cross-sectional images (slices) of the body. The CT scan (right) shows a greatly dilated right kidney (see diagram, below right).

technique called *PET* (positron emission tomography) *scanning*, in which very short-lived radioisotopes are introduced into tissues; the paths of gamma rays emitted are analyzed by a computer, giving information about brain function and structure.

In *radionuclide scanning*, a gamma camera records, and a computer transforms into images, radiation emitted from tissues into which a radioactive substance has been introduced. The computer may be used to obtain more information.

Imipramine

A tricyclic *antidepressant drug*. Imipramine is most commonly used as a long-term treatment for *depression*, but may take up to six weeks to have a beneficial effect.

Possible adverse effects include excessive sweating, blurred vision, dry mouth, dizziness, constipation, nausea, and difficulty passing urine in older men. Overdose, particularly in a child, can be fatal.

Immersion foot

A condition that occurs in shipwreck survivors and soldiers (in whom it is known as trench foot) resulting from the feet being wet and cold for a long time. Initially, the feet turn pale and have no detectable pulse; later, they become red, swollen, and painful, and have a strong pulse.

TREATMENT

If the feet are at the pale stage, they should be gradually and carefully rewarmed; overheating may lead to *gangrene* (tissue death). Conversely, if they are red and swollen, they should be gradually cooled.

If the condition is ignored and becomes severe, muscle weakness, skin ulcers, or gangrene may develop. Even with mild cases, the feet may be painful and sensitive to cold for several years afterward.

Immobility

Reduced physical activity and movement. Immobility is particularly harmful in the elderly because it causes muscle wasting and progressive loss of function.

CAUSES

Total immobility is rare; it occurs in coma, which is sometimes the result of *stroke*, *brain tumor*, or major *head injury*. *Catatonia* is associated with varying degrees of immobility.

Temporary loss of mobility, lasting a few days, occurs during recovery from any serious illness, such as a *myocardial infarction*, or from a major surgical procedure.

Fractures in a lower limb may be treated by *traction*, which requires several weeks in bed, or by use of a *cast*, which also hinders mobility.

Loss of mobility may be caused by the symptoms of a specific medical disorder, such as *asthma* or *angina pectoris* (chest pain due to reduced blood supply to the heart muscle). Both these conditions may, in severe cases, be aggravated by exercise. *Arthritis* (inflammation of joints) limits mobility if the hips, knees, ankles, or feet are affected by pain and stiffness. Nervous system disorders that restrict mobility include *hemiplegia* (paralysis on one side of the body), *Parkinson's disease*, and *multiple sclerosis*.

A person may find it difficult to move around because of deteriorating eyesight, or may lack motivation due to *depression* or the effects of alcohol or other drugs (such as tranquilizers).

COMPLICATIONS

Total immobility can cause *bedsores*, *pneumonia* caused by secretions building up in the lungs, or *contractures*.

A common complication of partial immobility is *edema* (abnormal retention of fluid in body tissues), which causes swelling of the legs as a result of the calf muscles not working to pump the fluid back to the heart in the circulation. Rarely, a *thrombosis* (blood clot) forms in one of the veins in the leg because of this lack of blood flow.

Obesity is more likely to occur in people who do not exercise. Stiffness tends to develop in any joint not being used properly. Muscle wasting and *osteoporosis* are common problems caused by immobility in the elderly.

TREATMENT

Regular *physical therapy* and adequate nursing care are important for any person who is totally immobile. Regular turning and the use of a special mattress and bed reduce the risk of bed sores. Stretching exercises may prevent contractures.

Early mobilization after serious illness or major surgery is usually encouraged to avoid the problems of prolonged bed rest. After a lower limb fracture, walking with the aid of crutches is started as soon as possible.

Aids for the disabled (see *Disability*) can increase mobility that is impaired by leg weakness, stiffness, loss of balance, or poor coordination. If the person is unable to walk despite assistance, exercises may be done in a chair or in bed to keep the muscles and joints in reasonable working order.

Immobilization

An orthopedic term for techniques used to prevent movement of joints or displacement of fractured bones so that the bones can unite properly. (See also *Fracture*.)

Immune response

A defensive reaction of the body to invading microorganisms, cancer cells, transplanted tissue, and other substances or materials that are recognized as antigenic or "foreign" (that is, different from normal body components). The response consists of the production of substances called *antibodies* or *immunoglobulins*, sensitized cells called *lymphocytes*, and other substances and cells that act to destroy the antigenic material. (See also *Immune system*.)

Immune serum globulin

A preparation of *antibodies*, also known as immune globulin and gamma globulin, used to prevent and sometimes treat infectious diseases.

Its main use is in the prevention of viral *hepatitis* (e.g., before traveling to a country where the disease is common). It is also given to prevent *measles* and *rubella* in people who are exposed to these infections and are not already immune to them from previous infection or *immunization*.

Immune serum globulin is also given to people with *immunodeficiency disorders* (impaired natural defenses).

HOW IT WORKS

Immune serum globulin provides immunity to a range of common infectious diseases. It works by passing on antibodies obtained from the blood of large numbers of people who have previously been exposed to these diseases and thus have developed antibodies to them.

POSSIBLE ADVERSE EFFECTS

Immune serum globulin may cause rash, fever, and pain and tenderness at the injection site.

Immune system

A collection of cells and proteins that works to protect the body from potentially harmful, infectious microorganisms (microscopic life-forms), such as bacteria, viruses, and fungi. The immune system also plays a role in the control of cancer and is responsible for the phenomena of *allergy*, *hypersensitivity*, and rejection problems when organs or tissue are transplanted.

Some of the main components of the body's immune system are described in the illustrated boxes.

A newborn child is, to some extent, protected against infection by barriers (such as the skin), by substances in the mouth, in the urinary tract, or on the eye surface that destroy microorganisms, and by *antibodies* or *immunoglobulins* (protective proteins) that have been passed to the child from the mother (including those received in breast milk).

This natural, or innate, immunity cannot guard against all disease-causing organisms. As the child grows, he or she encounters organisms that overcome the innate defenses and thus cause disease. The second line of immune defense, called the adaptive immune system, then comes into play. As the name implies, this system adapts its response specifically to fight the invading organism. In addition, it retains a memory of the invader so that defenses can be rallied instantly in the future. The person is then said to have acquired immunity to the infection. If these microorganisms invade again, they are quickly recognized and dealt with (which explains why diseases such as measles and diphtheria rarely affect the same person twice).

The acquisition of immunity in response to an infection can take a few days or weeks to develop; in the interim, a child or adult can become very ill or even die. In the past, many did die. Today, our chance of surviving, recovering, or totally avoiding infectious diseases is much improved, partly as a result of better general health and nutrition (which bolsters the immune system) and partly through *immunization* against specific disease-causing microorganisms.

INNATE IMMUNITY

The skin provides an impenetrable barrier to the vast majority of infectious agents, most of which can gain entry only via the mucous membranes (e.g., in the mouth, throat, eyes, intestines, vagina, or urinary tract). These areas are protected by the movement of mucus and other fluids (such as tears) and the presence of enzymes (such as lysozyme) that destroy bacteria.

If microorganisms are able to penetrate the outer layer of the skin or a mucous membrane, they soon encounter white blood cells called phagocytes (literally, "engulfing" cells), which attempt to destroy them, and other types of white cells, such as natural killer (cytotoxic) cells. Microorganisms may also meet naturally produced substances (such as *interferon*) or a system of blood proteins known as the complement system, which act to destroy the invading microorganisms.

ADAPTIVE IMMUNITY

The adaptive part of the immune system is extremely complex and only partly understood. Its function is to produce specific defenses against a range of different invading organisms or tumor cells. Broadly, however, it first must recognize part of an invading organism or tumor cell as an *antigen* (a protein that is foreign or different from any natural body protein).

A response (either humoral or cellular) is then mounted against the antigen. The humoral response consists of the production of soluble proteins, called antibodies or immunoglobulins, manufactured by cells called B-lymphocytes. Cellular responses center around the activities of the cells called T-lymphocytes.

HUMORAL IMMUNITY This type of immunity is particularly important in the defense against bacteria. After a complex recognition process, certain B-lymphocytes are stimulated to multiply. These cells then begin to produce vast numbers of antibodies that are able to bind to the antigens. Once this has occurred, the organisms bearing the antigens are easy prey to phagocytic ("engulfing") white cells. Binding of antibody and antigen may also activate the complement system, which increases the efficiency with which phagocytes engulf and destroy the invading organisms.

CELLULAR IMMUNITY This is particularly important in the defense against viruses, some types of parasites that hide within cells, and, possibly, cancer cells. The T-lymphocytes at the center of cellular immunity are of two types, called helper cells and killer cells. The helper cells play a role in the recognition of antigens. Along with various other functions, they activate the killer cells. Killer lymphocytes lock onto cells that have been invaded by viruses or other parasites that have left recognizable antigens on the cell surfaces. The killer lymphocytes then destroy these parasitized cells. They may act in a similar way against tumor cells and against the cells in transplanted tissue.

The memory of the immune system (which provides acquired immunity to certain diseases) relies on the long-term survival of lymphocytes that were activated or sensitized to antigens when these antigens were first encountered.

IMMUNE SYSTEM DEFECTS

The immune system is an essential asset for the protection of the body from infectious agents and probably cancer. In certain circumstances, however, it may itself be a cause of disease or other undesirable consequences. In some cases, the body's own proteins are misidentified as antigens, and an immunological attack is mounted against them, causing *autoimmune disorders*. In other cases, the immune system mounts an inappropriate response to what are usually innocuous antigens, such as pollen, causing *hypersensitivity* or *allergy*.

SUPPRESSION OF THE IMMUNE SYSTEM

In certain circumstances, such as after transplantation of tissues (see *Transplant surgery*) and in people with an autoimmune disorder, it is advantageous to suppress the immune system (especially the adaptive part of the immune system) through use of drugs. This prevents the rejection of the donor organ by lymphocytes and other cells that recognize proteins in the transplanted tissue as antigens. Immunosuppression can also occur as an inherited disorder or after infection with certain viruses, including HIV, the virus that causes *AIDS* (see *Immunodeficiency disorders*).

Immunity

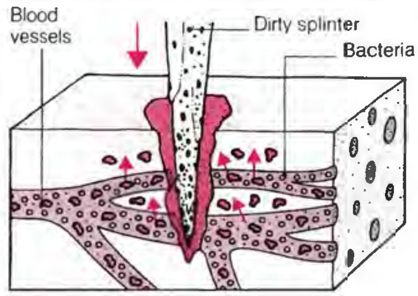
A state of protection against a disease or diseases through the activities of the *immune system*. Natural, or innate, immunity is present from birth and is the first line of defense against the vast majority of infectious agents. Acquired immunity is the second line of defense. It develops either through exposure to invading microorganisms (after they have broken through the innate immune defenses) or as a result of *immunization*.

Immunization

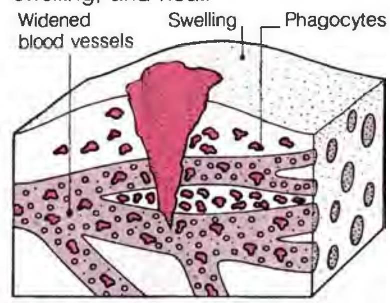
The process of inducing *immunity* as a preventive measure against certain infectious diseases. The incidence of a number of diseases (*diphtheria* and *measles*, for example) has declined dramatically since the introduction of effective immunization programs; one disease (*smallpox*) has been eradicated worldwide.

Although diseases such as diphtheria, measles, *mumps*, *rubella* (German measles), *poliomyelitis*, and *pertussis* (whooping cough) are today rare in the US, routine immunization against them must continue. If a large proportion of the population were nonimmunized, there would be a risk

THE INNATE IMMUNE SYSTEM



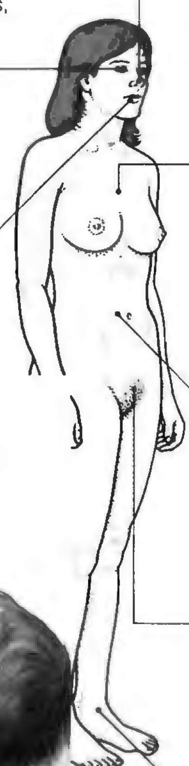
Each of us has many inborn defenses against infection, including external barriers (below), the inflammatory response (right), and phagocyte action (below right). Others include chemicals called complement (which is activated by and attacks bacteria) and *interferon* (which has antiviral effects).



All these defenses are nonspecific and quick-acting. By contrast, the adaptive immune system (next page) mounts specific attacks against particular microbes. These cells are most effective on second exposure to the organisms.

The two parts of the immune system work together; antibodies produced by the adaptive immune system assist phagocyte action.

THE INFLAMMATORY RESPONSE



If microbes break through the body's outermost barriers, inflammation is the second line of defense. Chemicals (such as histamine) are released, prompting the effects shown below, including the attraction of phagocytes to the microbes. The symptoms of inflammation are redness, pain, swelling, and heat.

Following tissue injury (here caused by a splinter) and entry of bacteria or other microbes, blood vessels in the area widen and there is increased leakage of fluid from the blood into the tissues. This allows easier access for immune system components that fight the invaders, including phagocytes and soluble factors (such as the group of chemicals known as complement).

Physical and chemical barriers
These barriers, summarized below, provide the first line of defense against harmful microbes (bacteria, viruses, and fungi).

Eyes
Tears produced by the lacrimal apparatus help wash away microorganisms; tears contain an enzyme (lysozyme) that can destroy bacteria.

Mouth
Lysozyme present in saliva destroys bacteria.

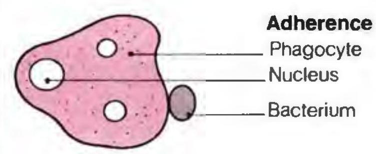
Nose
Hairs in the nose help prevent entry of microorganisms on dust particles. This process is assisted by the sneeze reflex.

Respiratory tract
Mucus secreted by cells lining the throat, windpipe, and bronchi traps microbes, which are then swept away by cilia (hairs on cells in the lining) or engulfed by phagocytes (types of white cells). The cough reflex also helps to expel microbes.

Stomach and intestines
Stomach acid destroys the vast majority of microorganisms. The intestines contain harmless bacteria (commensals) that compete with and control the harmful organisms.

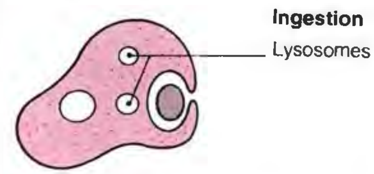
Genitourinary system
The vagina and urethra also contain commensals and are protected by mucus. Spermine in semen may exert some antimicrobial action.

Skin
Intact skin provides an effective barrier against most microbes. The sebaceous glands secrete chemicals that are highly toxic to many bacteria.



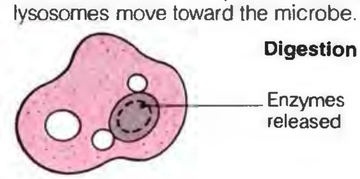
Breast-feeding
Antibodies (proteins with a protective role) formed by the mother against certain microbes are transferred to the baby in breast milk. This action provides some extra immunity until the baby can form his or her own specific antibodies.

ACTION OF PHAGOCYTES



These white blood cells are attracted to infection sites, where they engulf and digest microorganisms and debris.

Adherence

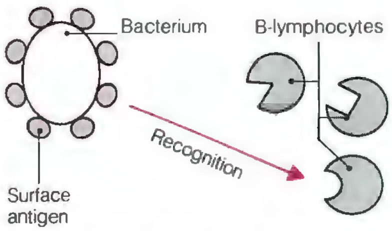


1 The phagocyte must first contact and recognize a microbe as foreign. This process is assisted by chemicals released during inflammation.

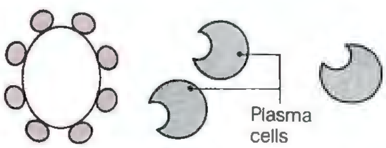
Ingestion

2 The phagocyte engulfs the microbe in a pouch formed in its membrane. Fluid-filled particles called lysosomes move toward the microbe.

Digestion

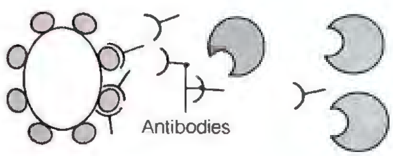


3 Enzymes within the lysosome are released into the pouch to help digest the microbe. Debris from this process is later ejected.

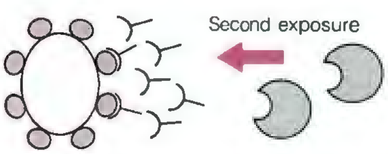


THE ADAPTIVE IMMUNE SYSTEM

This system is based on cells called lymphocytes. It has two parts. Humoral immunity relies on the production, by B-lymphocytes, of antibodies, which circulate and attack specific microbes. In cellular immunity, cells called T-lymphocytes are activated and attack specific microbes or abnormal cells (such as virally infected or tumor cells).

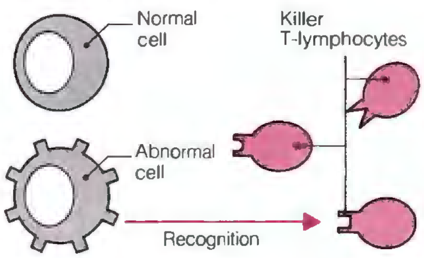


HUMORAL IMMUNITY

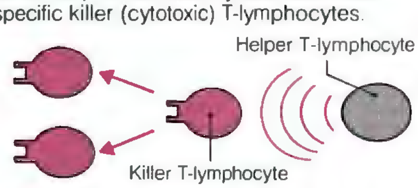


1 A humoral response is started when an antigen (foreign protein)—here on the surface of a bacterium—activates one type of B-lymphocyte.

2 The particular type of B-lymphocyte multiplies, forming cells called plasma cells, which make antibodies designed specifically to attack the bacterium.

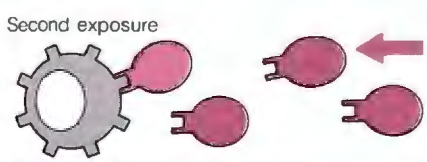


3 After a few days, the antibodies are released and travel to and attach to the antigen. This triggers more reactions, which ultimately destroy the bacterium.



4 Some B-lymphocytes remain in the body as memory cells; if the bacterium enters the body again, they rapidly produce antibodies to halt the infection.

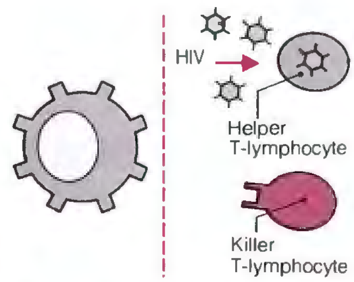
CELLULAR IMMUNITY



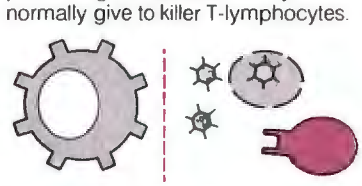
1 An antigen, here on the surface of an abnormal cell (such as a virus-infected or tumor cell), is identified by, and activates, specific killer (cytotoxic) T-lymphocytes.

2 With the assistance of helper T cells (another type of T-lymphocyte), the killer T-lymphocytes begin to multiply.

3 The killer T-lymphocytes travel to, and attach to, the abnormal cells (a), leading to their destruction (b). The T-lymphocytes survive and may go on to kill more targets.



4 Some of the killer T-lymphocytes remain as memory cells, and quickly attack abnormal cells should they reappear (e.g., after reinfection with a virus).



Lymphocyte
Lymphocytes are found in the blood and lymphoid organs (lymph nodes, spleen, and thymus). The two main types—B- and T-lymphocytes—have different functions but look identical under the microscope.

AIDS AND CELLULAR IMMUNITY

HIV—the virus responsible for AIDS—causes illness by disrupting the cellular part of the adaptive immune system.

1 HIV invades and destroys the helper T-lymphocytes, thus preventing the assistance they normally give to killer T-lymphocytes.

2 As a result, the killer T-lymphocytes fail to multiply and attack in response to abnormal cells or invading microorganisms.

3 Opportunistic viruses and other microbes or tumor cells may thus proliferate unchecked, causing the features of AIDS.

EXAMPLES OF INFECTIOUS ORGANISMS COMBATTED

Humoral immunity particularly important against:	Cell-mediated immunity particularly important against:
Some viruses (e.g., measles)	Many viruses (e.g., herpes simplex)
Many bacteria (e.g., cholera)	Some bacteria (e.g., tuberculosis)
Some parasites (e.g., malaria)	Some fungi (e.g., candidiasis)

of a new epidemic because there is still a steady flow of cases of infectious diseases (many imported).

IMMUNIZATION AND VACCINATION

Immunization may be active or passive (see diagram). The terms vaccination and active immunization are used interchangeably. The word vaccination is derived from the vaccinia virus (which is similar to the smallpox virus), which was used for vaccination against smallpox.

WHO SHOULD BE IMMUNIZED

Some types of immunization, such as against polio and DPT (diphtheria, pertussis, and *tetanus*), are aimed at the general population, primarily young children. Others are intended for specific people, such as those exposed to dangerous infections during local outbreaks or those who are at risk of contracting unusual infections through occupational exposure (e.g., laboratory workers or veterinarians).

Immunization before foreign travel may be necessary for entry into certain countries (today, this usually applies only to immunization against *yellow fever*) and to protect the traveler against infection. The traveler should determine a few months before departure which immunizations are necessary or recommended.

The accompanying table gives details of a typical immunization schedule during childhood. (See also *Travel immunization*.)

HOW IMMUNIZATION IS DONE

Most immunizations are given by injection, either into the muscle or into the tissues under the skin in the upper arm. If the injection contains a large volume of fluid, it may be given in the buttock. Polio vaccine is almost always given orally.

ADVERSE REACTIONS

Usually there are no aftereffects following immunization. Some vaccines cause pain and swelling at the injection site and may produce a slight fever and a feeling of irritability and malaise. Acetaminophen should be given to young children in whom fever develops after being immunized. Some vaccines, such as the measles vaccine, may produce a mild form of the disease.

In very rare cases, severe reactions (such as seizures) occur following immunization. This has led to controversy about the advisability of some types of vaccination, notably against pertussis (whooping cough). However, for most people, the risks of vaccination are much smaller than the risk of damage through the disease.

TYPICAL CHILDHOOD IMMUNIZATION SCHEDULE

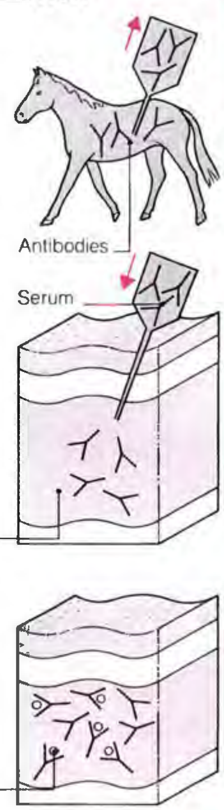
Age	Disease	
2 months	Diphtheria, pertussis (whooping cough), tetanus*	Poliomyelitis†
4 months	Diphtheria, pertussis, tetanus*	Poliomyelitis†
6 months	Diphtheria, pertussis, tetanus*	
15 months	Measles, mumps, rubella (German measles)*	
18 months	Diphtheria, pertussis, tetanus*	Poliomyelitis†
4 to 6 years	Diphtheria, pertussis, tetanus*	Poliomyelitis†
	* Combined injection	† Oral

Although most modern vaccines provide a reliable method of preventing disease, they do not all provide 100 percent protection. *Cholera* and *typhoid fever* vaccinations, in particular, give only partial protection, so other precautions (principally food and water hygiene) must be observed during travel to areas where there is a risk of these diseases.

WHO SHOULD NOT BE IMMUNIZED

Immunization should not be given to any person who suffers from an *immunodeficiency disorder* or a cancer

TYPES OF IMMUNIZATION



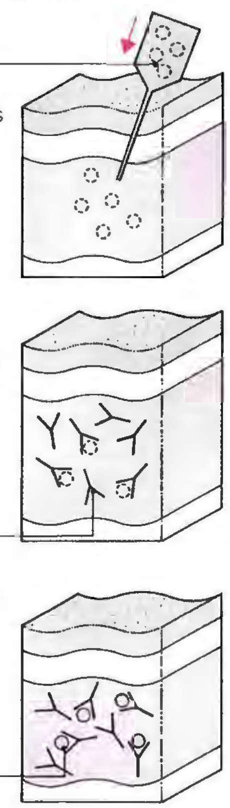
There are two main types. In passive immunization, antibodies (protective proteins) are injected and provide immediate, but short-lived, protection against specific disease-causing bacteria, viruses, or toxins. Active immunization primes the body to make its own antibodies against such microorganisms and confers longer-lasting immunity.

PASSIVE IMMUNIZATION

1 Blood is taken from a person or, rarely, an animal previously exposed to a specific microorganism. The blood contains antibodies against that organism.

2 An extract of the blood containing the antibodies (called immune serum or antiserum) is injected into the person to be protected

3 The antibodies help destroy the microorganism if it is present in the blood or enters it over the following few days.



ACTIVE IMMUNIZATION

1 The person to be protected is inoculated with a killed or modified microorganism (vaccine) that does not cause disease.

2 The immune system is provoked to make antibodies against the modified microorganism; it also retains a "memory" of the organism.

3 If the real microorganism then enters the blood, antibodies are produced in large numbers to halt the infection.

that has spread. Any person who is taking *corticosteroid drugs* or who has previously had a severe reaction to the same vaccine should not be vaccinated. Some vaccines, such as those for typhoid and yellow fever, should not be given to very young children. Vaccination should be deferred if the person has a fever or infection. A number of vaccines, particularly the rubella vaccine, should not be given during pregnancy due to the risk of affecting the fetus.

Immunoassay

A group of laboratory techniques that includes ELISA (enzyme-linked immunosorbent assay) and radioimmunoassay. Both are used in the diagnosis of infectious diseases; variants of radioimmunoassay, such as the radioallergosorbent test (RAST) and the radioimmunosorbent test (RIST), are also used in the diagnosis of allergies and in the measurement of blood hormone concentrations.

Either technique can determine the presence or absence in a person's blood of a specific protein—such as an *antigen* (a protein on the surface of a microorganism or an allergen), a specific *antibody* (a protein formed by the body's immune system to protect against a particular type of microorganism or allergen), or other protein, such as a hormone.

The principle underlying these techniques is that, for any specific antibody, there is a specific antigen. If molecules of these two proteins come in close contact, they will bind strongly to each other. Any specific antibody will bind only to its own antigen, and vice versa.

HOW IT IS DONE

First, the surface of a plate or the inside of a test tube is prepared with a covering of the specific protein (antigen or antibody) that will bind to the antibody or antigen whose presence in the blood is to be tested. For example, in the ELISA test for antibody to *HIV* (the virus responsible for *AIDS*), the inside of a test tube is lined with small amounts of antigen from HIV.

This surface is then exposed to plasma of the blood; if the antibody (or antigen) under test is present, it will stick strongly to the surface. The surface is then washed and a chemical added that will bind to the bound protein. This chemical is itself linked either to an enzyme called peroxidase (in the ELISA test) or to a radioactive isotope (in radioimmunoassay).

Any excess chemical is washed away, and, if the antibody or antigen was present, either peroxidase or radioactivity is left on the surface. Peroxidase can be detected by adding another chemical that changes color in its presence; radioactivity can be measured by a gamma counter.

The RIST differs from other types of radioimmunoassay in that the blood serum containing the substance being tested is first mixed with a solution containing the same substance, which has been radioactively labeled. The radioactive and the test versions compete to bind to the test plate. The result is that, after washing, the less radioactivity found on the test plate, the more test substance must have been present in the blood serum.

Immunodeficiency disorders

Disorders in which there is a failure of the *immune system's* defenses to fight infection and tumors. Immunodeficiency may be the result of an inherited or congenital defect that interferes with the normal development of the immune system or the result of acquired disease that damages the system's function. The result, in either case, is the appearance of persistent or recurrent infection by organisms that would not ordinarily cause disease, incomplete recovery from illness with poor response to customarily effective treatment, and an undue susceptibility to certain forms of cancer.

The infections seen in people with immunodeficiency disorders sometimes are called *opportunistic infections* because the microorganisms take advantage of the person's lowered defenses. Infections of this type include pneumonia caused by *PNEUMOCYSTIS CARINII*, widespread *herpes simplex* infections, and many *fungal infections*.

INHERITED IMMUNODEFICIENCY

The adaptive part of the immune system (which mounts specific defenses against particular microorganisms or tumor cells) has two major prongs. One of these, the humoral system, relies on the production of antibodies, or immunoglobulins, manufactured by *B-lymphocytes*. The other prong is called the cellular system and relies on the activity of T-lymphocytes. Congenital or inherited deficiencies can occur in either of these systems.

Deficiencies of the humoral system include hypogammaglobulinemia (in which the production of one or more types of immunoglobulin is interfered with) and agammaglobulinemia (in which there is an almost complete absence of B-lymphocytes and immunoglobulins). The most common type of hypogammaglobulinemia affects about one person in 600 and may cause no more than repeated mild attacks of respiratory infection. Agammaglobulinemia is a rare, grave condition that often has a fatal outcome in infancy or childhood.

Congenital deficiencies of the T-lymphocytes may lead to problems such as persistent and widespread *candidiasis* (thrush) affecting the skin, mouth, throat, and vagina. Problems of this type are caused by the inability of the immune system to fight fungi.

A combined deficiency of both prongs of the immune system is also known. It is called severe combined immunodeficiency. Infants with this combined deficiency usually die within the first year of life.

ACQUIRED IMMUNODEFICIENCY

Acquired deficiency of the immune system may occur in either of two ways—by damage to the immune system as a result of its suppression with drugs or by disease processes.

Deliberate suppression of the immune system with *immunosuppressant drugs* and *corticosteroid drugs* is usually carried out as part of the treatment of *autoimmune disorders* and after transplantation to minimize the risk of organ rejection.

Diseases that cause immunodeficiency include infection with *HIV* (human immunodeficiency virus), which leads to *AIDS* (acquired immunodeficiency syndrome). Severe malnutrition, especially with protein deficiency, and many types of cancer can also cause immunodeficiency.

IMMUNODEFICIENCY IN THE ELDERLY

A degree of immunodeficiency arises simply as a consequence of age. The thymus, which plays an important part in the production of T-lymphocytes, reaches peak size in puberty and steadily shrinks thereafter. This results in a decline in the number and activity of T-lymphocytes with age; there is also a decline in the numbers of B-lymphocytes.

Immunoglobulins

Proteins found in the blood serum and in tissue fluids, also known as *antibodies*. Immunoglobulins are produced by cells of the *immune system* called B-lymphocytes. Their function is to bind to substances in the body that are recognized as foreign antigens (often proteins on the surface of bac-

teria and viruses). This binding is a crucial event in the destruction of the microorganisms that bear the antigens. Immunoglobulins also play a central role in *allergies* and *hypersensitivity* reactions. In this case they bind to antigens that are not necessarily a threat to health, which may provoke an inflammatory reaction.

There are five classes of immunoglobulins; of these, immunoglobulin G (IgG) is the major immunoglobulin in human blood serum. The IgG molecule consists of two parts, one of which binds to antigen; the other binds to other cells of the immune system. These other cells are principally white cells called phagocytes, which then engulf the microorganisms bearing the antigen. The antigen-binding site of the IgG molecule is variable in its structure, the different versions of the molecule being capable of binding to an almost infinite number of antigens.

Immunoglobulins can be extracted from blood of recovering patients and used for passive *immunization* against certain infectious diseases.

Immunologist

A specialist in the functioning of the *immune system* who may also devise ways in which the immune system can be stimulated to provide immunity (principally through the use of *vaccines*) and who investigates and treats problems related to the immune system. The latter include *allergies*, *autoimmune disorders*, and *immunodeficiency disorders* such as *AIDS*.

Immunologists also play an important part in *transplant surgery*, looking preoperatively for a good immunological match between recipient and donor organ, and suppressing the recipient's immune system after transplantation to minimize the chances of organ rejection.

Immunology

The study of the functioning and disorders of the *immune system*.

Immunostimulant drugs

A group of drugs that increases the efficiency of the body's *immune system* (natural defenses against infection and abnormal cells). Immunostimulant drugs include *vaccines*, which protect against specific infectious diseases (see *Immunization*). Two drugs belonging to this group are *interferon* (used to treat viral infections and certain types of cancer) and *zidovudine* (used to treat *AIDS*).

Some immunostimulant drugs enhance the ability of a vaccine to stimulate the immune system and are added to the vaccine for this reason. Aluminum phosphate, for example, increases the effectiveness of the *tetanus* vaccine.

Immunosuppressant drugs

COMMON DRUGS
Anticancer drugs *Azathioprine Chlorambucil* *Cyclophosphamide Methotrexate*
Corticosteroid drugs *Dexamethasone Prednisone*
Others *Cyclosporine*

A group of drugs that reduces the activity of the body's *immune system* (natural defenses against infection and abnormal cells).

Immunosuppressant drugs are prescribed after *transplant surgery* to prevent the rejection of foreign tissues. They are also given to halt the progress of *autoimmune disorders* (in which the body's immune system attacks its own tissues) when other treatments are ineffective. They are unable, however, to restore tissue that has already been damaged.

HOW THEY WORK

Immunosuppressant drugs work by suppressing the production and activity of *lymphocytes*, a type of white blood cell that plays an important part in fighting infection and in eliminating abnormal cells that may form a malignant tumor.

POSSIBLE ADVERSE EFFECTS

Apart from the individual effects of each type, these drugs increase the risk of infection and of the development of certain cancers.

Immunotherapy

A preventive treatment of allergy to substances such as grass pollens, house-dust mites, and wasp and bee venom. Immunotherapy involves giving gradually increasing doses of the substance, or allergen, to which the person is allergic. This works by making the *immune system* less sensitive to that substance, probably by causing production of a particular "blocking" *antibody*, which reduces the symptoms of allergy when the substance is encountered in the future.

Before starting treatment, the physician and patient try to identify trigger factors for allergic symptoms. Skin or sometimes blood tests are performed to confirm the specific allergens to which the person has antibodies. Immunotherapy is usually recommended only if the person seems to be selectively sensitive to several allergens (such as grass).

HOW IT IS DONE

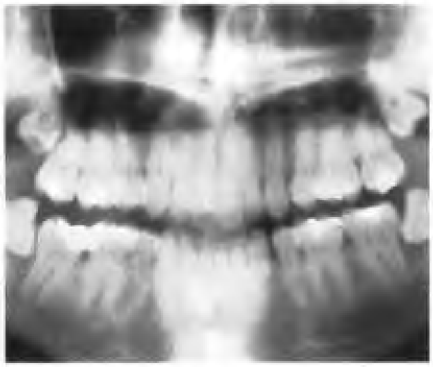
A purified extract of a small amount of the allergen is injected into the skin of the arm. An injection is given once a week for about 30 weeks, after which injections can be administered every two weeks. Eventually, injections can be given every four weeks; the duration of therapy is three to four years.

RISKS

There is a danger of *anaphylactic shock* (a severe allergic reaction) shortly after an injection. Therefore, immunotherapy requires medical supervision and is not done at times of exposure to the substance causing the allergy.

IMMUNOTHERAPY IN CANCER TREATMEMT

Another use of the term immunotherapy refers to stimulation of the immune system to treat cancer. It is still largely experimental, but it may prove a useful adjunct to other therapies, such as *chemotherapy*, in the treatment of *leukemia*, *lymphoma*, and some other cancers.



One type of immunotherapy relies on the use of immunostimulants, substances that cause general stimulation of the immune system.

Another technique is to inoculate the patient with tumor cells or cellular extracts, rendered harmless by irradiation, that have been taken from another person suffering from the same disease. The patient's immune system then produces its own *antibodies*, which attack the tumor cells. Alternatively, immunoglobulins (ready-made antibodies) from another person with the same type of tumor can be given to the patient. More recently, monoclonal antibodies (see *Antibodies, monoclonal*) to be directed against tumors have been produced artificially by *genetic engineering*. *Interferon* or chemical poisons can be linked to these antibodies to increase their ability to destroy tumor cells.

One drawback to the administration of some of these anticancer treatments is that they, too, may be recognized as foreign by the person's immune system, causing either allergic reactions (serum sickness) or new antibody production, which interferes with the activity against cancer.

Impaction, dental

Failure of a tooth to emerge fully or at all from the gum when, because of

Impacted wisdom teeth
This X ray shows impacted wisdom teeth lying horizontally in the lower jaw. The impacted teeth are wedged against the adjacent molars and are not able to erupt normally.

mechanical impediment, it is embedded in bone or soft tissue beyond its normal eruption time.

Impaction is caused by overcrowding of the teeth in places where little room is left for the teeth that erupt last (the wisdom teeth and the upper canines). It is also caused by the tooth traveling in the wrong direction and by dense bone that impedes the tooth's progress.

IMPACTED WISDOM TEETH

These are common, but usually cause no trouble unless they partially penetrate the gum, leaving a flap of tissue over most of the crown. Plaque bacteria and food debris then collect between the tooth and the gum, which often becomes inflamed and painful. There may also be swollen lymph nodes in the upper neck and difficulty opening the mouth.

Rinsing the area with warm, salt water and taking *analgesics* (painkillers) can relieve some symptoms of the condition, but, if it is severe, *antibiotic drugs* are required to clear up the infection. A dentist may decide that the tooth requires extraction to prevent more trouble.

IMPACTED UPPER CANINES

These teeth play a much more important part than do wisdom teeth in biting and chewing. If they are impacted, they are not usually removed, but instead are trained into the correct position by means of an *orthodontic appliance*.

Impetigo

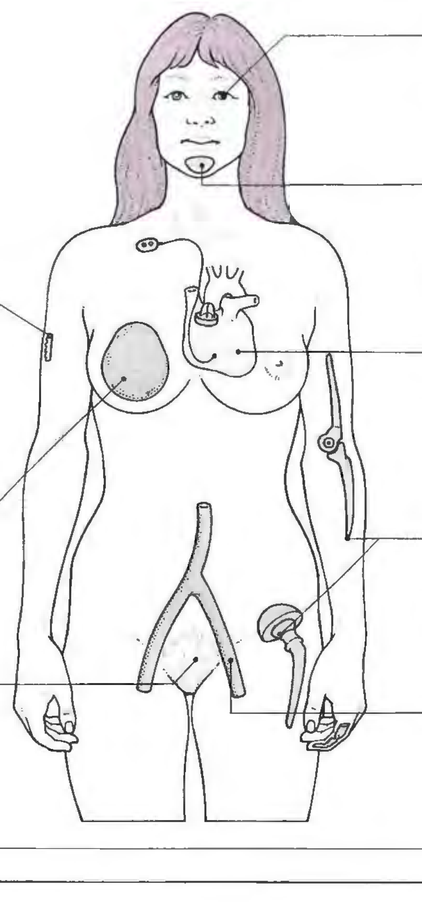
A highly contagious skin infection, common in children, that usually occurs around the nose and mouth.

CAUSES AND INCIDENCE

Impetigo is caused by bacteria entering the skin through a broken area, such as a cut, cold sore, or an area affected by *eczema*. The infection is more common in warm weather. Impetigo was once extremely common, but occurs less frequently now because of improved standards of personal hygiene. Small epidemics occasionally occur in schools.

SYMPTOMS AND SIGNS

The skin reddens and small, fluid-filled blisters appear on the surface. The blisters tend to burst, leaving moist, weeping areas underneath; the released fluid dries to leave honey-colored crusts on the skin. The infected area may spread at the edges or another patch may develop nearby.



In severe cases there may be swelling of the *lymph nodes* in the face or neck, accompanied by a fever. Very occasionally, complications such as *septicemia* (blood poisoning) or *glomerulonephritis* (inflammation of the kidneys) develop.

TREATMENT

Because impetigo spreads rapidly, it is advisable to consult a physician. *Antibiotic drugs* in tablet or ointment form usually clear up the problem in about

TYPES OF IMPLANTS

Implants may be inserted into various parts of the body. They can be used to replace a diseased structure, to improve appearance, to maintain proper functioning of an internal organ, to treat certain disorders, or to deliver drugs or hormones.

Hormonal
Some hormonal drugs (particularly hormonal contraceptives) can be placed in implants that are inserted under the skin to release the drug slowly over time. Alternatively, such drugs can be incorporated in some IUDs (intrauterine contraceptive devices).

Breast
Silicone implants can be used to restore breast shape after mastectomy (breast removal) for cancer or to increase breast size for cosmetic purposes (augmentation mammoplasty).

Therapeutic
Radioactive materials in sealed containers can be inserted into tissue to treat malignant tumors, for example, a cancer of the cervix.

Eye
An implant can be used to replace the lens of the eye after cataract removal, or the entire eyeball if it requires removal because of injury or disease.

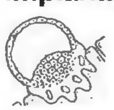
Face
Pieces of bone taken from another part of the body, or shaped pieces of silicone, can be implanted on the face to make a receding chin more prominent or to improve the contour at a fracture site.

Heart
Cardiac pacemakers (battery-powered electronic devices connected by wires to the heart muscle) can be implanted in the chest to regulate the heart beat; diseased heart valves may be replaced with artificial or natural substitutes.

Joints
Diseased joints can be replaced with artificial substitutes to help restore full function. The elbow, the hip, the knee, the finger joints, and the shoulder can all now be treated in this way.

Artery
Diseased sections of artery, such as the lower aorta and upper iliac arteries (shown here), can be replaced or bypassed with artificial tubular materials made from woven or knitted synthetic fibers.

The appearance of impetigo
Fluid-filled blisters appear on the skin (in this case, on the neck and chest). The blisters often burst, releasing fluid that dries to leave pale-brown crusts.



five days. Any loose crusts should be gently washed off with soap and water and the area dabbed dry.

To prevent spreading, pillowcases, towels, and washcloths should not be shared and should be boiled after use. Children should not touch affected skin and should stay out of school until the infection clears.

Implant

Any material, natural or artificial, inserted into the body (see box on the previous page).

Implantation, egg

Attachment of a fertilized ovum to the wall of the uterus. About six days after fertilization, the developing *embryo* comes into contact with the wall of the uterus and attaches to it. As the cells of the embryo divide, the outer cell layer grows into the lining of the uterus to obtain oxygen and nutrients from the mother's blood; later, this layer develops into the *placenta*.

The embryo usually implants in the upper part of the uterus; if it implants low down near the cervix, *placenta previa* may develop. Rarely, the embryo does not reach the uterus and implants in a fallopian tube, resulting in an *ectopic pregnancy*.

Impotence

The inability to achieve or maintain an *erection*. Impotence is the most common male sexual disorder, affecting most men at some time in their lives.

CAUSES

In the majority of men, impotence is caused by psychological factors. They may be temporary (caused by stress or fatigue) or long-standing (caused by anxiety and guilt that originated in childhood). Impotence may be a symptom of *depression*.

Approximately 10 percent of impotence is caused by a physical disorder (including *diabetes mellitus* or hormonal imbalance) or by a neurological disorder (such as spinal cord damage or chronic alcohol abuse). Impotence may be caused by taking various drugs—particularly antipsychotics, antidepressants, antihypertensives, and diuretics. Impotence is also more common as men get older, possibly because of altered circulation or, less often, lowered levels of the male sex hormone *testosterone*.

DIAGNOSIS AND TREATMENT

If the cause is psychological, counseling or *sex therapy* (preferably with the person's partner) is successful in more than half the cases of long-term impotence. To eliminate the possibility of any physical disorder, tests may be performed. The physician may stop medication or alter the dose to aid in diagnosis; attempts are also made to treat any depression or alcohol abuse. *Penile implants* help some men whose impotence is caused by disease.

Impression, dental

A mold taken of the teeth, gums, and sometimes the palate. A quick-setting material, such as alginate or a rubber compound, is placed in a shaped tray that is eased over the area of which a replica is to be made and left in position until the material has set. After the mold has been removed, plaster of Paris is poured into it to obtain a model of the area. This is then used as a base on which to build a *denture, bridge, inlay*, or *onlay*.

Impressions are also used in *orthodontics* to study the position of the teeth and the structure of the mouth, and to make any orthodontic appliances to correct the irregularities.

Impulse control disorders

A group of psychiatric disorders characterized by the inability to resist an impulse or temptation to do some-

INCIDENCE OF RELATIVELY SHORT-LIVED CONDITIONS* IN THE US

Incidence (new cases per 100,000 people per year)	**Categorization**	**Examples**
More than 10,000	Extremely common	Common cold
1,000 to 10,000	Very common	Sexually transmitted infection (all types)
100 to 1,000	Common	Basal cell carcinoma, gonorrhea, lung cancer, myocardial infarction, shingles, stroke
20 to 100	Fairly common	Breast cancer, viral hepatitis, intestinal cancer, symptomatic kidney stones
5 to 20	Uncommon	AIDS, brain tumor, acute leukemia, malignant melanoma, syphilis (primary and secondary), tuberculosis
0.5 to 5	Rare	Amebiasis, gallbladder cancer, Guillain-Barré syndrome, Hodgkin's disease, measles, motor neuron disease, pertussis
0.005 to 0.5	Very rare	Botulism, leptospirosis, lymphogranuloma venereum, malaria
Less than 0.005	Extremely rare	Cholera, diphtheria, rabies

* conditions that are self-resolving, curable, or fatal

thing that ultimately proves harmful to oneself. The group includes pathological *gambling*, *kleptomania*, *pyromania*, and *explosive disorders*.

Incest

Legally defined as sexual intercourse between close relatives (parent-child or brother-sister intercourse is regarded as first degree; with a grandparent, aunt, or uncle, it is regarded as second degree; with a cousin it is regarded as third degree).

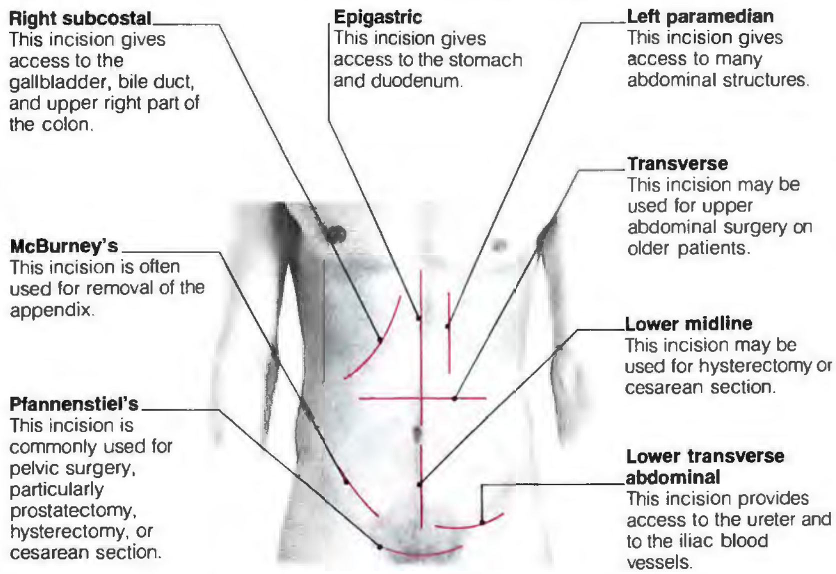
Marriage between close kin is forbidden by law in certain jurisdictions and religions, but permitted in others. Incest prohibitions are widespread and are probably based on concerns over the higher risk of certain congenital problems due to inbreeding.

The actual prevalence of incest is unknown. Recent estimates state that 5 to 10 percent of girls experienced sexual contact with a brother, father, or other male relative, as did 1 to 2 percent of boys with either a male or a female relative.

The 1978 Federal Child Abuse Laws mandate reporting to child protection authorities "any sexual act" (not just intercourse) between an adult and a child inside or outside the family; this aberrant and psychologically damaging behavior is regarded as criminal.

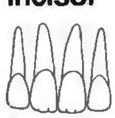
Incest was customary in the royal families of ancient Egypt and contemporary Hawaii. It is more common in isolated mountain and rural communities, where incest-accepting families remain unaware of the law. Education and individual and family therapy are useful.

Incidence



One of the two principal measures (the other is prevalence) of how common a disease is in a defined population. The incidence of a disease is the number of new cases that occurs during a given period (e.g., 17 cases per 100,000 people per year). Prevalence is the total number of cases of a disease in existence at any one time; it includes both new and old cases. Thus, in 100,000 people, there may be an incidence of, say, 400 cases of a specific type of cancer per year, but a prevalence of 4,000 cases, because the disease lasts an average of 10 years before being cured or causing death.

Incision



A cut made into the tissues of the body by a scalpel (surgical knife). Most incisions are made to gain access to tissue inside the body (usually to repair or remove a diseased organ) or to relieve pressure (e.g., from pus in an abscess). Standard incision sites for abdominal surgery are shown in the illustrated box.

ABDOMINAL INCISIONS

Surgery is frequently performed on the abdomen. Standard incision sites provide access to the diseased portion with minimum weakening of the abdominal wall. The most commonly used of these standard incision sites are shown in the diagram below.

Incisor

One of the eight front teeth (four in the upper jaw and four in the lower) used for incising (cutting through) food. (See *Teeth*.)

Incompetent cervix

See *Cervical incompetence*.

Incontinence, fecal

Inability to retain feces in the rectum.

CAUSES

The most common cause of fecal incontinence in the elderly and in children who have been toilet trained is *fecal impaction*. The feces lodged in the rectum irritate and inflame its lining and, as a result, fecal fluid and small pieces of feces are passed involuntarily. Temporary loss of continence may occur at any age with severe *diarrhea* when the need to evacuate the bowel becomes too great to contain.

Less common causes include injury to the anal muscles (for example, during childbirth or surgery), *paraplegia* (paralysis of the legs and lower trunk), mental handicap, and *dementia*.

TREATMENT

Impaction, often caused by constipation, may be prevented by a high-fiber diet. Glycerin suppositories taken daily (or laxative suppositories taken occasionally) may be used if the constipation has persisted for several days. Incontinence due to dementia or nerve injury can be avoided by regularly using enemas or suppositories to empty the rectum.

Incontinence, urinary

Uncontrollable, involuntary urination, often due to injury or disease of the *urinary tract*. This disorder often affects the elderly because the efficiency of the sphincter muscles surrounding the *urethra* declines with age. Women are affected more often than men.

TYPES AND SYMPTOMS

STRESS INCONTINENCE This refers to the involuntary escape of a small amount of urine when a person coughs, laughs, picks up a heavy package, or moves excessively (such as during athletic activity). Stress incontinence is very common in women, particularly after childbirth when the urethral sphincter muscles are stretched.

URGE INCONTINENCE In this type, an urgent desire to urinate is accompanied by inability to control the bladder. Urge incontinence may occur when walking or sitting, but is fre-

quently triggered by a sudden change in position. Once urination starts, it continues until the bladder is empty.

TOTAL INCONTINENCE This refers to a complete iack of bladder control resulting from the total absence of sphincter activity. In rare cases, total incontinence occurs because the urine bypasses the sphincter, as in a vesicovaginal fistula (a hole between the bladder and vagina) or an ectopic ureter (in which the ureter enters the urethra rather than the bladder).

OVERFLOW INCONTINENCE This occurs in chronic *urine retention*, a condition in which the sufferer is unable to empty the bladder normally, often because of an obstruction such as an enlarged *prostate gland*. The bladder is always full, leading to constant dribbling of the overflow. Relief of the obstruction restores continence.

CAUSES

Incontinence may be caused by localized disorders of the urinary tract (including infections, bladder stones, or tumors) or by *prolapse* of the uterus or vagina. Incontinence due to lack of control by the brain commonly occurs in the young (see *Enuresis*), the elderly, and those with mental impairment. Damage to the brain or spinal cord by injury or disease also affects bladder control, as does stress, anger, and anxiety. Weak pelvic muscles, a fractured pelvis, or cancer of the prostate can cause incontinence. *Irritable bladder*, in which the bladder muscle twitches intermittently, raises the pressure in the bladder to push some urine out of the urethra; this causes an intense desire to urinate.

DIAGNOSIS

Urinalysis (examination of the urine) is performed to eliminate the possibility of infection, inflammation, diabetes, or protein loss. *Ultrasound scanning*, intravenous *pyelography* (X rays of the kidney and ureters after injection of a dye), and a voiding *cystourethrogram* (X rays taken while the patient is urinating) are used to investigate the possibility of an obstruction. *Cystometry*, which measures the pressure within the bladder, can determine if the bladder is functioning normally or if there is any abnormality of the nerves supplying the bladder. *Cystoscopy* (examination of the urethra and bladder through a rigid or flexible viewing tube) is performed to look for the presence of bladder *calculi*, tumors, or cysts.

TREATMENT

If weak pelvic muscles are causing stress incontinence, *pelvic floor exercises* may help to restore sphincter function. Sometimes an operation is performed to tighten the urethra. In severe cases, an inflatable artificial plastic sphincter may be placed around the urethra; when urination is required, a trigger is pressed to deflate the mechanism to allow urine to flow.

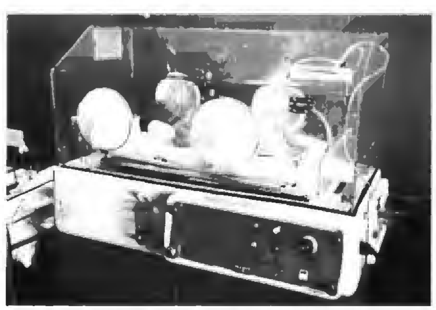
Anticholinergic drugs are sometimes used to relax the spastic bladder muscle if irritable bladder is the cause.

If normal bladder function cannot be restored, special incontinence underpants (with an internal pad to absorb the urine) can alleviate discomfort. Men can wear a sheath over the penis; the sheath leads into a tube connected to a portable urine bag. Some people are able to pass a catheter into the bladder four or five times a day to empty it and avoid incontinence.

If these measures are unsuccessful and the condition is severe, a *urinary diversion* operation to bypass the bladder may be necessary.

Incoordination

Loss of the ability to produce smooth, harmonious muscular movements, leading to clumsiness and unsteady balance. Incoordination can also mean the failure of a group of organs to work together successfully. (See *Ataxia*.)



Incubation period

The time during which any infectious disease develops, from the point when the infecting organism enters the body until the appearance of symptoms. Different infections have characteristic incubation periods—for example, 14 to 21 days for chickenpox and seven to 14 days for measles. The incubation period for cholera may be as short as several hours. (See also *Infectious disease* table.)

Incubator

A transparent plastic container in which oxygen, temperature, and humidity levels are controlled to provide premature or sick infants with ideal conditions for survival. An incubator also provides some protection from airborne infection.

Incubators have portholes to allow handling of the baby and smaller holes through which monitoring cables and intravenous and respiratory tubing can pass. The air temperature within the incubator is carefully regulated.

Premature infant in an incubator
Portholes make it possible to handle the infant without disturbing the special conditions provided by the incubator.

Indian medicine

In contrast to Chinese medicine, traditional East Indian medicine was based on empirical observation and practice rather than on philosophy. The earliest Indian literature, the Vedas, which date from about 1500 BC, contain detailed descriptions of numerous disorders and their treatments. Ayurvedism, as Vedic medicine is known, was based largely on herbal treatment, although early Vedic physicians also used simple surgical techniques and invented artificial limbs and eyes.

The Vedic era ended in about 800 BC, but the medical traditions of ayurvedism survived and were further developed (especially the surgical aspect) under the Brahmans, the caste of wise men. As a result, by about 500 AD, Indian medicine had become a scientifically based system with a wide range of surgical techniques available (such as operations for cataracts and kidney stones) along with the herbal tradition. The Brahmans, however, cloaked their medical knowledge in theology and superstition and traditional Indian medicine stagnated. Today, most Indian medicine follows Western practices.

Indigestion

A term covering a variety of symptoms brought on by eating, including *heartburn*, *abdominal pain*, *nausea*, and *flatulence* (excessive gas in the stomach or intestine, causing belching or discomfort).

Indigestion refers to a burning discomfort in the upper abdomen, often brought on by eating too much, too quickly, or by eating very rich, spicy, or fatty foods. Nervous indigestion is a common effect of stress. Occasionally, persistent or recurrent indigestion is associated with a *peptic ulcer*, *gallstones*, or *esophagitis* (inflammation of the esophagus).

TREATMENT

Self-help treatment includes avoiding foods and situations that bring on symptoms and finding time to eat

three or four times a day, at regular times, without rushing. Taking *antacid drugs* or drinking milk may make symptoms subside.

Anyone who takes antacid drugs regularly should see a physician so that the underlying cause of the problem can be investigated. If abdominal pain persists for more than six hours, or if there are other symptoms, such as prolonged vomiting, vomiting blood (which may appear brown), passing very dark or black feces, or feeling weak or faint, a physician should be consulted immediately.

Indomethacin

A *nonsteroidal anti-inflammatory drug* (NSAID) used to relieve pain, stiffness, and inflammation in disorders such as *osteoarthritis, rheumatoid arthritis, gout, ankylosing spondylitis,* and *tendinitis.* Indomethacin is also prescribed to relieve pain caused by injury to soft tissues, such as muscles and ligaments.

Treatment with indomethacin may cause abdominal pain, nausea, heartburn, headache, dizziness, and an increased risk of *peptic ulcer.*

Induction of labor

Use of artificial means to initiate the process of childbirth. Labor is induced if the health of the mother or baby would be endangered by allowing the pregnancy to continue. If the pregnancy is not at full term, the risks of induction are weighed against the risks of a premature delivery.

WHY IT IS DONE

The primary reason for inducing labor is that the pregnancy has continued past the estimated delivery date, which increases the chance of both maternal and fetal complications during childbirth. Most obstetricians induce labor if the delivery is more than two weeks overdue.

Labor is induced early if the mother is suffering from *eclampsia* or *preeclampsia,* or if she has chronic *hypertension.* Labor may also be induced if there is Rh incompatibility between the mother and baby (because of the risk of *hemolytic disease of the newborn*) or if there are indications of *intrauterine growth retardation.*

HOW IT IS DONE

The most common technique of inducing labor is to rupture the membrane around the baby to release some of the amniotic fluid. This is usually sufficient to start labor. If not, vaginal suppositories containing prostaglandin (a hormone that stimulates the uterus to contract) may be inserted high in the vagina. If this is unsuccessful, an intravenous infusion of *oxytocin* (another hormone that stimulates uterine contractions) may be necessary. If the uterus fails to respond to any of these treatments, the baby may be delivered by cesarean section.

COMPLICATIONS

The conditions of both the mother and baby are monitored closely during an induced labor because of the danger that *hypoxia* (reduced oxygen supply) may develop in the baby. Special care facilities are needed if the baby is born prematurely.

Industrial diseases

See *Occupational disease and injury.*

Infant

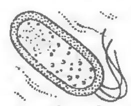
A baby up to the age of 12 months; sometimes this description also includes the period up to 24 months.

Infantile spasms

A rare type of recurrent seizure that affects babies. Infantile spasms are a form of *epilepsy* in which the baby suddenly stiffens, bending the trunk, limbs, and neck. There may be several hundred such spasms per day, each lasting a few seconds and sometimes preceded by a cry. In most cases the seizures are a sign of brain damage and affected babies grow up with severe mental retardation.

Infant mortality

The number of infants who die during the first year of life per 1,000 live births. About two thirds of all infant deaths occur during the neonatal period (the first month of life). Most of those who die are very premature (born before the 30th week of pregnancy) or have severe birth defects.



Infant mortality varies greatly among different countries and among different racial and social groups. For example, in Sweden (in the early 1980s), the mortality was low, at eight deaths per 1,000 live births, whereas, in certain African countries, it was as high as 150 per 1,000. In the US, the mortality was 19 per 1,000 live births for black infants, compared with 10 per 1,000 for white infants.

In most developed countries, there has been an overall decline in infant mortality since about the turn of the century. This is largely due to improvements in nutrition and in social conditions and to medical advances, particularly in *prenatal care* and neonatal intensive care.

Infarction

Death of an area of tissue caused by *ischemia* (lack of blood supply). Common examples include *myocardial infarction* (heart attack) and pulmonary infarction, which is lung damage caused by a *pulmonary embolism* (a blood clot that has moved into a vessel in the lung and is obstructing the flow of blood). See also *Necrosis.*

Infection

The establishment of a colony of disease-causing microorganisms (such as bacteria, viruses, or fungi) in the body. The organisms actively reproduce and cause disease directly by damage to cells or indirectly by toxins they release. Infection normally provokes a response from the *immune system,* which accounts for many of the features of the infection.

Toxic symptoms, such as fever, weakness, and joint aches, are expressions of *infectious disease.* In such cases, the microorganisms are often spread throughout the body (this is called "systemic" infection). Infection may also be localized within a particular tissue or area, often through spread of organisms from parts of the body where they are harmless to parts where they are harmful (e.g., through leakage from the intestines into the abdomen to cause *peritonitis*).

Entry of microorganisms from soil into wounds or during the course of surgical operations and procedures is another common cause of localized infection. In the early days of surgery, infection of internal body cavities was the major (and frequently fatal) risk to the patient. Antiseptic surgical techniques have largely eliminated this problem.

AVOIDANCE

Localized infections (as opposed to infectious diseases) can be avoided by standard hygienic measures, such as keeping the hands clean, not picking at blemishes, washing and covering cuts and grazes, having wounds attended to by a physician, and seeking regular dental treatment.

SYMPTOMS, DIAGNOSIS, AND TREATMENT

Localized infection is generally followed by *inflammation,* which increases the flow of blood to the infected area, bringing white blood cells and other components of the immune system. Symptoms and signs usually include pain, redness, swelling, formation of a pus-filled abscess at the site of infection, and sometimes a rise in temperature.

Any suspected infection should be brought to the attention of a physician. Once the nature of the causative microorganism has been discovered, treatment consists of an antimicrobial drug, such as an *antibiotic*.

Infection, congenital

Any infection present at birth that was acquired by the infant either in the uterus or during passage through the birth canal.

INFECTIONS ACQUIRED IN THE UTERUS

Many viruses, bacteria, and other microorganisms can pass from the mother's blood through the placenta and into the circulation of the growing fetus. Particularly serious are organisms responsible for *rubella* (German measles), *syphilis*, and *toxoplasmosis*, and the *cytomegalovirus*. Any of these infections may cause *intrauterine growth retardation*. Further effects depend on the stage of pregnancy at which the infection was acquired. Thus, rubella occurring at around nine to 10 weeks (the stage at which various organs are beginning to develop) may cause *deafness*, congenital *heart disease*, and other damage. If infection occurs much later in pregnancy, it may cause no serious harm.

A woman who is infected with the HIV virus (responsible for *AIDS*) risks passing the infection on to her baby during pregnancy. AIDS usually develops within the first two years of life in infants infected with HIV.

INFECTIONS ACQUIRED DURING BIRTH

These infections are almost always acquired from the mother's vaginal secretions or uterine fluid that has become infected with microorganisms. If the membranes rupture prematurely, the baby is at risk of infection from organisms ascending into the uterus from the birth canal.

Conditions acquired in this way include *conjunctivitis* (caused by infection with the organisms responsible for *gonorrhea*), genital *herpes*, a *chlamydial infection*, and infantile *diarrhea* (caused by salmonella or other bacteria). *Meningitis*, *hepatitis B*, *listeriosis*, and staphylococcal and streptococcal bacterial infections may also be acquired in this way. Babies who inhale infected maternal secretions may develop *pneumonia*.

PREVENTION

The risk of a baby acquiring an infection in the uterus is minimized by all girls being immunized against rubella in childhood and by pregnant women avoiding sexually transmitted disease (or by having any such disease treated promptly).

If a woman has an active genital herpes infection close to the time of delivery, cesarean section is usually performed, because infection of the newborn baby with herpes simplex virus is particularly serious and commonly fatal.

TREATMENT

If a baby is diagnosed as having an infection at birth, treatment against the infecting agent is started. Any stunting of growth that has occurred due to infection in the uterus cannot usually be reversed. Some types of birth defects caused by infection (e.g., heart defects) are treatable; others (such as deafness) usually are not.

Infectious disease

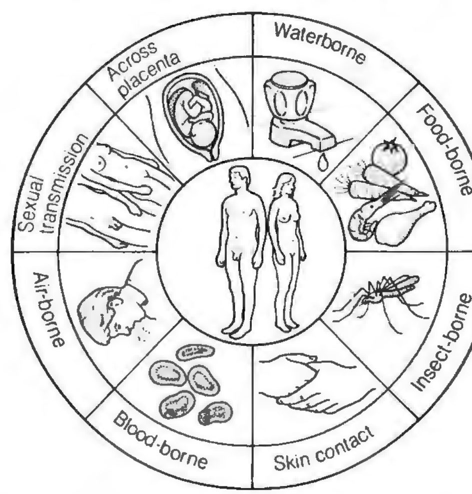
Any illness that is caused by a specific microorganism.

INCIDENCE

Infectious diseases are a large and important group of conditions and, until recently, were the major cause of illness and death throughout the world. (In many developing countries, they remain a major cause of death.) Over the last century or so, this situation has changed in the more developed countries as a result of four important advances. First, better methods are employed for controlling the spread of disease organisms—including better sanitation, water purification, housing, pest control, personal hygiene, and quarantining procedures (see *Public health*). Second, many effective antimicrobial drugs have been developed. Third, vaccines and other preparations have been developed to provide immunity to certain infectious diseases (see *Immunization*). Fourth, better general health and nutrition have bolstered immunity and improved survival.

In developed countries, such measures have brought about a dramatic decline in the incidence of some serious diseases (such as *poliomyelitis*, *smallpox*, *diphtheria*, and *tuberculosis*). In poorer countries, however, infectious diseases remain a huge problem, for reasons that include lack of resources, ignorance, low standards of public and personal hygiene, the presence of insect transmitters of disease, and, perhaps most importantly, malnutrition. Diseases such as measles have a mortality of 20 percent or more in malnourished children.

CAUSES



Disease-causing organisms fall into a number of well-defined groups. Among the most important are the *viruses*, *bacteria*, and *fungi*, along with three smaller groups, the rickettsiae, chlamydiae, and mycoplasmas. All

HOW INFECTIOUS DISEASES ARE TRANSMITTED

In developed countries, infectious diseases are usually spread by sexual transmission, airborne transmission, blood-borne transmission, or direct skin contact. In poorer countries, insect-borne, food-borne, and waterborne infection are other important mechanisms of transmission. Certain infections can also pass from a pregnant woman's blood across the placenta into the blood of the fetus.

Cholera bacteria
The comma-shaped bacteria that cause the dangerous infectious disease cholera are spread by contamination of water.

are relatively simple organisms that can readily multiply in a host's tissues when defenses are low. Other groups include the *protozoa* (single-celled animal parasites), *worms*, and *flukes*. These more complex parasites may spend only part of their life cycle in human tissues; the rest of their lives is spent in another animal or in soil. Colonization of the body by worms and flukes (along with external parasites, such as *scabies* and *lice*) is generally referred to as an *infestation* rather than an infection.

See table, below, for examples of transmission mechanisms.

AVOIDANCE

Serious infectious diseases can largely be avoided by measures such as *immunization*, good hygiene with respect to food and drink and washing the

SOME IMPORTANT INFECTIOUS DISEASES

VIRAL INFECTIONS

Infective agent	Transmission	Incubation period	Symptoms	Treatment
AIDS virus infection				
Human immunodeficiency virus (HIV)	Sexual contact; sharing hypodermic needles; mother to child; blood product infusion before March 1985	Variable, usually several years	Fever; weight loss; fatigue; diarrhea; swollen lymph nodes; shortness of breath	Treatment of complicating infections; zidovudine can prolong life expectancy
Chickenpox				
Varicella-zoster virus (herpes zoster virus)	Airborne droplets; direct contact	11 to 21 days	Slight fever; malaise; characteristic rash	Relief of symptoms; acyclovir beneficial in adults
Common cold				
Numerous rhinoviruses; coronaviruses	Airborne droplets; hand-to-hand contact	1 to 3 days	Sneezing; chills; muscle aches; runny nose; cough	Relief of symptoms
Hepatitis, viral				
Hepatitis virus types A and B; others	Infected food or water (type A); sexual contact; blood-borne transmission; sharing hypodermic needles (type B)	3 to 6 weeks (type A); a few weeks to several months (type B)	Influenzalike illness; jaundice; many people are asymptomatic	Relief of symptoms; interferon may be beneficial in some cases
Influenza				
Influenza viruses types A, B, or C	Airborne droplets	1 to 3 days	Fever; chills; aches; headache; sore throat; cough; runny nose	Relief of symptoms; fluids
Measles				
Measles virus (a paramyxovirus)	Airborne droplets	7 to 14 days	Fever; coldlike symptoms; characteristic rash; conjunctivitis	Relief of symptoms
Meningitis, viral				
Various viruses	Various methods, including via rodents	Variable	Fever; headache; drowsiness; confusion	Relief of symptoms; acyclovir in some cases
Mononucleosis, infectious				
Epstein-Barr virus	Possibly via saliva	1 to 6 weeks	Swollen glands; fever; sore throat; headache; malaise; lethargy	Relief of symptoms; rest; fluids
Poliomyelitis				
3 polioviruses	From feces to mouth via hands; airborne droplets	Minor illlness—3 to 5 days. Major illness—7 to 14 days	Minor illness—sore throat; headache; vomiting. Major illness—fever; stiff neck and back; muscle aches; paralysis	Relief of symptoms
Rabies				
Rabies virus (a rhabdovirus)	Bite from infected animal	10 days to 8 months	Fever; general malaise; irrationality; throat spasms; hydrophobia	No effective treatment
Rubella				
Rubella virus	Airborne droplets; mother to child	2 to 3 weeks	Low fever; characteristic rash	Relief of symptoms

CHLAMYDIAL INFECTIONS

Infective agent	Transmission	Incubation period	Symptoms	Treatment
Nonspecific urethritis				
Chlamydia trachomatis	Sexual contact	1 to 4 weeks	Pain on passing urine; watery, mucus discharge	Antibiotics
Psittacosis				
Chlamydia psittaci	Inhalation of dust containing feces from infected birds	1 to 3 weeks	Flulike and feverish symptoms, shortness of breath	Antibiotics

RICKETTSIAL INFECTIONS

Infective agent	Transmission	Incubation period	Symptoms	Treatment
Q fever				
Coxiella burnetti	Inhalation of infected dust	7 to 14 days	Sudden onset of fever and sweating; cough; chest pains; headache	Antibiotics
Rocky Mountain spotted fever				
Rickettsia rickettsii	Bite from infected tick	2 to 7 days	Severe headache; high fever; muscle aches; weakness; rash	Antibiotics

BACTERIAL INFECTIONS

Infective agent	Transmission	Incubation period	Symptoms	Treatment
Gonorrhea				
Neisseria gonorrhoeae	Sexual contact; mother to baby	2 to 6 days	Pain on passing urine; discharge; pain in abdomen	Penicillin; ampicillin; other antibiotics for resistant forms
Meningitis, bacterial				
Neisseria meningitidis (meningococcus); *Streptococcus pneumoniae;* others	Mother to baby via vagina; infection reaching bloodstream from another organ	Less than 3 weeks, could be less than 24 hours	High fever; stiff neck; nausea; confusion	Antibiotic treatment
Pertussis (whooping cough)				
Bordetella pertussis	Airborne droplets	1 to 2 weeks	Runny nose and moderate fever; slight cough leading to characteristic cough spasms	Erythromycin in early stage; small children may require hospitalization
Pneumonia				
Streptococcus pneumoniae, Legionella pneumophila; others	Airborne droplets	1 to 3 weeks	Cough; fever; chest pain; shortness of breath	Antibiotics
Tuberculosis				
Mycobacterium tuberculosis	Airborne transmission; cow's milk	Several weeks to several years	Malaise; weight loss; cough; shortness of breath; chest pain	Various antibiotics; possibly surgery
Typhoid fever				
Salmonella typhosa	Food or water contaminated with infected feces	1 to 2 weeks, sometimes longer	Headache; lethargy, intestinal upsets; very high, prolonged fever	Several effective drugs, but fever takes a long time to control

FUNGAL INFECTIONS

Infective agent	Transmission	Incubation period	Symptoms	Treatment
Histoplasmosis				
Histoplasma capsulatum	Inhalation of fungus from soil; bird or bat droppings, mostly in Ohio river valley region	2 to 3 weeks	Headache; chills; fever; cough; possible chest pain	Antifungal drugs
Meningitis, fungal				
Cryptococcus neoformans	Inhalation of fungus from pigeon droppings	Unknown	Headache; stiff neck; photophobia	Antifungal drugs

PROTOZOAL INFECTIONS

Infective agent	Transmission	Incubation period	Symptoms	Treatment
Amebiasis				
Entamoeba histolytica	Food or water contaminated by feces	A few weeks to many years	Severe diarrhea	Antiprotozoal drugs (e.g., metronidazole)
Giardiasis				
Giardia lamblia	Food or water contaminated by feces; sexual contact	3 to 40 days	Diarrhea; abdominal discomfort; bloating	Antiprotozoal drugs (e.g., metronidazole)
Malaria				
Plasmodium falciparum; Plasmodium vivax; others	Bite from infected mosquito	10 to 40 days	Chills; high fever; sweating; headache; fatigue	Various drugs (e.g., chloroquine)

hands after using the toilet, avoiding contact with animal feces and secretions, and prudence in choice of sexual partners (or precautions, such as the use of condoms). For travel outside of the US, Canada, Northern Europe, Australia, and New Zealand, extra immunizations, and, in some cases, antimalarial tablets and protective measures against insects, may be recommended by your travel agent and confirmed by your physician.

SYMPTOMS AND DIAGNOSIS

The symptoms of an infectious disease are caused in part by microorganisms damaging cells and tissues, releasing toxins, and drawing on their host's reserves of nutrients; symptoms are also caused by the efforts of the body's defenses (including the *immune system*) to destroy the microorganisms. The outcome depends on whether the microorganisms or the defenses (sometimes aided by drug therapy) gain the upper hand. The strength of a person's immune system, which reflects his or her general health, strongly influences this outcome.

Fever is a feature in many infectious diseases; symptoms generally are related to the system or organ attacked—for example, cough, diarrhea, or skin rash.

Apart from diseases in which the symptoms and signs are usually easily recognizable (such as *chickenpox*), diagnosis relies on identifying the causative microorganism; testing may be by direct microscope examination of a specimen of infected tissue or body fluid, by *culture* techniques, or by detecting antibodies (proteins manufactured by the body to defend against a particular organism) in blood serum (see *Immunoassay*).

A particular problem with infectious diseases is that there is always a time gap (the incubation period) between entry of the microorganisms into the body and the first appearance of symptoms. The incubation period may last from a few hours to several years; during this time, the infected person is likely to pass the microorganism to other people. Moreover, symptoms may never develop in some infected people, but they nonetheless continue to carry the disease organisms and unwittingly transmit them to others.

As a result, an epidemic can be well established before it is recognized and control measures introduced. This can be particularly devastating when the disease is a new one and has a long incubation period and a high mortality (*AIDS* is a classic example).

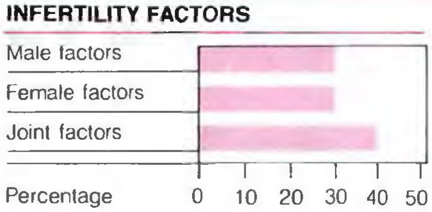
TREATMENT

The mainstay of treatment is the use of *antibiotic* and other antimicrobial drugs. Drug treatment must be carefully selected through culture and identification of organisms because certain microorganisms are susceptible only to certain antibiotics. For many viruses, no effective antiviral drug is available and treatment relies on supportive measures, such as reducing temperature, maintaining food and fluid intake, and so on.

OUTLOOK

Although great strides have been made in the fight against infectious diseases, many problems remain, even in developed countries. The spread of certain diseases (such as sexually transmitted infections) is difficult to control except by modifying human behavior. For many infections, no effective vaccine has been developed. The majority of viral illnesses cannot be effectively combated with drugs, and some bacteria have developed *resistance* to the drugs available. When a new infectious disease appears, it may be years before an effective vaccine or drug treatment can be devised. In the meantime, large numbers of people may die (AIDS again provides the most recent example).

Infectious mononucleosis
See *Mononucleosis, infectious.*



Inferiority complex
A neurotic state of mind that develops because of repeated hurts or failures in the past. Inferiority complex arises from a conflict between the positive wish to be recognized as someone worthwhile and the haunting fear of frustration and failure. Attempts to compensate for the sense of worthlessness may take the form of aggression and violence, or of overzealous involvement in activities. (See also *Superiority complex*.)

Infertility
The inability of a couple to conceive. Conception depends on the production of healthy sperm by the man, healthy eggs by the woman, and sexual intercourse so that the sperm reach the woman's fallopian tubes. There must not be a mechanical obstruction to prevent the sperm from reaching the egg, and the sperm must be able to fertilize the egg when they meet (see *Fertilization*). Next, the fertilized egg must be able to become implanted in the uterus (see *Implantation, egg*). Finally, the developing embryo must be healthy and its hormonal environment must be adequate for further development so that the pregnancy can continue to full term. Infertility may result from a disturbance of one or more of these factors.

INCIDENCE

Infertility is a common problem. As many as one in six couples requires help from a specialist. Infertility increases with age; the older a couple is when trying to conceive, the more difficult it may be.

INFERTILITY FACTORS

Factors responsible for infertility
In rough terms, about 30 percent of infertility cases are due to factors that affect the man; another 30 percent are due to factors that affect the woman. In the remaining 40 percent of cases, infertility is due to factors that affect both partners.

CAUSES

MALE INFERTILITY The major cause of male infertility is failure to produce enough healthy sperm. *Azoospermia* (in which there is no sperm) and *oligospermia* (in which few sperm are produced) both cause infertility.

In some cases the sperm are malformed or their life span after ejaculation is too short for them to travel far enough to reach the egg. Defects in the sperm may be due to a blockage of the spermatic tubes or damage to the spermatic ducts, usually due to a sexually transmitted disease, such as *gonorrhea*. A *varicocele* (varicose veins in the scrotum) may also be a factor. Abnormal development of the testes due to an endocrine disorder (see *Hypogonadism*) or damage to the testes by *orchitis* (inflammation of the testes) may also cause defective sperm. Toxins such as alcohol, cigarettes, or various drugs can lower the sperm count.

Infertility in men may also be caused by a failure to deliver the sperm into the vagina, as occurs in *impotence* or in disorders affecting ejaculation, such as inhibited ejaculation or retrograde ejaculation (see *Ejaculation, disorders of*).

In rare cases, there may be a chromosomal abnormality (such as *Klinefelter's syndrome*) or a genetic disease (such as *cystic fibrosis*) that causes infertility in men.

FEMALE INFERTILITY Anovulation (failure to ovulate) is the most common cause of female infertility. Failure to ovulate often occurs for no obvious reason. It can be caused by a hormonal imbalance, stress, or a disorder of the *ovary*, such as a tumor or cyst.

Blocked *fallopian tubes*, which frequently occur after *pelvic inflammatory disease*, may prevent the sperm from reaching the egg. The woman may have one tube or no tubes because of a congenital defect or because they were removed during surgery for *ectopic pregnancy*. Disorders of the uterus (such as *fibroids*) often cause infertility, as can *endometriosis*.

Infertility also occurs if the woman's cervical mucus provides a hostile environment to her partner's sperm by producing antibodies that kill or immobilize them.

Rarely, a chromosomal abnormality or allergy to her partner's sperm may cause a woman's infertility.

DIAGNOSIS

If pregnancy has not resulted after a year of unprotected intercourse (about 90 percent of women trying to get pregnant do so within a year), the couple may seek professional help.

A physical examination of both the man and the woman will be performed to determine the general state of their health, and to eliminate untreated physical disorders that may be causing the infertility. The couple is also interviewed, separately and together, regarding their sexual habits to determine if intercourse is taking place correctly for conception. If the cause of infertility remains undiagnosed after these examinations, special tests may be performed (see illustrated box).

TREATMENT

When no specific cause can be found, improving the general state of health may help. The physician may suggest changes in diet, such as reducing alcohol intake, and may suggest relaxing and eliminating stress.

Treatment of male infertility is limited. When azoospermia exists, the couple must accept their childless state or consider adoption or *artificial insemination* by donor. If the sperm count is low, artificial insemination by the husband may be tried, although its success rate varies. In some cases of male infertility due to an endocrine imbalance, drugs such as *clomiphene* or *gonadotropin hormone* therapy may prove useful.

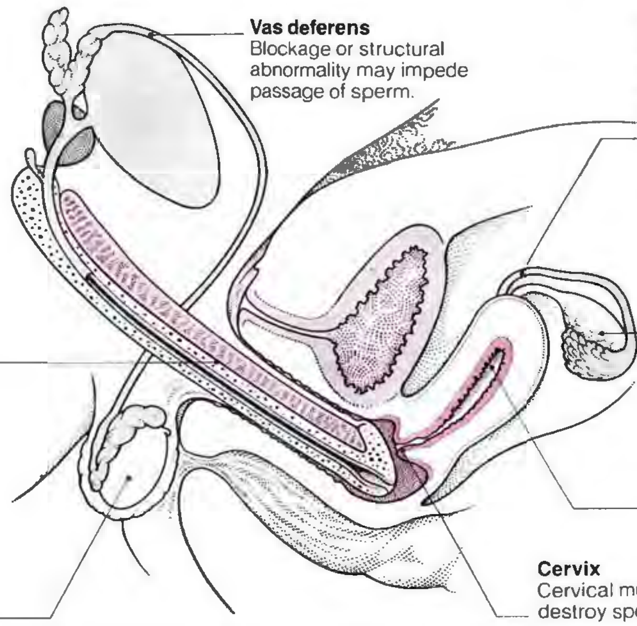
For female infertility, failure to ovulate requires ovarian stimulation with a drug such as clomiphene with or without a gonadotropin hormone. Microsurgery can sometimes repair damage to the fallopian tubes if it is not too severe. If surgery on the fallopian tubes is unsuccessful, *in vitro fertilization* is the only way that pregnancy will be possible. Uterine abnormalities or disorders, such as fibroids, may require treatment. If the cervical mucus has proved hostile, artificial insemination of the husband's semen directly into the cervix can prevent the sperm from coming into contact with the mucus.

OUTLOOK

Only about half the couples professionally treated for infertility achieve a pregnancy, but the chances vary according to cause.

Infestation

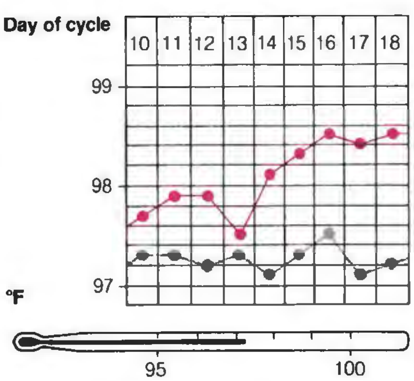
The presence of animal parasites (such as mites, ticks, or lice) in the skin or hair or of worms (such as tapeworms) inside the body.



Infiltrate
Accumulation of substances or cells within a tissue that are either not normally found in it or are usually present only in smaller amounts. Infiltrate

INVESTIGATING INFERTILITY

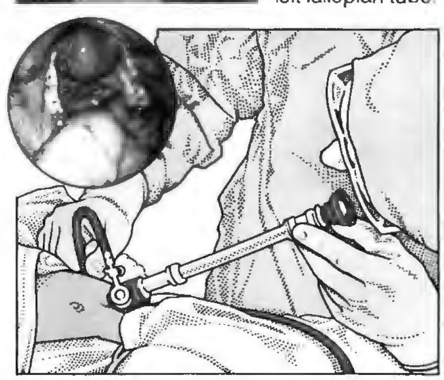
If no cause for infertility is found after a general checkup and/or a personal interview regarding sexual behavior, more specialized tests may be performed. Both partners may require testing because infertility can be attributed to one person, to both of them, or to mutual incompatibility.



CAUSES OF INFERTILITY

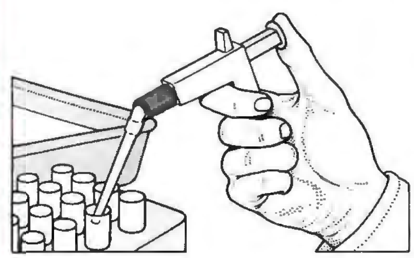
Conception is a complicated process; the organs involved can be affected in numerous ways, resulting in infertility. Some of the principal underlying causes of infertility—in men and women—are illustrated at right.

FEMALE INFERTILITY

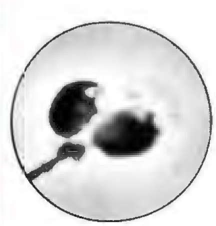


Investigations to discover the cause of a woman's infertility may include taking a menstrual history, a study of body temperature during the menstrual cycle (below) and/or blood and urine tests to discover whether ovulation is normal, hysterosalpingography (right), or laparoscopy (below right).

Body temperature and ovulation
Charting a woman's body temperature during her menstrual cycle can indicate abnormalities of ovulation. The chart above shows typical temperature fluctuations during a normal cycle (black line) and those associated with failure to ovulate (red line).



Hysterosalpingography
This X-ray technique is used to visualize the uterus and/or fallopian tubes. The image (left) shows a blockage of the left fallopian tube.



Laparoscopy
In this technique, a laparoscope (a type of viewing tube) is inserted through the abdominal wall to examine the woman's reproductive organs and determine whether an abnormality, such as a cyst or tumor, is present. The laparoscope view (above) shows a tumor in the left ovary.

MALE INFERTILITY

The first test for investigating male infertility is a semen analysis (below). If it reveals a low sperm count, more tests may be needed to investigate the underlying cause.

Semen analysis
Semen produced by masturbation is examined as soon as possible for the number, shape, and degree of motility of the sperm. A postcoital semen test may also be performed.

Abnormal sperm
The presence in the semen of large numbers of abnormally shaped sperm, such as the two-headed one (left), may reduce a man's fertility.

may refer to a drug (such as a local anesthetic) that has been injected into a tissue or to the buildup of a substance within an organ (such as of fat in the liver caused by excessive alcohol consumption). Radiologists use the term to refer to the presence of a tumor or pneumonia within a tissue (such as lung cancer or bronchopneumonia as seen on a chest X ray).

Inflammation

Redness, swelling, heat, and pain in a tissue due to chemical or physical injury, or to infection.

When body tissues are damaged, specialized *mast cells* release a chemical called *histamine* (other substances are also involved in the inflammatory response, but histamine is believed to be responsible for most of the effects). Histamine increases blood flow to the damaged tissue, which causes the redness and heat. It also makes the blood capillaries more leaky, resulting in fluid oozing out of them and into the tissues, which causes localized swelling. The pain of inflammation is due to stimulation of nerve endings by the inflammatory chemicals.

Inflammation is usually accompanied by an accumulation of white blood cells, which are attracted by the inflammatory chemicals. These white cells help destroy invading microorganisms and are involved in repairing the damaged tissue. Thus, inflammation is an essential part of the body's response to injury and infection.

If inflammation is inappropriate (as in *rheumatoid arthritis* and some other *autoimmune disorders*), it may be suppressed by *corticosteroid drugs* or *nonsteroidal anti-inflammatory drugs*.

Inflammatory bowel disease

A general term for a pair of chronic inflammatory disorders affecting the small and/or large intestine. The cause is unknown. Specific conditions within this group are *Crohn's disease* and nonspecific *ulcerative colitis*.

Influenza

A viral infection of the respiratory tract (air passages) that causes fever, headache, muscle ache, and weakness. Popularly known as "the flu," it is spread by virus-infected droplets coughed or sneezed into the air. Influenza usually occurs in small outbreaks, or every few years in epidemics. Outbreaks tend to occur in winter; they spread particularly rapidly through schools and institutions for the elderly.

CAUSES

There are three main types of influenza virus, called A, B, and C. A person who has had an attack with the type C virus acquires antibodies (proteins made by the *immune system*) that provide immunity against the type C virus for life. Anyone who has been infected with a certain strain of the type A or B viruses acquires immunity to that strain. Both the A- and B-type viruses occasionally alter to produce new strains that may be able to dodge or overcome immunity built up from a previous attack, thus leading to a new infection.

The type B virus is fairly stable, but it occasionally alters sufficiently to overcome resistance. The new strain often causes small outbreaks of infection. The type A virus is highly unstable; new strains arise constantly throughout the world. These are the strains that caused the influenza *pandemics* of this century, most notably Spanish flu in 1918, Asian flu in 1957, and Hong Kong flu in 1968.

SYMPTOMS

The classic symptoms of flu (chills, fever, headache, muscular aches, loss of appetite, and fatigue) are brought on by types A and B. Type C causes only a mild illness that is indistinguishable from a common cold. In general, type A is more debilitating than type B.

The general symptoms described, which are more common in adults than in children, are usually followed by a cough (often accompanied by chest pain), a sore throat, and a runny nose. After two days, fever and other symptoms start to subside and, after five days, these symptoms have usually disappeared. Respiratory symptoms persist, however; the sufferer may feel weak and sometimes depressed. The illness usually clears up completely within seven to ten days. In rare cases, however, it takes a severe form, causing acute pneumonia that may be fatal within a day or two even in healthy young adults. The Spanish flu epidemic of 1918 killed millions of young adults in all countries of the world.

Type B infections in children sometimes mimic *appendicitis* and have been implicated in *Reye's syndrome*. In babies, the type A virus can cause febrile *seizures*.

Secondary bacterial infection is common, particularly in the elderly and in those with lung or heart disease; it may cause fatal *bronchitis*, *bronchiolitis*, or *pneumonia*.

PREVENTION

Anti-influenza vaccines, containing killed strains of types A and B virus currently in circulation, are available, but have only a 60 to 70 percent success rate in preventing infection. In addition, any immunity provided is short-lived. Vaccination must be repeated each year just before the start of the influenza season. It is recommended that older people and sufferers of respiratory or circulatory disease be vaccinated, especially those living in institutions.

TREATMENT

In all but the mildest cases, a person with influenza should rest in bed in a warm, well-ventilated room. Analgesics (painkillers) should be taken to relieve aches and pains and to reduce fever. Warm fluids soothe a sore throat and inhaling steam has a soothing effect on the lungs.

In the case of an elderly person or someone with a lung or heart disease, a physician should be called as soon as symptoms develop. The drug amantadine, which can reduce the severity of an attack if given within 24 hours of onset of symptoms, may be given. Antibiotics may also be used to combat secondary bacterial infection.

Once the fever has abated, the patient can get out of bed, but still needs rest. When he or she has started to regain strength, the return to normal activities should be gradual.

Informed consent

Before a medical diagnostic procedure (or a surgical operation) a careful explanation is provided and the patient is asked to state that he or she understands the procedure and the risks involved, and that he or she consents to it. In most hospitals, the patient signs a consent form before an operation. (See also *Consent*.)

Infrared

A term denoting the part of the electromagnetic spectrum immediately beyond the red end of the visible light spectrum. Directed onto the skin, infrared radiation heats the skin and the tissues immediately below it.

The infrared wave band includes heat waves; an infrared lamp is one means of giving *heat treatment*.

Infusion, intravenous

See *Intravenous infusion*.

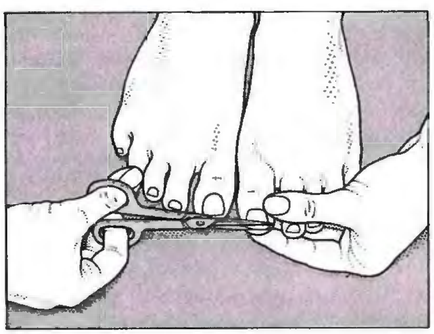
Ingestion

The act of taking any substance (i.e., food, drink, or medications) into the

body through the mouth. The term also refers to the process by which certain cells (e.g., some white blood cells) surround and engulf small particles.

Ingrown toenail

A painful condition of the big toe in which one or both edges of the nail press into the adjacent skin, leading to infection and inflammation.



Infection is usually caused by poor personal hygiene, wearing tight-fitting shoes, or cutting the nail incorrectly. The nail should be cut straight across (not down the sides) to avoid exposing tender skin that easily becomes infected if a splinter of nail from the cut edge grows into it.

TREATMENT

While waiting for medical treatment, pain can be relieved by bathing the foot in a strong, warm, salt solution once or twice a day and covering the nail with a dry gauze dressing.

The condition is usually treated by giving antibiotics to control infection and, if necessary, by removing the edge of the affected nail after applying a local anesthetic.

Unless preventive measures are taken, the problem is likely to recur.

Preventing ingrown toenails
Cutting the toenails straight does not damage the skin at the corners of the nail and helps to prevent ingrown toenails.

Inguinal

Relating to the groin (the area between the abdomen and thigh), as in inguinal *hernia*, the protrusion of part of the intestine into the muscles of the groin.

Inhalation

The act of breathing in air (see *Breathing*). An inhalation is also a substance in gas, vapor, powder, or aerosol form to be breathed in.

Inhaler

A device used for administering a drug in powder or vapor form. Inhalers are used principally in the treatment of various respiratory disorders, including *asthma*, chronic *bronchitis*, and *alveolitis*. Among the medications administered in this way are *bronchodilator drugs* (to widen the airways) and *corticosteroid drugs* (to reduce inflammation).

HOW TO USE AN INHALER

With each type, the user puts the nozzle of the inhaler in the mouth, presses the end to release the drug, and simultaneously breathes in through the mouth. If the device is used correctly, the drug is dispersed to the bronchi. A *nebulizer* is a special type of inhaler that delivers the drug as a fine mist through a face mask.

Aerosol inhaler
This type of inhaler delivers the drug as an aerosol spray when the user presses the top of the canister.

Turbo-inhaler
Here, a drug capsule is placed in the end chamber, the top of which is pressed to pierce the capsule and release the drug.

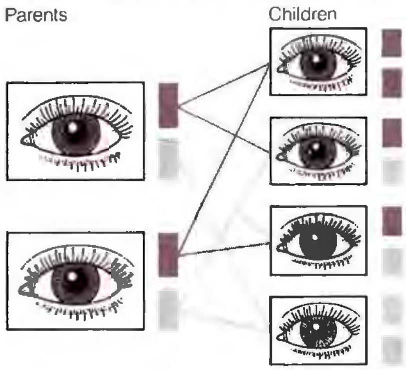
Inheritance

The transmission of traits, characteristics, and disorders from parents to their children through the influence of *genes*. Genes are the units of DNA (deoxyribonucleic acid) in a person's cells; DNA controls all growth and body functioning. Half of a person's genes come from the mother, half from the father.

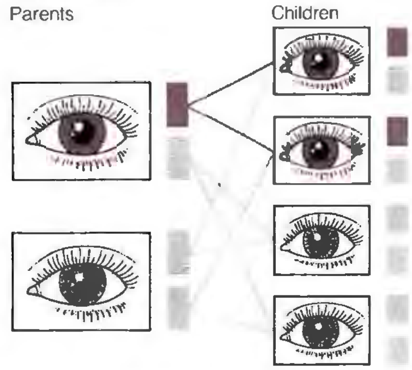
Children tend to resemble their parents, particularly in their physical characteristics. However, this resemblance may also apply to mental abilities, mannerisms, personality, and behavior. In addition, many disorders show a moderate to very notable tendency to "run in families."

Although there is a temptation to ascribe similarities in a family to inheritance, there are equally plausible alternative explanations for many family traits. For example, all the members of a family may be fat not through the influence of genes, but because they all eat the same fattening food and rarely exercise. Children may behave like their mother not because of inheritance, but because they imitate her. Certain abilities and behaviors (e.g., the language a person speaks) are clearly not inherited. Nevertheless, it is accepted that most physical characteristics, many disorders, and some mental abilities and aspects of personality are inherited.

MECHANISMS OF INHERITANCE

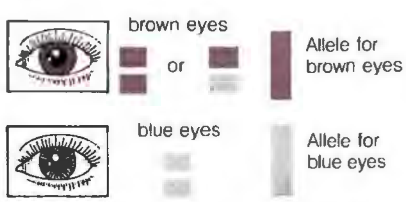


Each of a person's cells contains exactly the same genes, which come originally from the egg and sperm cells from which he or she is derived.



The genes in a cell are organized into long strands of DNA called *chromosomes*. The genes controlling most characteristics come in pairs—one gene originating from the father, the other from the mother. Everyone has 22 pairs of chromosomes (called autosomes) bearing these paired genes. In addition, every individual has two more chromosomes called sex chromosomes. Women have two X chromosomes; men have an X chromosome and a Y chromosome.

The inheritance of normal traits and disorders can be divided into those



INHERITANCE OF EYE COLOR

Eye color is determined by two main alleles (forms of a gene), one coding for brown eyes and the other for blue eyes. The brown allele is dominant to the blue one (which is therefore recessive).

Key

Eye color of offspring
Two brown-eyed parents (each with the brown/blue combination of alleles) have a one in four chance of producing a blue-eyed child (above left). But there is a one in two chance of having a blue-eyed child when one parent is brown-eyed (with brown/blue alleles) and the other is blue-eyed (above).

controlled by a single pair of genes on the autosomal chromosomes (unifactorial inheritance); those controlled by genes on the sex chromosomes (sex-linked inheritance); and those controlled by the combination of many genes (multifactorial inheritance).

UNIFACTORIAL INHERITANCE

A large number of variable traits, such as eye color, blood groups, and the ability to taste certain substances, is thought to be controlled by a single pair of genes. The ways in which these traits are inherited conform to laws first elucidated in the 19th century by the Austrian monk Gregor Mendel. Since then, they have been referred to as the laws of Mendelian inheritance.

Either of the pair of genes controlling a trait may take any of several forms, which are known as alleles. For example, the genes controlling eye color exist as two main alleles, coding for blue and brown eye color. Thus, an individual's gene pair for eye color may be blue/blue (giving blue eyes), brown/brown (giving brown eyes) or brown/blue (also giving brown eyes, because the brown allele is dominant, or "masks," the blue allele, which is called recessive to the brown allele).

When a couple has a child, only one of the pair of genes controlling a trait is passed to the child. For example, someone with the brown/blue combination for eye color has a 50 percent chance of passing the blue gene, and a 50 percent chance of passing on the brown gene, to any child. This factor is combined with the gene coming from the other parent, according to dominant or recessive relationships, to determine the child's eye color. According to the combination of the parental genes, the numbers of brown- and blue-eyed offspring of a particular couple tend to conform to a certain ratio, in accordance with Mendelian laws (see illustration).

Similar laws and ratios apply to the inheritance of other traits controlled by single gene pairs, and also to the inheritance of certain *genetic disorders* (e.g., *cystic fibrosis* and *achondroplasia*).

SEX-LINKED INHERITANCE

The most obvious example of sex-linked inheritance is gender itself. Male gender is caused by the existence in males of the genes on the Y chromosome, which is present only in males and is inherited by boys from their fathers. The genes on the Y chromosome almost certainly direct the development of the male primary sex organs (the testicles) and all male characteristics derive from the secretion of hormones by these organs.

The X chromosome, on the other hand, is less closely associated with the female sex because it is present in both males (in a single dose) and in females (in a double dose). It seems that female gender is the natural course of development in the absence of the Y chromosome, does not require any extra genes to direct it, and that the X chromosome is concerned with general development.

Any faults in a male's genes on the X chromosome tend to be expressed outwardly, because such a fault cannot (as it can in females) be masked by the presence of a normal gene on a second X chromosome. Faults in the genes of the X chromosome include those responsible for *color vision deficiency*, *hemophilia*, and other sex-linked inherited disorders, which almost exclusively affect males.

MULTIFACTORIAL INHERITANCE

A number of traits (such as height and build) are believed to be controlled by the combined effects of many genes, along with environmental effects. Using height as an example, a simple model proposes that there are several genes determining a person's stature, some of which are "tall" genes and others "short." A person's height depends on the relative number of tall to short genes.

When two people have children, a child may, in rare cases, inherit all the tall or all the short genes from both parents, and thus be exceptionally tall or short. The laws of chance dictate, however, that, in most cases, a child will inherit a mixture of tall and short genes and thus be in the range of average stature. Nevertheless, the child of tall parents tends to inherit more tall genes than the child of short parents. Dietary and other factors also affect growth so that a person with many short genes may still attain an average stature through good diet.

Multifactorial inheritance, along with the effects of environment, may also play a part in causing disorders, such as *diabetes mellitus* and *spina bifida* (see *Genetic disorders*).

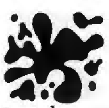
Inhibition

The process of preventing any mental or physical activity. Inhibition in the brain and spinal cord is carried out by special *neurons*, which damp down the action of other nerve cells to keep the brain's activity in balance.

In a psychological sense, certain mental activities can be described as inhibiting other thoughts or reflexes.

In *psychoanalysis*, an inhibition refers to the unconscious restraint of instinctual impulses. Such inhibition may cause symptoms, such as being temporarily unable to write because writing arouses forbidden ideas.

Injection



Introduction of a drug or vaccine into the body from a syringe through a needle. An injection may be intravenous (into a vein), intramuscular (into a muscle), subcutaneous (under the skin), or intra-articular (into a joint).

Injury

Harm to any part of the body. Injury may arise from a wide variety of causes, including physical influences (such as force, heat, cold, electricity, vibration, and radiation), chemical causes (such as poisons and caustic substances), animal or human bites, or oxygen deprivation.

(See *Accidents; Bite, animal; Bite, human; Bleeding; Burns; Cold injury; Dislocation, joint; Electrical injury; First aid; Fractures; Head injury; Heat stroke; Insect bites; Poisoning; Radiation sickness; Snakebites; Soft-tissue injury; Spinal injury; Sports injuries; Sprains; Venomous bites and stings; Wounds.*)

Ink blot test

A psychological test in which the subject is asked to interpret a number of ink blots. The most widely used example is the *Rorschach test.*

Inlay, dental

A filling of porcelain or gold made outside the mouth and used to restore a badly decayed tooth. An inlay may be needed for back teeth or to provide protection for a weakened tooth.

The dentist first makes an angular cavity in the tooth to accept the inlay. A replica of the cavity is then made, generally using a wax *impression;* the inlay is constructed on the replica and cemented in place in the tooth.

Inoculation

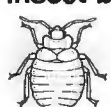
The act of introducing a small quantity of a foreign substance into the body, usually by injection, for the purpose of stimulating the *immune system* to produce *antibodies* (protective proteins) against the substance. Inoculation is usually done to protect against future infection by particular bacteria or viruses. (See *Immunization.*)

Inoperable

A term applied to any condition that cannot be alleviated or cured by surgery, such as a very advanced cancer that has spread to many parts of the body or a brain tumor that is not surgically accessible.

Inorganic

A term used to refer to any of the large group of substances that do not contain carbon (excepting certain simple carbon compounds such as *carbon dioxide* and *carbon monoxide*). Common examples of inorganic substances include table salt (sodium chloride) and bicarbonate of soda (sodium bicarbonate). See also *Organic.*



Inpatient treatment

Medical care given to a patient who has been admitted to a hospital.

Insanity

The common term for serious mental disorder. Today it has no technical meaning for psychiatrists, but is used in law to indicate a mental state that renders a person not legally responsible for his or her own actions. The "insanity defense" was introduced to ensure that people committing criminal acts as a result of mental illness or deficiency would not be imprisoned or given the death penalty, but would instead receive proper treatment. *Psychosis* now covers serious illnesses formerly denoted by insanity.

Insect bites

Tiny puncture wounds in the skin inflicted by blood-sucking insects, such as mosquitoes, lice, midges, gnats, horseflies, sand flies, fleas, and bedbugs. Some small arachnids (eight-legged animals similar to insects), such as ticks and mites, can cause similar injuries.

Most bites cause only temporary pain (or itching for a day or two) although some people have severe skin reactions. In the tropics and subtropics, insect bites are potentially more serious because certain biting species can transmit disease (see *Insects and disease*).

CAUSES

Insects that bite do so to obtain a blood meal. The mouthparts of biting insects are specially adapted for piercing skin and sucking blood. Insect bites are most common on exposed parts of the head, hands, arms, or legs.

Although mosquitoes (which attack mainly after dark) may be the most troublesome biting insects, many bites blamed on mosquitoes are in fact caused by cat or dog fleas. These fleas inhabit various domestic locations where the pet habitually rests (e.g., carpets, sleeping baskets, or sofas); when their normal host is absent, they may jump onto humans to feed.

Of the more easily visible insects, horseflies can produce a particularly painful bite, while gnats can be a menace if encountered in a swarm.

SYMPTOMS

All insect bites provoke a reaction in the skin that is primarily an allergic response to substances in the insect's saliva or its feces, which are often deposited at or near the site of the bite and rubbed in by scratching. Reactions vary from innocuous red pimples to painful swellings (which may weep) or an intensely itching rash. People vary in their reactions to the same biting insect; in some people the reaction is extremely severe.

AVOIDANCE

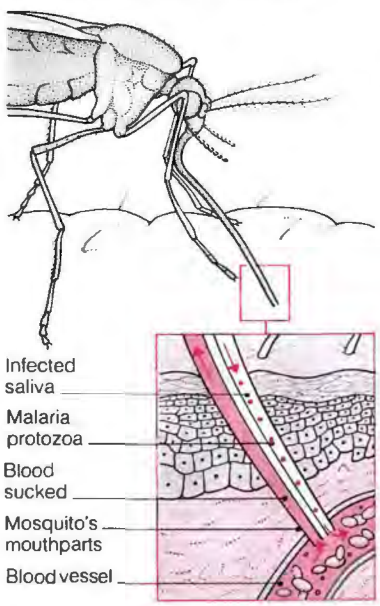
Avoiding insect bites can be particularly important for campers and hikers, anyone living in a mosquito-infested area, and travelers or residents in tropical countries.

Bites outdoors can be reduced by wearing trousers, socks, and long-sleeved shirts (especially after dark, when mosquitoes are most active), and by using insect repellents.

Indoors, bites can be reduced by using insect screens over open windows and by spraying bedrooms with aerosols containing pyrethroid insecticides before going to bed. If this fails, it may be necessary to use mosquito nets and slow-burning antimosquito coils that give off pyrethroids.

TREATMENT

Bites or bitten areas should be thoroughly washed with soap and water, and a soothing ointment, such as calamine lotion, should be applied. Scratching should be avoided. If there is a severe reaction, a physician should be called; a cream containing an antihistamine may be required.



Severe itching on the scalp or in the pubic hair suggests the possibility of a louse infestation, which is treated with insecticidal lotions (see *Lice*). In the case of flea bites, the entire residence (not just the pet) may require treatment with insecticide to kill the flea population. (See also *Spider bites; Mites and disease; Ticks and disease.*)

Insects and disease

Insects are six-legged animals with a pair of antennae, a firm exterior skeleton, and, in many cases, wings. They include such animals as ants, bees, cockroaches, fleas, flies, lice, and mosquitoes, but not mites, ticks, or spiders, which belong to another animal group, the arachnids. The insects and arachnids belong to a larger animal group, the arthropods.

INSECT-BORNE DISEASES

Malaria is by far the most prevalent of the insect-borne diseases, affecting an estimated 200 to 300 million people worldwide.

Transmission of malaria

When an infected *ANOPHELES* mosquito feeds on a person's blood, it injects saliva through its mouthparts; the protozoa that cause malaria enter the blood via the insect's saliva.

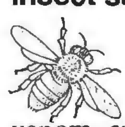
DISEASE CAUSED BY INSECTS

There are about 1 million known species of insects; most are either harmless or positively beneficial to humans. The majority of the harmful species cause sickness by attacking crops or stored food, thus contributing to malnutrition and famine.

Other insects are a more direct cause of illness or disease. Certain insects directly parasitize humans, living underneath the skin or on the body surface (see *Lice*; *Chigoe*; *Myiasis*). Still others will sting if provoked, causing moderate discomfort (in most cases) to a severe life-threatening reaction (see *Insect stings*).

The most troublesome insects are flies and various biting insects. Many types of flies settle first on human or animal excrement and then on food to lay eggs or to feed. They can transmit disease organisms from excrement to food via their feet and legs. This is probably important in the spread of intestinal infections such as *typhoid fever* and *shigellosis*.

Insect bites are irritating in themselves, but the much more serious risk is of an insect spreading infectious organisms as a result of its bite. Serious diseases spread by biting insects include *malaria* and *filariasis* (transmitted by mosquitoes), *sleeping sickness* (tsetse flies), *leishmaniasis* (sand flies), epidemic *typhus* (lice), and *plague* (rat fleas). Also, various mosquitoes, sand flies, and ticks spread a group of viral illnesses called the arthropod-borne or arboviruses. They include *yellow fever*, *dengue*, and some types of viral *encephalitis*.



In each case, organisms picked up when an insect ingests blood from an infected animal or person are able to survive or multiply in the insect. Later, the organisms are either injected into a new human host via the insect's saliva or deposited in the feces at or near the site of the bite and later rubbed in by the victim.

Most of these diseases (of which malaria is by far the most important) are confined to the tropics and subtropics. However, some cases of plague and arthropod-borne encephalitis occur each year in the US. Leishmaniasis can be contracted by sand-fly bites in the Mediterranean.

AVOIDANCE

The avoidance of insect-borne disease is largely a matter of keeping flies off food, discouraging insect bites by the use of suitable clothing and insect repellents, and, in areas of the world where malaria is present, the use of mosquito nets and screens, *pesticides*, and antimalarial tablets.

Insect stings

A fairly small number of insects (bees, wasps, hornets, and yellow jackets) are capable of stings. Insect venom contains inflammatory substances that cause local pain, redness, and swelling for about 48 hours. Normally, a very large number of stings (hundreds in the case of an adult) must be received for them to be life-threatening. However, about one person in 200 is allergic to insect venom. This means that, after the person's *immune system* has been sensitized by the venom from a sting, one subsequent sting (possibly months or years later) can provoke a severe allergic reaction leading to *anaphylactic shock*. The symptoms may include a severe itchy rash (hives), dizziness, facial and throat swellings, wheezing, vomiting, breathing difficulties, and collapse. About 50 to 100 people die of this cause annually in the US (more deaths than from snake bites).

Immunotherapy—a technique for reducing sensitivity to bee or wasp venom (and some other types of allergy)—is recommended for those known to suffer hypersensitivity.

TREATMENT

A bee often leaves its sting sac in the wound. The sac should be gently scraped out with a knife blade or fingernail, not by grasping with fingers or tweezers (which injects more venom). The stung area should be washed with soap and water, a cold compress applied, and analgesics taken to ease the discomfort.

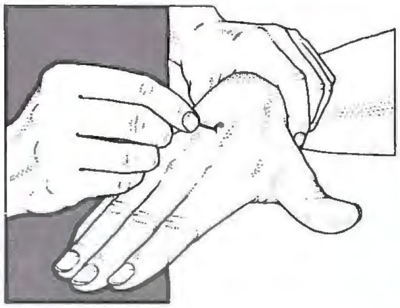
If the symptoms of anaphylactic shock develop, obtain medical help immediately for emergency treatment, which initially consists of an injection of *epinephrine*. Any person known to be hypersensitive to bee or wasp venom should obtain and carry an emergency kit for self-injecting epinephrine. In severe cases, the victims of insect stings require *cardiopulmonary resuscitation*.

A sting in the mouth or throat may also be dangerous because swelling may obstruct breathing. Again, seek medical help immediately and give the victim ice cubes to suck. (See also *Scorpion stings*.)

Insecurity

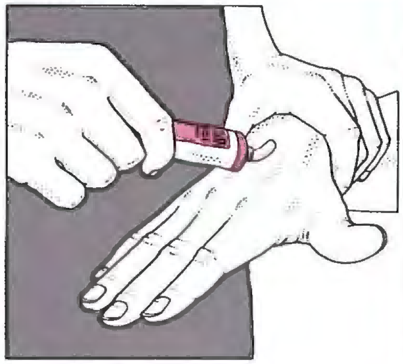
Lack of self-confidence and uncertainty about one's abilities, aims, and relationships with others. Repeated changes of environment (such as frequent moves of home or school) can lead to a sense of insecurity, especially in childhood. A feeling of insecurity may be a feature of *anxiety* and other neurotic mental disorders.

Insight



Being aware of one's own mental state. In a general sense, this means knowing one's own strengths, weaknesses, and abilities.

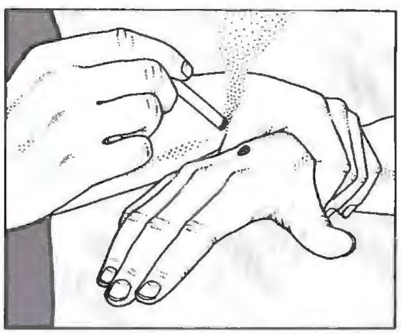
The term insight also has the specific psychiatric meaning of knowing that one's symptoms are an illness. Some psychiatrists thus regard loss of insight as a sign of a *psychosis*, since it indicates being out of touch with reality. Others, however, point out that many people with psychotic illness know when they are ill and seek treatment, while those with neurotic and personality disorders often deny they are ill and fail to see the causes or results of their behavior.



In *psychoanalysis*, insight refers to a deep emotional understanding of one's inner feelings; it is regarded as essential to successful treatment.

FIRST AID: INSECT STINGS AND BITES

INSECT STING



1 Use a needle to remove the stinger and poison bag by dragging the stinger out of the skin's surface. Do not use tweezers because you may squeeze more poison into the wound.

2 Apply some hydrocortisone cream or a weak solution of ammonia to the wound. An ice pack held on the wound will help reduce swelling.

TICK BITE

1 If the tick is still clinging to the skin, dislodge it by holding the glowing end of a cigarette or an extinguished match to its body. Do not attempt to pull it off.

2 Use soap and warm water to wash the area thoroughly. Then rinse well and dry gently. Apply hydrocortisone cream.

In situ

A Latin term meaning "in place." The phrase "carcinoma in situ" is used to describe tissue (particularly of the skin or cervix) that is cancerous only in its surface cells and is completely surrounded by normal cells without any signs of spread to deeper layers.

Insomnia

Trouble sleeping. Insomnia is a common problem. A national survey has shown that one in every three US adults has some trouble sleeping and that hypnotic drugs are among the most widely used of all medicines. People with insomnia have difficulty falling asleep or staying asleep. Most insomnia sufferers also complain of increased daytime fatigue, irritability, and difficulty coping.

CAUSES

The most common cause of insomnia is worry about a problem (such as bad news received during the day or a difficult task to cope with the following morning), but other causes are implicated in about half of all cases.

Causes include physical disorders such as *sleep apnea* (a breathing problem), *restless legs*, environmental factors (such as noise and light), life-style factors (such as too much coffee in the evening, lack of exercise during the day, or keeping erratic hours), or misuse of hypnotic drugs (see *Antianxiety drugs; Barbiturate drugs*).

Insomnia also can be a symptom of a psychiatric illness. People with *anxiety* and/or *depression* may have difficulty getting to sleep; those suffering from depression typically wake early in the morning. Sleeping much less than usual is common in *mania*, in which the person is so full of drive and energy that he or she does not need much sleep. *Schizophrenia* often causes people to pace at night, aroused by "voices" or delusions. People with *dementia* or other brain disorders may be afraid in the dark and become restless and noisy, confused by the shadows and sounds of the night.

Withdrawal syndrome from hypnotic drugs, antidepressants, tranquilizers, and illicit drugs (such as heroin) may cause many weeks of insomnia.

People sometimes believe they have insomnia because of a misconception about the amount of sleep they need. In fact, sleep needs vary greatly, with some people requiring less than four hours and others needing more than 10. Some people who think they have insomnia are in fact "out of phase," lying awake for hours after going to bed, but sleeping normally if allowed to sleep late in the morning.

INVESTIGATION AND TREATMENT

If there is an obvious physical or psychological cause for insomnia, it is treated. For long-term insomnia with no obvious cause, *EEG* recordings of brain-wave patterns and an assessment of breathing, muscle activity, and other bodily functions during sleep may be useful in discovering the extent and pattern of the problem. Keeping a log of sleep patterns may also be helpful.

Studies have shown that many insomniacs sleep much more than they think they do. However, they also tend to wake more frequently than normal sleepers. It is the quality, more than the quantity, of sleep that is the problem in insomnia. People with insomnia should ensure they are active during the day and should establish a regular time and routine for going to bed each night and a regular time for waking in the morning. *Sleeping drugs* should be used only with a physician's advice.

Instinct

An innate primitive urge. The needs for warmth, food, love, and sex are forms of instinct, although the instinct for survival is probably the most powerful. An instinct is distinguished from a reflex, which is an involuntary response to a stimulus (such as withdrawing one's hand from a fire).

In animals, instincts often take the form of specific inherited patterns of behavior. For example, ducks follow their mothers, birds fly, and beavers

build dams—activities that do not appear to have been learned.

Humans have few of these set behaviors, and instincts may be more appropriately regarded as motivators of behavior. This idea was first developed as a central part of *Freudian theory*. Freud believed that instincts arose from energy aroused in the unconscious. The aim of the instinct was to calm the aroused state by directing the energy onto some outside object (e.g., sexual arousal leads to intercourse and orgasm).

Freud also described two "primal" (most important) instincts—Eros, the life instinct (which is positive, creative, and aimed at preserving life), and Thanatos, the death instinct (which is negative and destructive). Life was seen as a continual struggle between these two instincts.

Institutionalization

The loss of personal independence that stems from living for long periods in a mental hospital, prison, or other large institution. Apathy, obeying orders unquestioningly, accepting a standard routine, and loss of interests are the main features. They are thought to be caused by a lack of rights and personal responsibility, the attitudes of controlling staff, and the effects of drugs.

Care of the long-term sick within the community (as an alternative to hospitalization) is designed to combat the institutionalization process.

Insulin

A hormone produced by the *pancreas* in varying amounts depending on the level of blood glucose (sugar). Carbohydrate is absorbed as glucose, increasing the blood glucose level and stimulating the pancreas to produce insulin. Insulin promotes the absorption of glucose into the liver and into muscle cells (where it is converted into energy). In the liver, glucose is stored as glycogen, which is reconverted to glucose in response to stress or exercise. Insulin thus prevents a buildup of blood glucose and ensures that various tissues have sufficient amounts of glucose.

Diabetes mellitus occurs when the pancreas produces little or no insulin, causing *hyperglycemia* (abnormally high blood glucose). An *insulinoma* is a rare benign tumor that causes excessive production of insulin.

INSULIN THERAPY

Insulin supplements have been used in the treatment of diabetes mellitus since 1922. Insulin preparations are produced from pig or ox pancreas (and now by *genetic engineering*). A variety of short-, intermediate-, or long-acting preparations is available.

Insulin is used in all cases of insulin-dependent diabetes mellitus (total absence of insulin production) and, occasionally, when oral *hypoglycemic* drugs are unable to control non-insulin-dependent diabetes mellitus (deficient production of insulin), such as during serious illness, surgery, or pregnancy. Insulin therapy is used to prevent hyperglycemia (high blood glucose) and *ketosis* (a buildup of certain acids in the blood), which, in severe cases, may cause coma.

Insulin is given to mimic the body's production of the natural hormone. Insulin may be self-injected before meals to act on the increase in blood glucose that occurs after eating. Alternatively, an insulin pump (see *Pump, insulin*) may be used to deliver insulin over 24 hours; the dose is increased before each meal.

Adjustment of the dose is often needed when there are variations in diet and exercise, and during illness (especially when there has been vomiting). Regular self-monitoring of the blood glucose level, either by blood or urine tests, is necessary to ensure adequate control.

POSSIBLE ADVERSE EFFECTS

Insulin injections may cause irritation or dimpling of the skin. Too high a dose causes hypoglycemia with symptoms (such as dizziness, sweating, irritability, and a feeling of weakness) that are relieved by consuming food or a sugary drink. Severe hypoglycemia may cause coma, for which emergency treatment with an injection of glucose or *glucagon* (a hormone that opposes the effects of insulin) is necessary.

Allergic reactions to insulin, causing rash or breathing difficulty, are rare. Pig or ox insulin may make the body produce *antibodies* that reduce the effectiveness of the insulin preparation. If this occurs, an alternative preparation is taken.

Insulinoma

A rare benign tumor of the insulin-producing cells of the pancreas. Such a tumor can produce abnormal quantities of *insulin* so that the amount of glucose in the blood (which is reduced by insulin) can fall to dangerously low levels. This is called *hypoglycemia* and, unless sugar is given immediately, can cause *coma* and death.

Blood insulin levels are normally low during fasting; insulinoma can be diagnosed by finding high levels after a period of fasting. A drug (diazoxide) is administered to prevent hypoglycemia until surgery can be performed to remove the tumor.

Intelligence

The ability to understand concepts and reason them out. There is much confusion about the precise definition of intelligence. Many people use the word to mean a special degree of knowledge. The widespread use of *intelligence tests* has led to the idea that intelligence is a single quality.

Many scientists prefer to divide intelligence into various factors. Some see it as having three basic parts—speed of thought, learning, and problem-solving. Others argue that a general factor of intelligence exists, made up of seven special abilities—understanding the meaning of words, fluency with words, working with numbers, visualizing things in space, memory, speed of perception, and reasoning ability. Other researchers go further, dividing intelligence into more than 100 different factors.

Intelligence can also be considered as having three entirely separate forms—abstract intelligence (understanding ideas and symbols); practical intelligence (aptitude in dealing with practical problems, such as repairing machinery); and social intelligence (coping reasonably and wisely with human relationships). Personality plays an important role in this last type of intelligence.

AGE AND INTELLIGENCE

Intelligence, however it is defined, increases up to the age of about 6 years and then stabilizes. Intelligence quotient (IQ), as measured by intelligence tests, continues to increase to about age 26, stays the same until about age 40, and then gradually declines (the drop occurring later in a person with an intellectually demanding job).

HEREDITY AND INTELLIGENCE

The role of heredity in intelligence is much argued, but there is no doubt that intelligence is inherited in a fashion similar to height. Environment also plays a major part, as does physical health and personality. Intelligent parents tend to have intelligent children, but, even within one family, some children may be brighter than others. Adopted children from deprived social backgrounds, although having IQs closer to their biological than their adopted

parents, often score higher than would be expected had they been reared by their biological parents.

Whether or not some races are more intelligent than others is unknown since so many factors having to do with culture, health, and environment must be taken into account. People from different countries seem to excel at different sports, artistic activities, and occupations, but the reasons for these differences are unknown.

There are extremes of intelligence, as seen in *mental retardation* (defined by a low IQ) and the very gifted (defined by scores over 140). The latter are often very successful, but not always. Personality and social adjustment are equally important.

Intelligence tests

Tests designed to provide an estimate of a person's mental abilities.

TYPES

WECHSLER TESTS These are the most widely used of all tests today. There are two basic versions—the Wechsler Adult Intelligence Scale (WAIS) and the Wechsler Intelligence Scale for Children (WISC). Each is divided into verbal and performance sections, which can be used separately or combined to produce an overall score. The verbal sections are concerned with language skills and include measures of vocabulary, general knowledge, verbal reasoning, and verbal memory. The performance sections include measures of constructional ability and visual-spatial and perceptual ability (interpretation of shapes).

The performance sections of the test may be used separately for people with language problems. In this sense they can measure basic intellectual ability; verbal tests tend to be more culture-bound since they test skills that reflect social background.

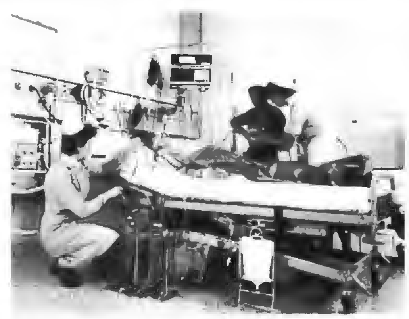
STANFORD-BINET TEST This is a revised version of one of the oldest intelligence tests, devised by the Frenchman Alfred Binet (1857-1911). It is still widely used, mainly as a measure of scholastic ability.

OTHER TESTS Numerous tests that concentrate on testing one particular aspect of intelligence have been devised. The Goodenough-Harris test assesses performance by asking a child to make a picture of a man; scoring counts such items as details of the body, proportions, and clothing.

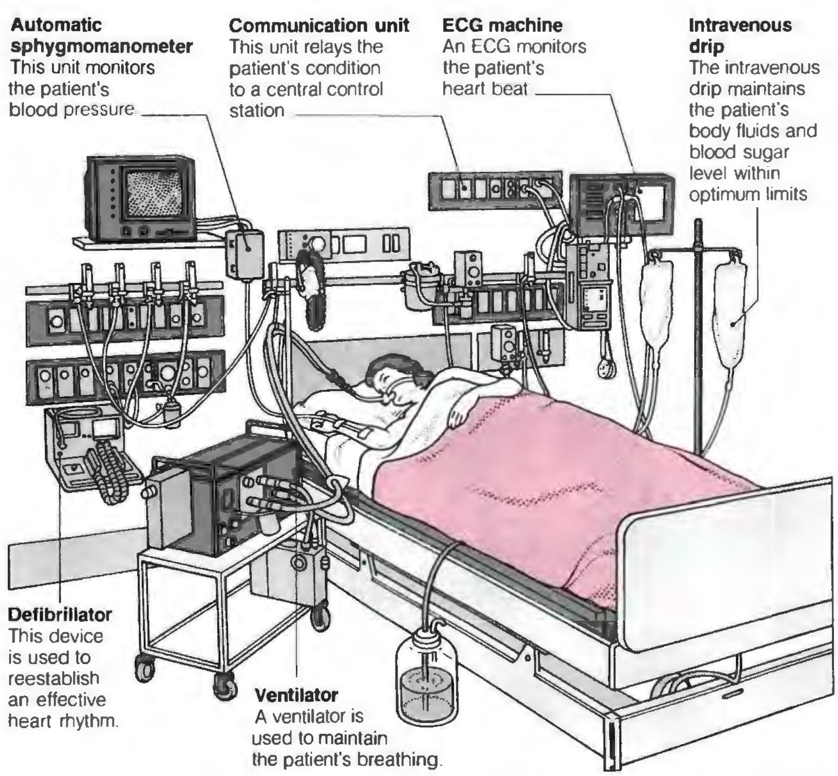
SCORING

In most intelligence tests, scoring is based on the notion of mental age (MA) in relation to actual chronological age (CA), since intelligence normally increases with maturity. The intelligence quotient (IQ) is therefore MA divided by CA, multiplied by 100 to simplify the results. The tests are devised to ensure that three quarters of people have an IQ between 80 and 120. They are also standardized so that the score indicates the same relative ability at different age levels. Regardless of age group, an IQ of 65 indicates that a person is in the lower 1 percent of his or her age group; an IQ of 135 indicates the person is in the upper 1 percent of his or her age group.

USES



Intelligence tests are useful in predicting whether a person has the ability to cope with certain jobs or pass certain exams; they may be used to assess school or job aptitude. However, intelligence tests have been criticized for their alleged bias regarding gender and race. The tests are also used to define the legal notion of *mental retardation* and to assess the effects of brain disease or dementia. In particular, a large difference in verbal and performance scores helps in assessing the degree of brain disease. Children with a particular difficulty (such as delayed reading) may be tested to assess the severity and nature of the problem so remedial teaching can be planned.



Intensive care

The constant, close monitoring of seriously ill patients, which enables immediate treatment to be given if the patient's condition deteriorates. The intensive-care unit of a hospital contains electronic monitoring equipment

A TYPICAL INTENSIVE-CARE UNIT

A modern intensive-care unit has a wide variety of sophisticated equipment so that the condition of seriously ill patients can be continuously monitored and any deterioration treated immediately.

that allows continuous assessment of vital body functions, such as blood pressure and heart and respiratory rate. Medical and nursing staff are in a high ratio to patients and are specially trained in the techniques of resuscitation. Most intensive-care units are under the supervision of hospital-employed specialists.

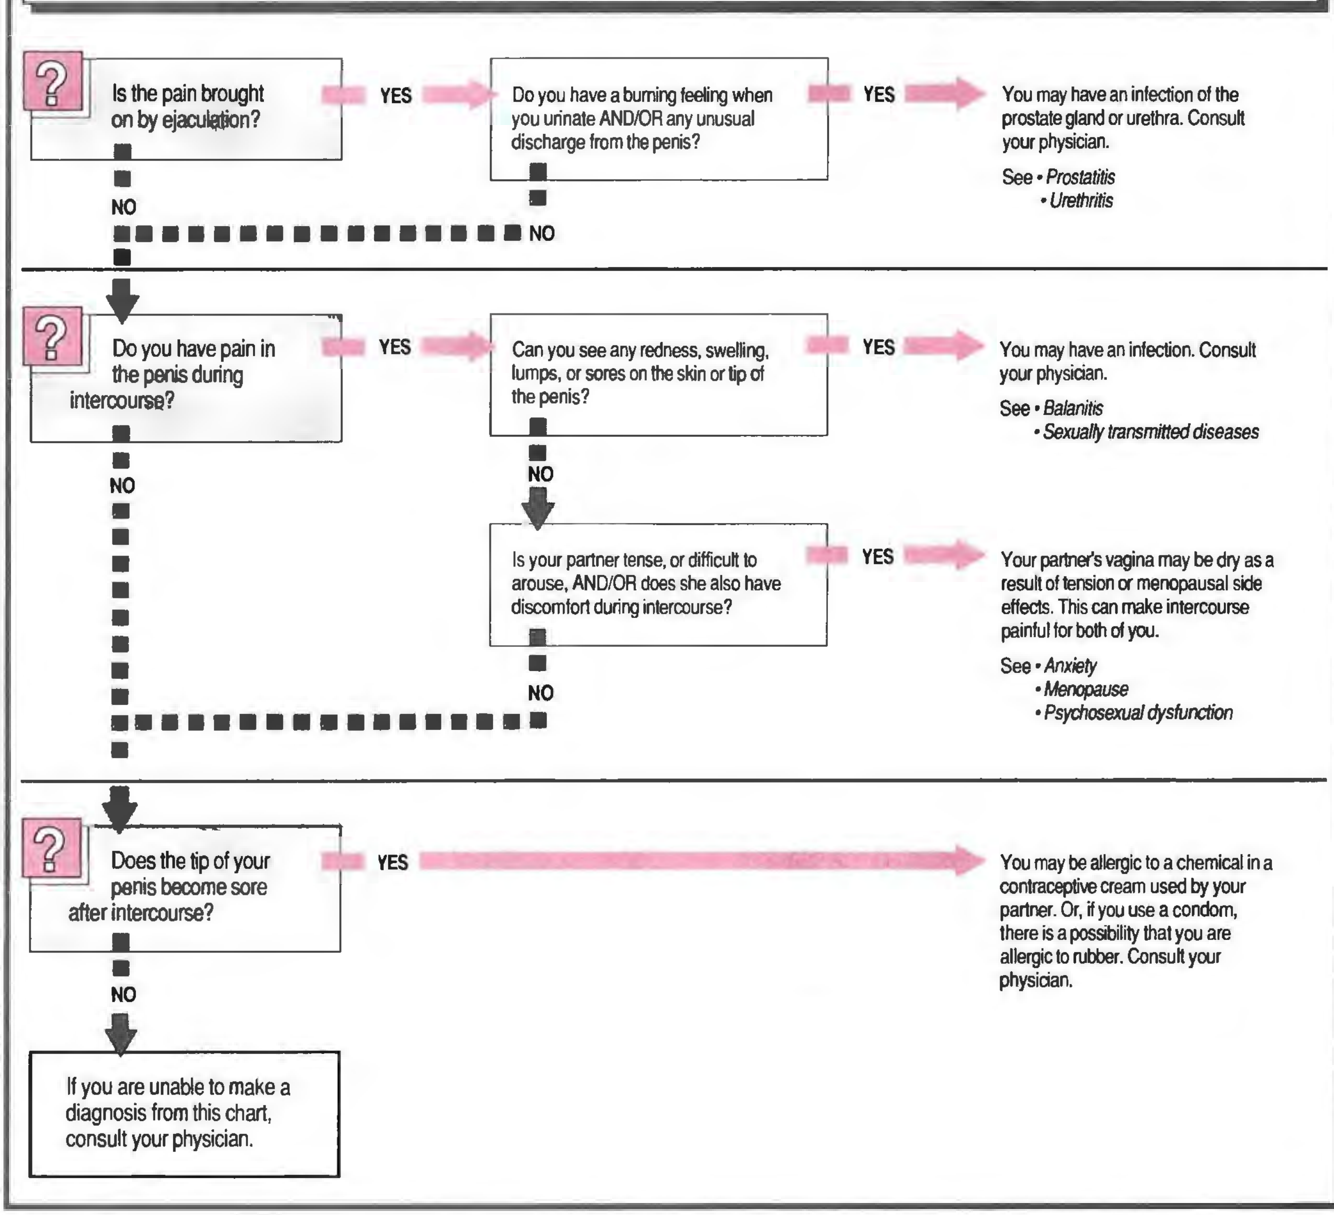
Intensive care is most often needed for patients who are on artificial *ventilation;* they may be unconscious and not breathing or may be suffering from a respiratory illness. Close monitoring in an intensive-care unit is also required for people recovering from a myocardial infarction or after major surgery, for patients in *shock* who are not responding to emergency treatment, and for those with acute *renal failure* who require *dialysis*. (See also *Coronary care unit*.)

Inter-

A prefix that means between, as in intercostal (between the ribs). See also *Intra-*.

Intercostal

The medical term for between the ribs, as in the intercostal muscles, thin sheets of muscle between each rib that help expand and contract the chest during breathing.



Intercourse, painful

Known as dyspareunia, pain during intercourse can affect both men and women. The pain may be superficial, occurring around the external genitals, or it may be experienced deep within the pelvis.

CAUSES

Superficial pain is usually due to the condition of the external genitals. *Sexually transmitted diseases* (such as genital *herpes*, *gonorrhea*, or *chlamydial infections*) cause dyspareunia, with the pain being felt on the penis or around the vulval area. *Spermicides* sometimes cause a burning sensation in both men and women.

PAINFUL INTERCOURSE IN MEN Pain or discomfort during or just after sexual intercourse.

PAINFUL INTERCOURSE IN WOMEN

Pain or discomfort during or just after sexual intercourse.

? Are you starting your first or a new sexual relationship?

YES → A bruised or sore feeling is normal in these circumstances. Allow your body to recover before having intercourse again.

NO ↓

? Have you just started intercourse again after having a baby?

YES → Do you have soreness at the entrance to the vagina where you had an episiotomy?

- YES → Soreness of the vagina is a common problem in the weeks following childbirth. This is particularly likely if you had an episiotomy.
- NO → Many women take a while to rediscover their enjoyment of sex after having a baby. Tension can lead to pain or discomfort.

NO ↓

? Have you noticed any abnormal vaginal discharge?

YES → A vaginal infection may cause pain during intercourse. Consult your physician.

See • *Candidiasis*
• *Trichomoniasis*

NO ↓

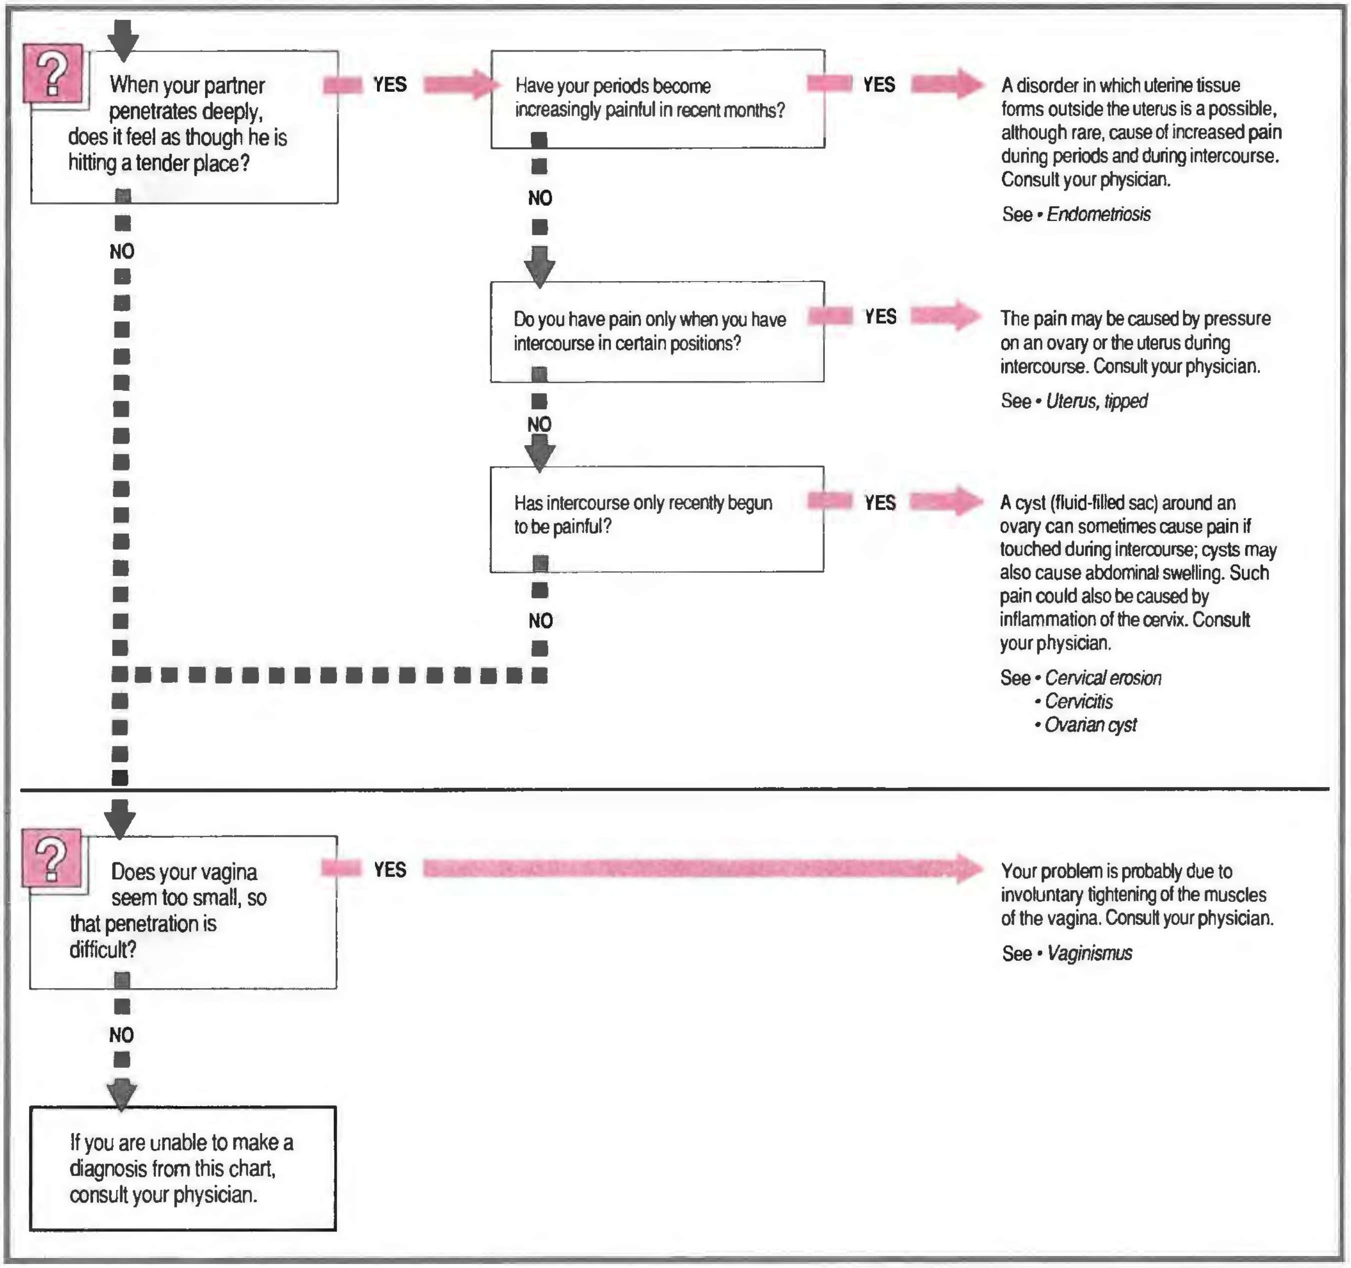
? Are you urinating more often than usual?

YES → Your bladder may have become inflamed as the result of infection. Consult your physician.

See • *Cystitis*

NO ↓

? Does your vagina feel dry and tight so that penetration is difficult and painful?



YES → Are you between 45 and 65 years old?

- YES → See • *Menopause*
- NO → Anxiety and/or lack of arousal can lead to tension during intercourse. This can prevent normal lubrication of the vagina and relaxation of the surrounding muscles and tissues.

  See • *Anxiety*
  • *Psychosexual dysfunction*

NO ↓

Continued on next page

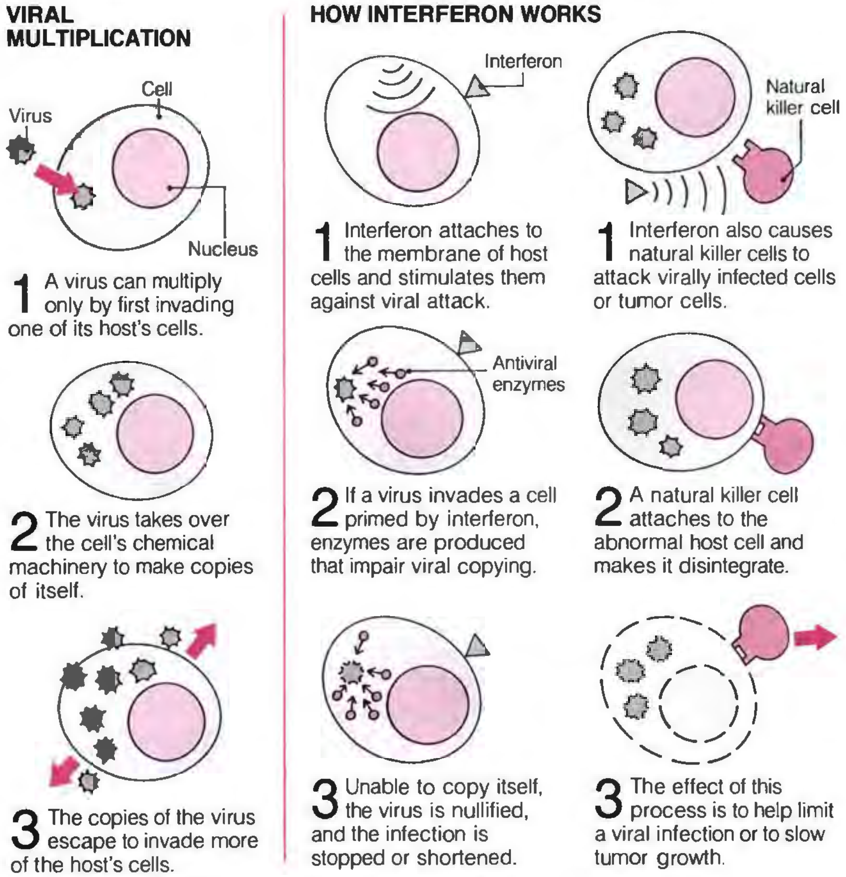
In men, superficial pain during intercourse may be caused by anatomical abnormalities, such as *chordee* (bowed erection) or *phimosis* (tight foreskin). *Prostatitis* may cause a sharp, stabbing pain from the penis tip; there may also be a widespread pelvic ache or a burning sensation.

In some women, scarring (after tears from delivery or a poorly healed *episiotomy* repair, for example) may cause dyspareunia. Insufficient vaginal lubrication, especially after the menopause, is another cause of painful intercourse in women.

Deep dyspareunia in women is often caused by pelvic disorders (such as *fibroids*, *ectopic pregnancy*, or *pelvic inflammatory disease*) or by disorders of the *ovary* (such as ovarian cysts or tumors). *Endometriosis* can cause thickening behind the uterus, resulting in deep pain during intercourse. Varicose veins in the pelvis and cervical disorders (such as tumors or infections) can also cause deep pain during intercourse. *Cystitis* commonly causes pain, primarily in women, as do other urinary tract infections.

Psychosexual problems may also cause painful intercourse. *Vaginismus*, in which the muscles of the vagina go into spasm, preventing insertion of the penis, is usually psychological.

TREATMENT



Treatment is directed at the underlying cause of the pain (for example, antibiotics for an infection or a lubricant for vaginal dryness). Analgesics (painkillers) may be helpful. If the discomfort is psychological in origin, special counseling may be required (see *Sex therapy*).

Interferon

The name given to a group of proteins produced naturally by body cells in response to viral infections and other stimuli. Interferon inhibits viral multiplication (see illustration) and increases the activity of natural killer

HOW INTERFERON FIGHTS VIRAL INFECTIONS

Interferon is part of the body's immune system, providing a defense against many different types of virally infected or tumor cells. It is produced naturally in the body during viral infections, but can also be given as a drug to enhance its natural actions.

VIRAL MULTIPLICATION

1 A virus can multiply only by first invading one of its host's cells.

2 The virus takes over the cell's chemical machinery to make copies of itself.

3 The copies of the virus escape to invade more of the host's cells.

HOW INTERFERON WORKS

1 Interferon attaches to the membrane of host cells and stimulates them against viral attack.

1 Interferon also causes natural killer cells to attack virally infected cells or tumor cells.

2 If a virus invades a cell primed by interferon, enzymes are produced that impair viral copying.

2 A natural killer cell attaches to the abnormal host cell and makes it disintegrate.

3 Unable to copy itself, the virus is nullified, and the infection is stopped or shortened.

3 The effect of this process is to help limit a viral infection or to slow tumor growth.

cells—types of *lymphocytes* that form part of the body's *immune system* (natural defenses).

USE AS DRUG

Interferon has been approved for use in the treatment of hairy cell *leukemia*. It is currently under investigation for use in the treatment of various types of cancer, especially *Kaposi's sarcoma* (a skin cancer common in people with *AIDS*). Interferon is also being assessed as a treatment for life-threatening viral infections, particularly in people who have *immunodeficiency disorders*.

Interferon is produced from a culture of human cells exposed to a specific virus or is synthesized in the laboratory from specific nucleic acids (genetic material). It is given by injection or taken as a nasal spray. Possible adverse reactions include fever, headache, aching muscles, fatigue, nausea and vomiting, hair loss, and abnormal bleeding.

Intern

A term for a medical graduate in the first year of hospital training.

Internist

A specialist in the diagnosis and treatment of diseases in adults, particularly those related to the internal organs. Internists often provide a person's primary care.

Intersex

A group of abnormalities in which the affected person has ambiguous genitalia (abnormal external sex organs that could be of either sex) or in which the external genitalia have the opposite appearance to the chromosomal sex of the individual. (See also *Sex determination*.)

Interstitial pulmonary fibrosis

Scarring and thickening of the deep lung tissues, leading to shortness of breath; it is also known as IPF.

TYPES AND CAUSES

The most important form of the disorder is known as idiopathic or diffuse interstitial pulmonary fibrosis, or fibrosing alveolitis. It is of unknown cause, but is probably an *autoimmune disorder* (caused by the body's *immune system* attacking its own tissues).

Less common causes include occupational exposure to mineral dusts and chemical fumes, radiation therapy, reactions to certain drugs, *lung cancer*, and allergic *alveolitis*.

SYMPTOMS AND DIAGNOSIS

The symptoms are progressive shortness of breath, cough, chest pain, and finger clubbing, as well as symptoms of any underlying disease. The diagnosis is based on the patient's history and physical examination and is confirmed by *chest X ray* and lung *biopsy*.

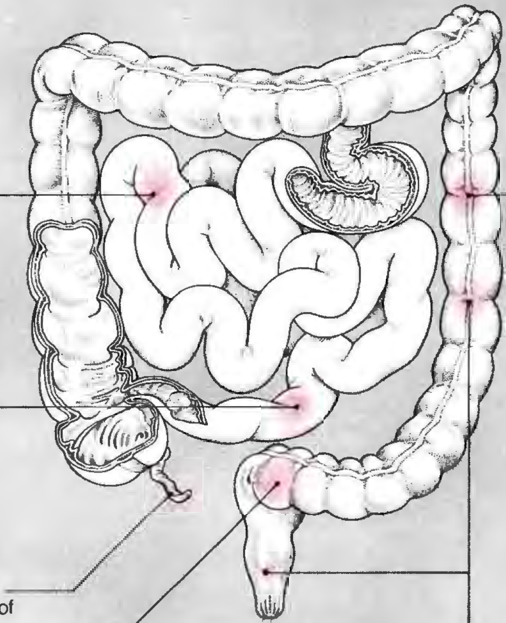
TREATMENT AND OUTLOOK

Treatment of idiopathic IPF often includes azathioprine and *corticosteroid drugs*, which suppress the immune system. In other cases, treatment of the disorder is directed to the underlying cause.

The outlook for recovery is generally poor for occupational dust diseases and idiopathic IPF, in which the lungs progressively stiffen. Progression of the disease may lead to heart failure and bronchopneumonia.

When IPF is caused by allergic alveolitis, the condition is more easily treated or reversible and the outlook may not be as gloomy.

Interstitial radiation therapy



Treatment of a malignant tumor by inserting radioactive material into the growth (also called brachytherapy) or into neighboring tissue. With this method, radiation can be directed more accurately than is possible with X rays to the diseased area; there is also less risk of radiation harming healthy tissue.

HOW IT IS DONE

The patient is given a general anesthetic. Radioactive material (usually artificial isotopes) contained in wires or small tubes is then implanted into or near the diseased tissue. If the tumor is in an easily accessible area (such as the mouth), the containers may be pushed in by means of a special needle; for a tumor deep in the body, a surgical procedure is necessary. The material is left in place for variable amounts of time (and sometimes permanently), depending on the radioactive substance and the tumor being treated. (See also *Intracavitary therapy; Radiation therapy*.)

DISORDERS OF THE INTESTINE

The intestine is subject to various structural abnormalities and to the effects of many infective organisms and parasites; it may also be affected by tumors, impaired blood supply, and other disorders.

CONGENITAL DEFECTS

Babies are sometimes born with an obstruction to the flow of the intestinal contents. This may be due to *atresia* (congenital closure), *stenosis* (narrowing), *volvulus* (twisting of loops of bowel), or blockage by meconium (fetal intestinal contents). Early surgery may be required.

INFECTION AND INFLAMMATION

The general term for inflammation of the stomach and intestines is *gastroenteritis.* This is caused most commonly by viral or bacterial infections, which can range from the trivial to the life-threatening. They encompass many cases of *food poisoning* and travelers' diarrhea as well as serious diseases such as *typhoid fever* and *cholera*. Protozoal infections (caused by simple, single-celled parasites) include *giardiasis* and *amebiasis*.

Intestinal worm infestations are exceedingly common worldwide (see *Roundworms; Tapeworms*), although, in the US, only a few species of worms—including the *pinworm*—are prevalent.

Two important inflammatory conditions of the intestine, not caused by infection, are *ulcerative colitis* (mainly affecting the colon) and *Crohn's disease* (which may affect any part of the digestive tract but usually the small intestine). Sometimes, inflammation is confined to a localized area, such as in *appendicitis* and *diverticular disease*.

TUMORS

Tumors of the small intestine are rare, but *lymphomas,* carcinoid tumors (producing *carcinoid syndrome*), and benign growths occur.

By contrast, tumors of the large intestine are very common (see *Intestine, cancer of*). Certain forms of familial *polyposis* (a disorder in which benign polyplike tumors grow in the colon) may progress to cancer.

IMPAIRED BLOOD SUPPLY

Like other organs, the intestine is dependent on an adequate blood supply. *Ischemia* (lack of blood) may result from several causes. Causes include partial or complete obstruction of the arteries in the abdominal wall (from disease such as *atherosclerosis, thrombosis,* or *embolism*) or from the blood vessels being compressed or trapped, as in *volvulus, intussusception,* or *hernias* (protrusion of intestines through the abdominal wall). Loss of blood supply to a segment of intestine may cause *gangrene* (tissue death) requiring immediate surgery.

OBSTRUCTION

Intestinal obstruction may be caused by pressure from the outside, disease of the intestinal wall (such as cancer, Crohn's disease, or diverticular disease), or internal blockage (such as from *gallstones* or intussusception). One of the most common causes is paralytic *ileus,* in which intestinal contractions cease and the intestinal contents are no longer transported.

OTHER DISORDERS

Peptic ulcer of the duodenum is a very common disorder, thought to affect 10 percent of the population. Ulceration of the small intestine occurs in typhoid and Crohn's disease and may cause bleeding into the intestine or even perforation (hole formation). Ulceration of the large intestine occurs in amebiasis and in ulcerative colitis.

Diverticula are small outpouchings from the inside of the bowel. They are usually harmless, but, in diverticular disease, become inflamed. *Malabsorption* and *celiac sprue* result from changes to the intestinal lining. Finally, *irritable bowel syndrome* is associated with persistent abdominal pain and either constipation or diarrhea (or both) and is the most common intestinal disorder in Western societies.

INVESTIGATION

Intestinal disorders are investigated by physical examination, and by techniques such as *barium X-ray examination, sigmoidoscopy,* or possibly *colonoscopy,* and by laboratory examination of the feces or of a *biopsy* specimen taken from the intestinal lining.

Intertrigo

Inflammation of the skin caused by two surfaces rubbing together. Intertrigo is most common in obese people and usually occurs on the inner thighs, in the armpits, on the underside of the breasts, in folds of the abdomen, and between fingers and toes. The affected skin is red, moist, and may have an odor; there may be scales or blisters. The condition is made worse by sweating. It is sometimes accompanied by seborrheic *dermatitis* or *candidiasis* (thrush).

Treatment consists of weight reduction, keeping affected areas as clean and dry as possible, and, if dermatitis or candidiasis is present, applying a *corticosteroid* or *antifungal* cream.

Intestinal imaging

See *Barium X-ray examinations.*

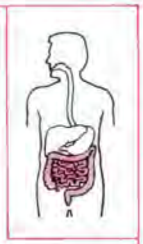
Intestinal lipodystrophy

See *Whipple's disease.*

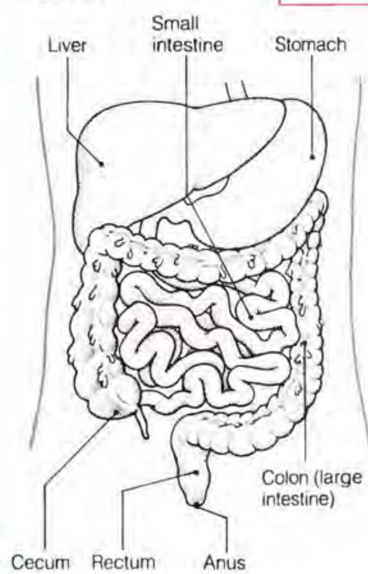
Intestine

The major part of the digestive tract, extending from the exit of the stomach to the anus. The intestine forms a long tube divided into two main sections—the small intestine and the large intestine. The function of the intestine is to break down and absorb food and water into the bloodstream and carry away the waste products of digestion to be passed as feces.

STRUCTURE



The small intestine is about 21 feet (6.5 m) in length and 1.5 inches (35 mm) in diameter. It has three sections—the duodenum (a short, curved segment fixed to the back wall of the abdomen) and the jejunum and ileum (two larger, coiled, and mobile segments). The bile and pancreatic ducts enter the duodenum (see *Biliary system*).



The walls of the intestine consist of circular and longitudinal muscles with an internal lining (the mucosa) and an external covering (the serosa). *Peristalsis* (the rhythmic contraction of the muscles) forces partially digested food along the intestine. The mucosa consists of many *villi* (small, fingerlike projections) covered with millions of fronds that create a large surface area to help the absorption of substances into the blood.

The large intestine is about 6 feet (1.8 m) in length and 2 inches (50 mm) in diameter; it frames the loops of the small intestine. Unlike the small intestine, much of it is fixed in position, the muscles run in bands rather than forming a continuous sheet along its length, and there are no internal villi. The main section, the colon, is divided into an ascending, a transverse, a descending, and a pelvic portion (the sigmoid colon) that hangs down into the pelvis. The appendix hangs from a pouch (the cecum) between the small intestine and the colon. The final section of intestine, before the anus, is the rectum.

LOCATION OF THE INTESTINE

Situated below the stomach and liver, the intestine occupies much of the central and lower parts of the abdomen.

FUNCTION

The small intestine is concerned with the digestion of food and the absorption of food into the bloodstream. Some digestion occurs in the stomach, but more digestive enzymes and bile are added to the partly digested food in the duodenum. Glands within the walls of each section of the small intestine produce mucus and more enzymes, all of which help to break down the food into easily absorbable chemical units. The numerous blood vessels in the intestinal walls then carry the digested food to the liver for distribution to the rest of the body.

Unabsorbed material leaves the small intestine in the form of liquid and fiber. As they pass through the large intestine, water, vitamins, and mineral salts are absorbed into the bloodstream, leaving feces made up of undigested food residue, small amounts of fat, secretions from the stomach, liver, pancreas, and bowel wall, and various bacteria. The feces are gradually compressed and pass into the rectum. Distention of the rectum usually produces the desire to empty the bowel.

Intestine, cancer of

Cancerous tumors in the small intestine are extremely rare, but the large intestine is overall the second most common cancer site (after the lung). Colorectal cancer accounts for about 20 percent of all cancer deaths in the US.

Types found in both the small and large intestine include carcinoid tumors and lymphomas. Carcinoid tumors are very slow growing and usually symptomless (however, they may spread to the liver, leading to *carcinoid syndrome*). Lymphomas, which damage the wall of the intestine and nearby lymph nodes, cause malabsorption of food.

CAUSES

Although there is no single cause of intestinal cancer, there are a number of possible contributory factors.

The higher incidence of cancer of the colon (by far the most common type of intestinal cancer) in Western countries suggests an environmental, probably dietary, factor. It is believed that a high-meat, high-fat, and low-fiber diet encourages the production and concentration of *carcinogens*.

There is also thought to be a genetic factor. Brothers, sisters, and children of people suffering from cancer of the colon are more likely than average to acquire the disease later in life.

Cancer of the colon frequently occurs in association with other diseases of the colon, such as *ulcerative colitis* and familial *polyposis*.

SYMPTOMS

An inexplicable change in bowel movements (either constipation or diarrhea) lasting for 10 days or so may be one of the first symptoms of cancer of the large intestine.

Blood mixed in the feces (as opposed to the blood from *hemorrhoids*, which usually coats the feces) is another important warning signal, although, if the growth is high up in the colon, the blood can be detected only by chemical tests.

There may be pain and tenderness in the lower abdomen. Sometimes, however, there are no symptoms at all until the tumor grows so big that it causes an obstruction in the intestine or causes the intestine to rupture.

DIAGNOSIS AND TREATMENT

Tests on feces, *barium X-ray examinations*, *sigmoidoscopy*, and *colonoscopy* may be carried out.

Treatment depends on the stage of development of the cancer, but, in most cases, a partial *colectomy* is performed. The diseased tissue and a small amount of surrounding normal tissue are removed and the cut ends are sewn together to reestablish the channel. If the disease is extensive, surgery may not be possible.

OUTLOOK

The long-term prospects vary according to the stage the disease has reached when it is discovered. More than 50 percent of patients survive in good health for at least five years after a colectomy. Nonsurgical treatments merely arrest the growth and spread of the cancer and are not curative. The earlier the tumor is detected, the greater the chances of a full recovery after treatment. Anyone over the age of 50 who suddenly experiences a change in bowel movements should see a physician without delay. (See also *Rectum, cancer of*.)

Intestine, obstruction of

A partial or complete blockage of the small or large intestine. Without treatment, complete obstruction of the intestine is usually fatal.

CAUSES

The most common cause of intestinal obstruction is paralytic *ileus*, in which (for no medical reason) *peristalsis* (the rhythmic muscle contractions of the intestine) stops, the bowel dilates, and the intestinal contents are no longer moved along the digestive tract.

Other common causes, which have a mechanical basis, are strangulated *hernia*, *atresia* (congenital closure), *stenosis* (narrowing of the intestinal canal), adhesions (postoperative bands of scar tissue that bridge across the outer surface of segments of bowel, sometimes trapping another loop), *volvulus* (twisting or knotting of the bowel), and *intussusception*.

Intestinal obstruction also occurs in diseases (such as *Crohn's disease*, *diverticular disease*, and tumors) that affect the intestinal wall. Less commonly, internal blockage of the intestinal canal is caused by impacted food, feces, gallstones, or by some accidentally swallowed object.

SYMPTOMS

The location and type of obstruction (partial or complete) dictate the symptoms. A blockage in the small intestine usually causes intermittent cramplike middle abdominal pain, which tends to be more severe the higher the obstruction. This is accompanied by increasingly frequent bouts of vomiting and by failure to pass gas or stools.

The symptoms of obstruction in the large intestine, particularly the colon, are pain, distention (swelling) of the abdomen, and failure to pass stools; the blockage may be so complete that even gas cannot be passed. Partial obstruction may be accompanied by diarrhea when the obstruction is intermittent. There is temporary relief when the liquid stool is able to pass through the remaining gap and the symptoms abate for a while.

DIAGNOSIS AND TREATMENT

A careful history and physical examination are usually all the physician requires to make a diagnosis. Abdominal *X rays* are confirmatory. Most of the gas and intestinal contents are removed through a flexible tube inserted down the throat. Complete mechanical obstruction must be corrected by surgery, but the actual type of operation depends on the nature and site of the blockage to the flow of intestinal contents.

OUTLOOK

The prospects for a full recovery after surgery are excellent, particularly if the underlying problem is a hernia, congenital atresia, or intussusception. However, if the problem is a tumor in the colon of an elderly patient, the risks of the operation are greater.

Intestine, tumors of

Tumors of the intestine may be cancerous or benign (noncancerous). Cancers of the intestine include carcinoid tumors, lymphomas, cancer of the colon (see *Intestine, cancer of*), and cancer of the rectum (see *Rectum, cancer of*).

Noncancerous tumors are rare, but *polyps* in the colon, and *adenomas*, *leiomyomas*, *lipomas*, and *angiomas* in the small intestine are occasionally found. These tumors are usually symptomless and are often discovered only accidentally when *barium X-ray examinations* are being carried out for some other reason.

Very occasionally polyps undergo transformation and become cancerous, which is why they are usually removed at an early stage.

Intoxication

A general term for a condition resulting from *poisoning*; it customarily refers to the effects of excessive drinking (see *Alcohol intoxication*), but also includes *drug poisoning* or poisoning from accumulation of metabolic substances in the body.

Intra-

A prefix that means within, as in intramuscular (within a muscle). See also *Inter-*.

Intracavitary therapy

Treatment of a malignant tumor in a body cavity by placing radioactive material within the cavity. The treatment is used mainly for cancer of the uterus, cervix (neck of the uterus), vagina, or rectum.

HOW IT IS DONE

The radioactive material (usually in the form of artificial isotopes embedded in wires or small tubes) is introduced into the cavity and left there for a period of time, using a general or local anesthetic.

Sometimes *anticancer drugs* are introduced directly into the abdominal cavity or pleural cavity (the space around the lungs) to treat a malignant effusion (a fluid containing cancerous cells). A needle, sometimes with a catheter (fine tube) attached, is passed through the wall of the abdomen or chest into the cavity, using a local anesthetic. The needle is used to draw off the effusion and then to inject the drug. (See also *Interstitial radiation therapy*; *Radiation therapy*.)

Intracerebral hemorrhage

Bleeding into the brain from a ruptured vessel. Intracerebral hemorrhage is one of the three main mechanisms by which a *stroke* can occur.

INCIDENCE AND CAUSES

Each year in the US, about one person in 2,500 suffers an intracerebral hemorrhage. Most victims are middle-aged or elderly people with untreated *hypertension* (high blood pressure) or *atherosclerosis* (fatty deposits causing narrowing of the arteries) in the brain. Unlike most cases of *subdural* and *extradural hemorrhage* (bleeding between the surface of the brain and the skull), an intracerebral hemorrhage can occur without any injury or blow to the head.

The ruptured artery is usually in the cerebrum (the main mass of the brain), although sometimes it is in other brain structures (such as the cerebellum or the brain stem). The escaped blood seeps outward, forming a circular or oval mass up to a few inches in diameter, disrupting brain tissue in its path as bleeding continues and its volume

increases. Adjacent brain tissues are displaced and compressed.

SYMPTOMS

The symptoms are sudden headache, weakness, and confusion, and often loss of consciousness. Usually the victim falls unconscious to the ground with no warning. Signs resulting from disruption of brain tissue (speech loss, facial paralysis, or one-sided weakness) may develop over periods of minutes or hours.

DIAGNOSIS, TREATMENT, AND OUTLOOK

Diagnosis is by *CT scanning*. Surgical treatment is usually impossible due to the inaccessibility of the rupture, so treatment is aimed at life-support and reduction of blood pressure.

Large hemorrhages are usually fatal, and, overall, only about 25 percent of patients survive. Recurrent bleeding from the same site is uncommon. For the survivor of an intracerebral hemorrhage, rehabilitation and outlook are as for stroke.

Intractable

Any condition that does not respond to treatment.

Intramuscular

A medical term meaning within a muscle, as in an intramuscular injection, in which a drug is injected deep within a muscle. Such injections are usually given into the upper, outer part of the buttock. The drug is absorbed from the muscle into the bloodstream, which distributes it throughout the body.

Intraocular pressure

The balance between the rate of production and removal of aqueous humor within the eye, which maintains the shape of the eyeball. Aqueous humor enters the eye from the ciliary body, which constantly produces the fluid, and exits from the drainage angle (a network of tissue between the iris and cornea).

If drainage is impeded, intraocular pressure builds up and leads to *glaucoma*. Intraocular pressure is usually measured by *tonometry* during a routine eye examination.

Intrauterine contraceptive device

See *IUD*.

Intrauterine growth retardation

Poor fetal growth, usually due to a fetal defect or to failure of the placenta to provide adequate nutrients. Intrauterine growth retardation causes the fetus to be smaller than expected for the length of gestation.

CAUSES

Intrauterine growth retardation may be due to a chromosomal defect, such as *Down's syndrome*, which causes the fetus to be "small for dates." A maternal infection, such as *rubella* (German measles), in which the virus passes through the placenta, can also cause poor fetal growth.

Maternal factors may also be responsible, especially when the fetus is otherwise normal. Conditions such as *preeclampsia*, *hypertension*, or chronic *renal failure* can affect fetal growth, as can the mother's diet. Cigarette smoking is a major cause of intrauterine growth retardation, as are malnutrition and alcoholism.

DIAGNOSIS AND TREATMENT

The physician can check whether the uterus is smaller than expected during a prenatal examination; *ultrasound scanning* may be performed to estimate the fetal growth. The mother may be required to rest, and tests of placental function may be needed, including blood tests or electrical monitoring of the baby's heart.

If intrauterine growth retardation is diagnosed, the pregnancy is carefully monitored and the underlying cause of the placental insufficiency treated, if possible. If the baby's growth is slowing, *induction of labor* or a *cesarean section* may be necessary.

OUTLOOK

Because babies suffering intrauterine growth retardation have been chronically undernourished in the uterus, they are usually underweight and may be premature if labor has been induced. Because they are prone to low blood sugar, *hypothermia*, and infection, they are usually transferred to an *incubator* immediately after birth to provide them with special care.

Intravenous

A term meaning within a vein, as in *intravenous infusion* (slow introduction of a substance into a vein) and intravenous *injection* (rapid introduction of a substance into a vein).

Intravenous infusion

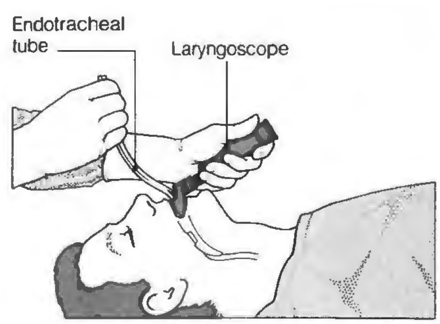
The slow introduction of a volume of fluid into the bloodstream. The fluid passes down from a plastic or glass container through tubing into a cannula (thin plastic tube) inserted into a vein, usually in the patient's forearm. The rate at which the fluid drips into the circulation is controlled by an adjustable valve.

An intravenous infusion, commonly known as a drip, is used to give blood (or plasma) to replace that lost in a serious accident or during an operation (see *Blood transfusion*). It is also used to replace or maintain body fluids in patients who are unable to drink or eat. In this case, the fluid is usually a mixture of glucose (sugar) and saline (salt solution). Other uses include providing more varied and concentrated nutrients to people unable to digest food normally (see *Feeding, artificial*) and administering certain drugs.

Intravenous pyelography

See *Pyelography*.

Introitus



A general term for the entrance to a body cavity or space, most commonly the vagina.

Introvert

A person more concerned with his or her inner world. Introverts prefer to work alone, are shy, quiet, and withdrawn when under stress. (See also *Extrovert*; *Personality*.)

Intubation

The process of passing an *endotracheal tube* (breathing tube) into the trachea (windpipe). Intubation is performed if a person needs mechanical ventilation to deliver oxygen to the lungs—for example, because he or she is in a coma, is anesthetized, or has severe respiratory disease.

Endotracheal intubation
Guided by an anesthesiologist, the endotracheal tube is passed through the patient's mouth and down the throat into the trachea.

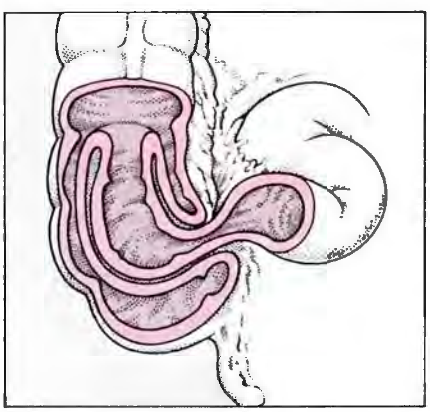
HOW IT IS DONE

The anesthesiologist looks at the patient's throat with a laryngoscope (a viewing instrument) to identify the vocal cords. An endotracheal tube is passed through the patient's mouth and down the throat between the vocal cords into the trachea. Alter-

natively, the tube is passed through the nose. The external end of the tube is then secured by tape; an inflatable cuff may be used to hold the tube in place within the trachea.

Intubation also refers to the placement of a gastric or intestinal tube for purposes of suction or the giving of nutrients (see *Feeding, artificial*).

Intussusception

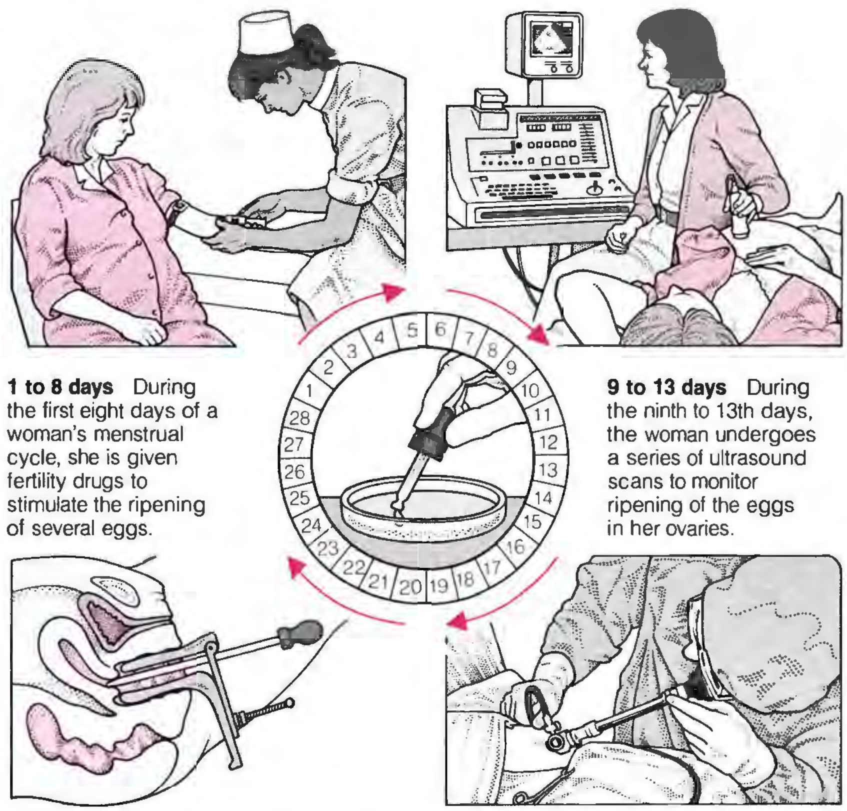


A condition in which part of the intestine telescopes in on itself, forming a tube within a tube (like pulling a shirt sleeve partially inside out), usually resulting in intestinal obstruction (see *Intestine, obstruction of*). Intussusception occurs primarily in young children.

CAUSES AND INCIDENCE

It is not known exactly why this condition occurs, but in some cases there is a definite association with a recent infection. In other instances it may start at the site of a *polyp* or *Meckel's diverticulum* (a small, pouchlike projection from the end section of the small intestine). An intussusception is the most common cause of intestinal obstruction in children under 2 years, affecting approximately two babies per 1,000.

SYMPTOMS



Severe abdominal colic usually develops in the child, causing intermittent screaming attacks. Vomiting is a common feature, and blood and mucus are often found in the feces. In severe cases, the blood supply to the intestine becomes blocked and *peritonitis* (inflammation of the membrane covering the organs in the abdomen), *perforation* (formation of a hole in the intestine wall), or *gangrene* (tissue death) may follow.

Intussusception
This disorder is characterized by part of the intestine telescoping in on itself. It usually affects parts of the small intestine and is most common in infants.

PROCEDURE FOR IN VITRO FERTILIZATION

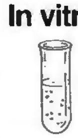
Fertilization of eggs outside a woman's body can be used to treat some types of infertility. The main stages involved in the procedure of in vitro fertilization are illustrated below.

1 to 8 days During the first eight days of a woman's menstrual cycle, she is given fertility drugs to stimulate the ripening of several eggs.

9 to 13 days During the ninth to 13th days, the woman undergoes a series of ultrasound scans to monitor ripening of the eggs in her ovaries.

14 to 15 days Immediately before ovulation (which may be induced with drugs), ripe eggs are removed by laparoscopy or by ultrasound-guided needle aspiration through the vagina or abdomen. The eggs are mixed with the man's sperm in a dish, which is then put in an incubator.

16 to 17 days After about 40 hours, the eggs are examined to see if they have been fertilized and have started to develop into embryos. If they have, several embryos (usually at the two- or four-cell stage) are placed in the woman's uterus through the vagina.



DIAGNOSIS AND TREATMENT

A barium enema (see *Barium X-ray examinations*) is usually sufficient to reveal the obstruction. Sometimes the barium enema actually treats the condition; the pressure applied when the enema is introduced can force the prolapsed segment back into position. Otherwise, an operation is carried out. Usually, the intestine is gently squeezed to push out the inner segment, permitting surgery on the cause that led the segment of bowel to telescope. In rare cases, the prolapsed intestine must be cut out.

Invasive

Having the tendency to spread throughout body tissues; the term is usually applied to malignant tumors or harmful microorganisms. An invasive medical procedure is one in which body tissues are penetrated by an instrument. *Angiography* is an example. (See also *Noninvasive*.)

In vitro

The performance of biological processes in the laboratory rather than in the body; in vitro literally means "in glass." Tests successfully carried out in vitro do not always work the same way in the body.

In vitro fertilization

A method of treating *infertility* in which an egg is surgically removed from the ovary and fertilized outside the body. In vitro, which literally means "in glass," refers to the glass Petri dish that is used in the process.

The first successful birth as a result of in vitro fertilization (IVF) occurred in England in 1978.

WHY IT IS DONE

In vitro fertilization may be performed when the woman's *fallopian tubes* are permanently blocked or absent. IVF may also be done if the man's sperm count is very low or if it is thought that antibodies in the woman's cervical mucus are killing the sperm.

HOW IT IS DONE

Stages in the procedure are shown in the illustrated box.

After IVF, the woman's condition is monitored for a few days to determine if the fertilized eggs have become safely implanted in the uterine wall. Once this occurs, the pregnancy usually continues normally, although the early miscarriage rate is high, and multiple births may occur because more than one of the eggs "takes."

OUTLOOK

It is unlikely that in vitro fertilization will become a widespread treatment for infertility, at least in the near future. Currently, this highly specialized procedure is available only at a small number of clinics. It is expensive (costing about $5,000 per implantation attempt) and the success rate is limited.

Research into IVF has shown that half or more of all eggs have abnormal chromosomes and cannot develop into normal embryos; after fertilization, the eggs begin to divide, but the pregnancy miscarries. Only about 10 percent of couples achieve pregnancy on the first attempt, and many tries may be needed before a successful pregnancy is achieved. In addition, the legality of in vitro fertilization is still unclear. In the US, the procedure is prohibited in a number of states because of laws governing the rights of the embryo.

In vivo

Biological processes occurring, or caused to occur, within the body.

Involuntary movements

Uncontrollable movements of the body, usually affecting the face, head, limbs, and trunk. These movements occur spontaneously and may be slow and writhing (see *Athetosis*); rapid, jerky, and random (see *Chorea*); or predictable, stereotyped, and affecting one part of the body, usually the face (see *Tic*). They may be a feature of a disease (*Huntington's chorea*, for example) or a side effect of certain psychotherapeutic drugs.

Iodine

An element essential for the formation of *thyroid hormones* (thyroxine and triiodothyronine). These hormones control the body's *metabolism* (internal chemistry), promote growth and development, burn excessive fat, improve mental processes, and promote the formation of healthy hair, skin, nails, and teeth.

Iodine is found in seafood (the best dietary source), dairy products, bread, and some table salt preparations. Adequate amounts are obtained from a well-balanced diet. Iodine deficiency may cause a *goiter* (enlarged thyroid gland), *hypothyroidism* (underactive thyroid gland), and, in babies, *cretinism*.

MEDICAL USES

Iodine is sometimes given to people to protect against the effects of consuming food or drink contaminated with radioactive iodine (see *Radiation hazards*). Saturation with radiation-free iodine prevents the thyroid gland from absorbing and being damaged by radioactive iodine.

Radioactive iodine is sometimes given to deliberately damage the thyroid gland to treat *thyrotoxicosis* (overactive thyroid gland).

Some iodine compounds are used as *antiseptics*; others are included in *cough remedies*. Iodine is also a constituent of the radiopaque contrast medium used in some X-ray procedures (see *Imaging techniques*).

POSSIBLE ADVERSE EFFECTS

Iodine supplements rarely cause an allergic reaction. Possible symptoms of allergy to iodine include rash, facial swelling, abdominal pain, vomiting, and headache.

Ion

A particle (either an atom or a group of atoms) that carries an electrical charge; positively charged ions are called cations and negatively charged ions are called anions. Important cations in the body include sodium, potassium, hydrogen, and calcium. Important anions include bicarbonate, chloride, and phosphate.

ROLE IN THE BODY

Many vital body processes depend on the movement of ions across cell membranes. For example, the exchange of sodium for potassium across the membranes around nerve and muscle cells is the mechanism by which nerve impulses are transmitted and by which muscle contraction occurs. Calcium also plays an important role in muscle contraction, in addition to being involved in blood clotting and bone growth.

IMPORTANT IONS AND THEIR ROLES

Cations (positively charged ions)	Major roles in body
Ammonium	Acid-base balance; produced by protein metabolism
Calcium	Nerve conduction; muscle contraction; blood clotting; bone and tooth formation; heart action
Hydrogen	Acid-base balance; component of stomach acid
Magnesium	Nerve conduction; muscle contraction; bone and tooth formation; enzyme activation; protein metabolism
Potassium	Nerve conduction; muscle contraction; water balance; acid-base balance
Sodium	Nerve conduction; muscle contraction; water balance; acid-base balance
Anions (negatively charged ions)	
Bicarbonate	Acid-base balance; neutralizes stomach acid
Chloride	Acid-base balance; water balance; component of stomach acid
Phosphate	Acid-base balance; bone and tooth formation; protein metabolism; energy metabolism; structure of cell membranes

Sodium is the principal cation in extracellular fluid (which surrounds all cells in the body), where it affects the flow of water into and out of cells (see *Osmosis*) and thereby influences the concentration of body fluids.

The levels of sodium, potassium, and calcium are regulated by the kidneys, which control the amount lost from the body in the urine. The level of calcium is also affected by hormonal effects on bones.

The acidity of the blood and other body fluids depends on the level of hydrogen cations, which are produced by various metabolic processes. To prevent these fluids from becoming too acidic, hydrogen cations are neutralized by bicarbonate anions in the extracellular fluid and blood, and by phosphate anions inside cells (see *Acid-base balance*).

ION DISTURBANCES

For the body to function normally, the level of each ion must be maintained within narrow limits; any substantial deviation can cause symptoms, such as muscle weakness caused by hypokalemia (too low a level of potassium cations in the blood).

Dehydration caused by insufficient water intake or excessive water loss (from diarrhea, vomiting, or sweating) increases the concentration of all ions. This may cause thirst, muscle cramps, dizziness, and faintness.

Ipecac

A drug used to induce vomiting in the treatment of *poisoning*. Ipecac (also known as ipecacuanha) is derived from a plant native to South and Central America. It is available over-the-counter in syrup form. It should not be used if poisoning has been caused by corrosive or petroleum-based substances, if the victim is not fully conscious, or if the victim is less than 1 year old.

Ipratropium

An *anticholinergic drug* used as a *bronchodilator drug* in the treatment of *asthma* and chronic *bronchitis*. It is also used as a *decongestant drug* in the treatment of *rhinitis*.

IQ

Abbreviation for intelligence quotient, an age-related measure of intelligence (see *Intelligence tests*).

Iridectomy

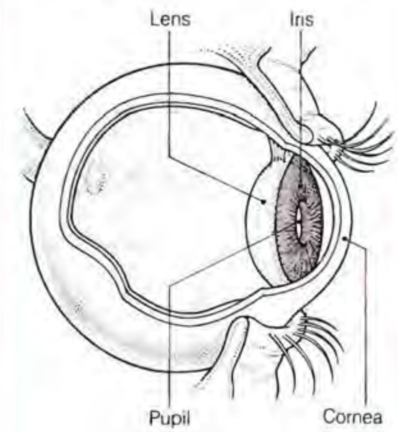
Removal of part of the *iris*, usually to treat narrow-angle *glaucoma*. Iridectomy involves making a small opening near the root of the iris to form a channel through which aqueous humor can drain. Called a "peripheral iridectomy," the opening is made by laser or by operative surgery.

Iridectomy is sometimes performed to remove tumors and to improve the vision of children who have small central cataracts.

Iridencleisis

A surgical procedure that was used in the 1940s and 1950s (to control chronic *glaucoma*) in which an artificial channel was created for the drainage of aqueous humor. Iridencleisis has been replaced by *trabeculectomy*, which is a more reliable procedure.

Iridocyclitis



Inflammation of the *iris* and ciliary body. The term is rarely used today; the condition is now called anterior *uveitis*. (See also *Eye* disorders box.)

Iris

The colored part of the eye that lies behind the cornea. The iris is connected at its outer edge to the ciliary body and has a central perforation called the *pupil* through which light enters the eye and falls on the retina. This loose framework of transparent *collagen* (a fibrous protein) and muscle fibers constantly contracts and dilates to alter the size of the pupil and control the amount of light that passes through the pupil. The color of the iris is mostly due to the amount and distribution of the pigment cells on the back of the iris.

LOCATION OF THE IRIS

The iris lies behind the cornea and in front of the lens. The outer edge of the iris is connected to the ciliary body; at the center is an aperture called the pupil.

Iritis

An infrequently employed term for inflammation of the *iris*; the condition is now known as *uveitis*.

Iron

A mineral essential for certain *enzymes* (proteins that stimulate chemical reactions) and for the formation of *hemoglobin* (red blood cell pigment) and *myoglobin* (muscle cell pigment).

Iron is contained in a variety of foods, such as liver, eggs, fish, green leafy vegetables, nuts, and beans. Adequate amounts are usually obtained from a well-balanced diet. During pregnancy, iron supplements may be necessary for the healthy development of the baby.

Iron deficiency leading to anemia (see *Anemia, iron-deficiency*) is usually caused by abnormal blood loss, such as that from *menorrhagia* (heavy periods) or a *peptic ulcer*.

Iron supplements may cause nausea, abdominal pain, constipation, or diarrhea. They also color the feces black. Excessive intake of iron may cause *cirrhosis* of the liver.

Iron-deficiency anemia

See *Anemia, iron-deficiency*.

Irradiation

See *Radiation hazards*; *Radiation therapy*.

Irrigation, wound

The cleansing of a deep wound by repeatedly washing it out with a medicated solution or sterile saline.

WHY IT IS DONE

A deep wound is often contaminated with infected foreign material, and, unless it is completely cleansed before repair, it may fail to heal, an abscess may form in it, or, in extreme cases, *gangrene* may result. If the wound contains soil, *tetanus* is a risk.

Irritable bladder

Intermittent, uncontrolled contractions of the muscles in the bladder. Irritable bladder may cause urge incontinence (see *Incontinence, urinary*).

Irritability of the bladder is commonly due to a urinary tract infection (see *Cystitis*), the presence of a catheter within the bladder, a bladder stone (see *Calculus, urinary tract*), or obstruction to the outflow of urine by an enlarged *prostate gland*. In many cases of irritable bladder, however, no underlying cause for the muscular irritability and spasm is found.

Symptoms may be relieved by *antispasmodic drugs*; other treatment is directed at any underlying cause.

Irritable bowel syndrome

A combination of intermittent abdominal pain and irregular bowel habit (i.e., constipation, diarrhea, or both, alternating) that occurs in the absence of demonstrable disease. Alternative names are irritable colon syndrome and spastic colon.

Although symptoms subside and even disappear for periods of time, the condition usually is recurrent throughout life and, without being life-threatening or leading to complications, can cause much distress.

CAUSES AND INCIDENCE

The cause is not fully understood, but the basic abnormality is a disturbance of involuntary muscle movement in the large intestine. However, there is no abnormality in the intestinal structure and people with irritable bowel syndrome neither lose weight nor become malnourished. It is the most common disorder of the intestine, accounting for more than half the patients seen by gastroenterologists.

The condition is twice as common in women as in men, usually beginning in early or middle adulthood. Sufferers are usually otherwise in good health and have had the condition for some time before seeking medical advice.

A psychological element, particularly anxiety, is believed by some physicians to be the main causative factor; emotional stress tends to exacerbate the condition. However, bowel upset is a normal reaction to stress in many people who do not suffer from the illness.

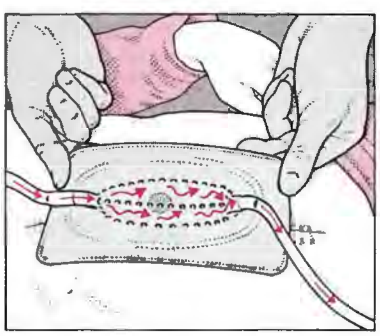
SYMPTOMS

The symptoms include intermittent cramplike pain in the abdomen, abdominal distention (swelling), often on the left side, transient relief of pain by bowel movement or passing gas, mucus in the feces, sense of incomplete evacuation of the bowels, excessive gas, and symptoms aggravated by food. Various other symptoms may also occur (which are not precisely part of the irritable bowel syndrome), such as heartburn, back pain, weakness, faintness, agitation, tendency to tire easily, reduced appetite, and palpitations.

DIAGNOSIS

Following a careful history and physical examination (which is valuable in both diagnosis and treatment), patients may have their feces tested and may be given a *barium X-ray examination* and a *sigmoidoscopy* (examination of the colon through an endoscope passed via the anus). These tests are intended to exclude conditions, such as cancer and inflammatory bowel disease, that may have similar symptoms.

TREATMENT

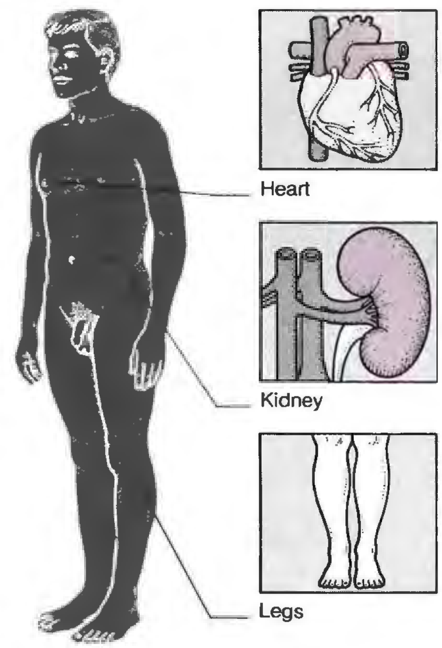


Bulk-forming agents, such as bran or methylcellulose, may be prescribed for constipation along with an *antispasmodic drug* to relieve some of the muscular spasm. *Antidiarrheal drugs* (such as loperamide) may be given briefly for prolonged diarrhea. A high-fiber diet is advised for certain types of irritable bowel syndrome. Although these treatments can alleviate the disorder's troublesome symptoms, there is no cure.

IRRIGATION TECHNIQUES

After removal of contaminated tissue, a wound may be cleansed either by forced syringe (or catheter) irrigation or by using an irrigation chamber.

Forced syringe irrigation
A syringe (sometimes with a catheter attached) is used to flush irrigation fluid repeatedly into and out of the wound until the drained fluid is clear.



Irrigation chamber
A flexible, plastic irrigation chamber is sealed over the wound; irrigation fluid is then run through the chamber until the drained fluid is clear.

Ischemia

Insufficient supply of blood to a specific organ or tissue. Ischemia is usually caused by a blood vessel disease, such as *atherosclerosis*, but may also result from injury to a vessel, constriction of a vessel due to spasm of the muscles in the vessel wall, or inadequate blood flow due to inefficient pumping action of the heart. The symptoms of ischemia depend on the part of the body affected.

Treatment may include *vasodilator drugs* to widen the blood vessels or, in more severe cases, an *angioplasty* or *bypass operation*.

Symptoms of ischemia
Ischemia (insufficient blood supply) of the heart causes the chest pain of angina pectoris; ischemia of blood vessels in the legs may cause a cramplike pain during exercise. Ischemia may also affect the kidneys (causing renal failure) or the brain (resulting in a stroke).

Isocarboxazid

A monoamine oxidase inhibitor *antidepressant drug*. Like other monoamine oxidase inhibitors, isocarboxazid is not usually prescribed unless other antidepressant drugs are ineffective or the patient is intolerant of other antidepressant drugs.

Possible adverse effects of isocarboxazid include headache, dizziness, blurred vision, tremor, and constipation. If taken with foods containing tyramine (such as cheese and red wine) or certain other drugs, isocarboxazid may cause a dangerous rise in blood pressure.

Isolation
Nursing procedures designed to prevent a patient from infecting others or from being infected by them. In either case, the patient is usually isolated in an individual room.

TYPES

COMPLETE ISOLATION This is used if a patient has a contagious disease, such as *tuberculosis* or *Lassa fever*, that can be transmitted to others both by direct contact and by airborne germs. All nursing staff members wear masks, gowns, caps, and gloves, which afterward are incinerated or sterilized. Bed linen, eating utensils, bedpans, and any other items that come in contact with the patient are also sterilized and, even though they wear gloves, staff members wash their hands thoroughly after each nursing task.

PARTIAL ISOLATION This is carried out if the patient's disease is transmitted in a more limited way—for example, only by respiration (as in *pertussis*) or only by contact with infected skin (as in *impetigo*), blood (as in *AIDS*), or feces (as in *cholera*). In these cases, some of the precautions taken in complete isolation nursing are unnecessary.

Child being nursed in an isolator
The plastic tent and strict sterilization procedures protect the patient from infection.

REVERSE ISOLATION This technique is used to protect a patient whose resistance to infection has been severely lowered. Air entering the room is first filtered. Visiting is drastically limited and all staff members and visitors wear caps, gowns, masks, and gloves. Bed linen and all items used by the patient are sterilized. When these measures do not give enough protection (such as after *bone marrow transplantation*), the patient is placed in an isolator (plastic tent) or in a room ventilated with specially purified air.

Occasionally, long-term reverse isolation is needed for patients with severe combined *immunodeficiency*; these people are born without normal defenses against infection.

Isoniazid
An *antibacterial drug* used to prevent and treat *tuberculosis*. As a preventive measure, isoniazid may be given to close contacts of people suffering from tuberculosis. To treat the disease, isoniazid is given in combination with other antibacterial drugs, usually for at least nine months.

Adverse effects are rare and include nausea, fatigue, numbness, twitching, and insomnia. Because isoniazid may increase the amount of pyridoxine (vitamin B_6) lost from the body, vitamin B_6 supplements are usually given to prevent nerve damage.

Isoproterenol
A *bronchodilator drug* used in the treatment of lung disorders (such as *asthma*, chronic *bronchitis*, and *emphysema*). Isoproterenol widens the airways in the lungs and thus improves air flow and relieves breathing difficulty. Isoproterenol is also given in the emergency treatment of *heart block* (abnormally slow heart beat) before a *pacemaker* is fitted.

Adverse effects are dry mouth, nervousness, dizziness, and palpitations.

Isosorbide dinitrate
A long-acting form of nitroglycerin that acts as a *vasodilator drug*. It is used to reduce the severity and frequency of *angina pectoris* (chest pain due to impaired blood supply to heart muscle). Isosorbide dinitrate is also given to treat severe *heart failure* (reduced pumping efficiency).

Adverse effects include headache, hot flashes, and dizziness.

Isotope scanning
See *Radionuclide scanning*.

Isotretinoin
A drug derived from *vitamin A* used in the treatment of severe *acne* when other treatments have proved ineffective. Isotretinoin is also given to treat *ichthyosis* (a disorder characterized by thickening and scaling of the skin). It works by reducing the formation of sebum (natural skin oils) and keratin (the tough, outer layer of skin).

POSSIBLE ADVERSE EFFECTS

Isotretinoin may cause itching, dryness, and flaking of the skin. Rarely, it may cause liver damage and an increased risk of *coronary heart disease* and *peripheral vascular disease*. Isotretinoin may damage a developing fetus; pregnancy should be avoided during treatment and for at least three months after taking the drug.

Isoxsuprine
A *vasodilator drug* used in the treatment of *peripheral vascular disease*, *transient ischemic attacks* (symptoms of *stroke* lasting less than 24 hours), and *dementia* caused by reduced blood supply to the brain. Its efficacy in the treatment of these disorders is questioned by many physicians.

Isoxsuprine also relaxes muscles in the uterus and is given to suppress contractions in premature labor.

Adverse effects of isoxsuprine include dizziness and palpitations.

Itching
Intense, distracting irritation or tickling sensation in the skin that may be generalized (felt all over the skin's surface) or local (confined to one area). The reason for the sensation is not fully understood.

Itching is the most prominent symptom in skin disease, but does not itself necessarily indicate an underlying skin disorder. People differ in their tolerance to itching, and a person's threshold can be altered by stress, emotions, or other factors. Itching is worse when the skin is warm and when there are few distractions, making it more noticeable at night.

CAUSES

GENERALIZED ITCHING Excessive bathing, which removes the skin's natural oils and may leave the skin excessively dry and scaly, is a common cause of itching. Some people experience itching after taking certain drugs, such as cocaine, codeine, and some antibiotics. Soap, detergents, and roughly textured clothing (e.g., made of wool) also produce itching in some people.

Many elderly people suffer for no apparent reason from dry, itchy skin, especially on their backs. A similar condition affects some younger people in cold weather. Itching commonly occurs during pregnancy.

Many skin conditions produce an itchy rash—for example, *chickenpox*, *urticaria* (hives), *eczema*, and fungal infections (see *Tinea*). Less common causes include *psoriasis* or *dermatitis herpetiformis*.

Generalized skin itchiness can be a result of *diabetes mellitus*, *renal failure*, *jaundice*, and thyroid disorders. Disorders of the blood (such as *leukemia*) and of the lymphatic system (e.g., *Hodgkin's disease* may occasionally cause itching.

LOCAL ITCHING Pruritus ani (itching around the anal region) occurs in adults, particularly those with such problems as *hemorrhoids*, *anal fissure*,

and persistent diarrhea. Pruritus ani often results from irritation caused by overzealous cleansing after defecation. Worm infestation is the most likely cause of itching in children.

Another form of intense skin irritation confined to one area occurs with pruritus vulvae; it affects the external genitalia in women. The condition may be due to *candidiasis*, hormonal changes (at puberty, pregnancy, and the menopause), or to use of spermicides or vaginal suppositories, ointments, and deodorants.

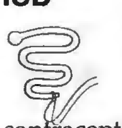
Lice and scabies infestations cause notable itching. Insect bites, too, can produce intense skin irritation.

TREATMENT

Specific treatment depends on the underlying cause, if known. Cooling lotions, such as calamine, relieve irritation; *emollients* reduce dryness.

Soaps often irritate itchy skin, especially if a rash is visible. They should be used only when necessary. Often, extremely mild cleansing lotions or water alone is sufficient to keep most of the skin adequately clean. Itchy skin should be handled very gently. Scratching temporarily relieves itching, but makes the itching worse in the long run. The scratching habit can be suppressed by applying a soothing lotion, salve, or wet compress to the affected areas when the urge to scratch occurs.

-itis



A suffix meaning "inflammation of." Virtually every organ or tissue in the body can suffer inflammation (the most common form of tissue disorder), so "-itis" is by far the most common word ending in medicine. An example of its use is *bronchitis* (inflammation of the bronchi).

The term -itis is applied strictly to cases of inflammation with redness, pain, heat, and swelling. The term should not be used loosely to imply general disorder, for which the ending "-opathy" is appropriate.

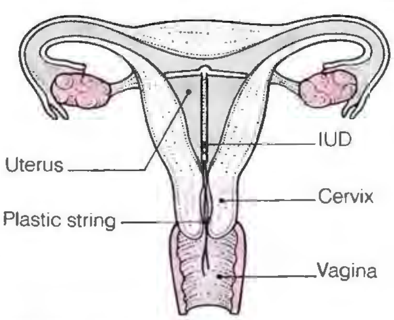
IUCD

Abbreviation for intrauterine contraceptive device. (See *IUD*.)

IUD

A mechanical device inserted into the uterus for the purposes of *contraception*. IUDs (intrauterine contraceptive devices) became widely used in the 1960s and 1970s; except for two types, they are no longer being manufactured or sold in the US.

TYPES



Most types of IUD are made of plastic molded into various forms and shapes. They have a plastic string that, once inserted, comes through the cervix into the vagina. The string makes removal easier and indicates the presence of the IUD.

Some IUDs are inert; others contain bioactive substances. Because of their larger size, inert IUDs are more suitable for women who have had at least one child. They must be replaced about every five years.

The bioactive (progesterone-containing) IUDs are much smaller than inert IUDs and may be used by women who have never had children, although most physicians recommend their use only by women who do not plan to have children in the future. Devices containing copper need replacing every two to three years; the progesterone-containing types should be replaced once a year.

HOW THEY WORK

IUDs are about 97 to 98 percent effective, though it is still not certain exactly how they work. It is thought that a foreign body in the uterus prevents pregnancy by creating an inflammation in the uterine lining that destroys sperm as they pass through the uterus. It is also thought that the presence of an IUD may inhibit implantation of the fertilized egg in the uterine wall (see *Implantation, egg*).

Site of an IUD
An IUD is inserted into the uterus; it has a plastic string that hangs down through the cervix and into the vagina.

HOW THEY ARE USED

An IUD is usually inserted by the woman's gynecologist or family practitioner. It can be inserted any time during the menstrual cycle, but the preferred time is during or just after menstruation (because it is unlikely that the woman is pregnant and because the cervix is easier to handle). After a full-term pregnancy, a woman should wait six weeks before having an IUD inserted.

An IUD is inserted through the vagina and cervix into the uterine cavity. Most IUDs are loaded in a small plastic tube that is inserted through the cervical canal; the device is gently pushed out by means of a plunger. Once an IUD is in place, it provides immediate protection. The woman should check once or twice a week that the string is present. If it is not, the string has probably curled up into the uterus, but it is possible that the IUD has been expelled.

WHO SHOULD NOT USE IUDS

Women who have never been pregnant are more likely to have serious complications than women who have had children. Women with no previous pregnancies usually have more pain on insertion, higher expulsion rates, and a heavier menstrual flow. A woman with *fibroids* may be advised not to have an IUD. Any woman with a history of pelvic disease or tubal infection should not use an IUD. Women with multiple partners (or whose partner has other sexual partners) are at increased risk of *pelvic inflammatory disease* (PID) and should probably avoid IUDs. Young women have a higher infection rate than older women. Women with heavy or painful periods may find the IUD makes the symptoms worse.

COMPLICATIONS

Immediately after insertion, there may be heavy bleeding, pain, or vaginal discharge. Menstrual periods after insertion may become irregular, heavier, and more painful.

Women with IUDs also have a higher rate of *ectopic pregnancy*, especially if the pregnancy occurred with the IUD still in place. Pelvic inflammatory disease may be severe and lead to permanent infertility. A rare complication of IUD use is a perforated uterus, in which the device works its way through the wall of the uterus into the abdominal cavity, causing infection.

OUTLOOK

Most pharmaceutical companies have discontinued the manufacture and sale of IUDs in the US because of economic factors. The cost of the large number of lawsuits claiming that IUDs have caused serious complications has been enormous.

IVF

See *In vitro fertilization*.

IVP

The abbreviation for intravenous *pyelography*.

J

Jakob-Creutzfeldt disease

See *Creutzfeldt-Jakob syndrome*.

Jaundice

Yellowing of the skin and the whites of the eyes caused by an accumulation of the yellow-brown bile pigment bilirubin in the blood. Jaundice is the chief sign of many disorders of the liver and biliary system.

TYPES AND CAUSES

Bilirubin is formed from *hemoglobin* (the oxygen-carrying substance in red blood cells) when old red cells are broken down, mainly by the spleen. The pigment is absorbed from the blood by the liver, where it is made soluble in water and is excreted in bile. The process can be upset in any of three ways, causing the main types of jaundice: hemolytic, hepatocellular, and obstructive.

In hemolytic jaundice, the amount of bilirubin produced is too great for the liver to process. This is caused by excessive *hemolysis* (breakdown of red cells), which can have many causes (see *Anemia, hemolytic*). Similar types of jaundice can develop in the newborn as a result of an insufficiently developed capacity of the liver to take up bilirubin. In adults, a type of jaundice similar to hemolytic jaundice can develop as a result of a mild liver disorder called *Gilbert's disease*.

In hepatocellular jaundice, bilirubin builds up in the blood because its transfer from liver cells to bile is prevented, usually as the result of acute *hepatitis* (inflammation of the liver) or *liver failure*.

In obstructive jaundice, bile is prevented from flowing out of the liver because of disorders causing blockage of the bile ducts (see *Bile duct obstruction*) such as *gallstones* or a tumor. Obstructive jaundice can also occur if the bile ducts are not present (as in *biliary atresia*) or have been destroyed within the liver (for example, in primary *biliary cirrhosis*). As a result, bile stagnates in the liver (a condition called *cholestasis*) and bilirubin is forced back into the blood.

SYMPTOMS AND SIGNS

Sometimes (as in acute hepatitis) jaundice is only one of several signs and symptoms. In other cases (such as Gilbert's disease) it may be the sole sign of a disorder.

Obstructive or cholestatic jaundice is usually accompanied by two other characteristic features: pale feces and dark urine. The feces are pale because bilirubin, which normally colors feces brown, does not reach the intestine; the urine is dark due to large amounts of water-soluble bilirubin being filtered into it from the blood. Bilirubin may also be deposited in the skin, causing itching.

In hemolytic jaundice, both urine and feces color are normal. In hepatocellular jaundice, the feces are normal but the urine may be dark.

DIAGNOSIS AND TREATMENT

If excessive hemolysis is suspected, *blood tests* are carried out to determine the amount of water-insoluble bilirubin. A *blood smear* indicates whether large numbers of immature red cells are present; if they are, hemolysis is the suspected cause of the jaundice.

To diagnose hepatocellular jaundice, the blood is tested and a *liver biopsy* (removal of a small sample of tissue for analysis) may be performed.

If the physician suspects obstructive jaundice, *ultrasound scanning*, *liver function tests*, and *cholangiography* may be carried out to determine if the bile ducts are diseased or blocked.

In all cases, treatment is for the underlying cause.

Jaw

The lowest and only mobile bone of the face, also known as the mandible. The term jaw sometimes includes the bone that extends from the inner rims of the eyes to the mouth, more commonly known as the *maxilla*.

The mandible is U-shaped as seen from above and bears the lower teeth on its upper surface. It is connected to the base of the skull at the temporomandibular joints, which can be felt in the cheek just in front of the earlobe. Powerful muscles, arising from the temple on either side, attach to the jaw for movements needed in chewing and biting; other muscles allow side-to-side and downward movement.

Jaw, dislocated

Displacement of the lower jaw from one or both of the temporomandibular joints (the joints between the jaw and the base of the skull). A dislocated jaw is usually caused by a blow or by yawning. The jaw is the most commonly dislocated joint because it is very unstable. Once dislocation has happened, it tends to recur.

SYMPTOMS

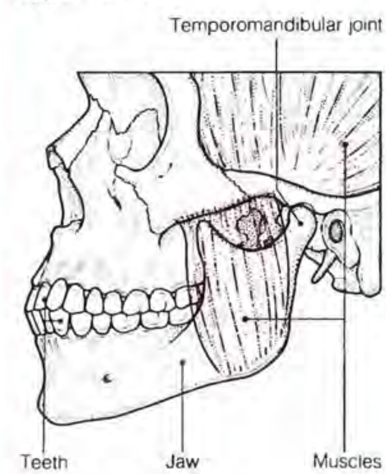
There is pain in front of the ear on the affected side or sides and the jaw projects forward. The mouth cannot be fully closed and, as a result, the victim drools and has difficulty speaking.

TREATMENT

A second person can easily correct the dislocation. He or she should stand in front of the victim, place a thumb on the lower back teeth at each side, and press downward. The lower jaw should then click back into position. To avoid causing injury when the teeth snap shut, the thumbs should be wrapped in cloth.

Recurrent dislocation requires an operation to stabilize the joint, such as strengthening the ligaments with stitches. However, surgery is rarely successful in curing the problem.

Jaw, fractured



Fractures of the jaw are most often caused by a direct blow to the face. Because of the shape of the jaw, fracture often occurs not only at the site of the blow, but also on the other side of the jaw.

SYMPTOMS

If the fracture is minor, the only symptoms may be some tenderness, pain on biting, and slight stiffness of

ANATOMY OF THE JAW

The U-shaped, mobile bone of the face that meets the skull in front of the ears at the temporomandibular joint. The jaw bears teeth on its upper surface.

the jaw. In more severe injuries, teeth may be loosened or damaged, movement of the jaw may be severely limited, and there may be loss of feeling in the lower lip.

DIAGNOSIS AND TREATMENT

If a fracture is suspected, X rays of the area are taken. Minor fractures are normally left to heal on their own.

For severe fractures in which the bones have become displaced, surgical treatment is required. The bone fragments are first manipulated back into the correct position. Teeth too badly damaged to be saved may require extraction. The jaw is immobilized to allow healing to occur, usually by wiring the upper and lower teeth together. If the patient has no teeth, special dentures can be constructed to hold the wires.

Some fractures cannot be adequately immobilized by this method. In such cases, an incision is made in the skin to expose the jaw bone, holes are drilled in each bone fragment, and wires are inserted and twisted together. The skin incision is sewn up with the wires in position.

RECOVERY PERIOD

If the teeth have been wired together, the patient is given a liquid diet. The wires are usually removed after about six weeks.

Jealousy, morbid

Preoccupation with the sexual infidelity of one's partner. The sufferer, usually a man, becomes convinced that his partner is having an affair; he constantly spies on her and often resorts to physical violence.

Morbid jealousy is usually due to *personality disorder*, *depression*, or *paranoia*, but may also occur in those suffering from *alcohol dependence* or organic *brain syndrome*.

Treatment of the underlying disorder may improve the condition, but the outlook is generally poor. Psychiatrists usually recommend separation of the partners, since morbid jealousy is a significant cause of murder within established relationships.

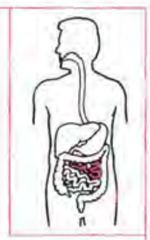
Jejunal biopsy

A diagnostic test in which a small piece of tissue is removed from the lining of the *jejunum* (the middle, coiled section of the small intestine) for laboratory examination under the microscope.

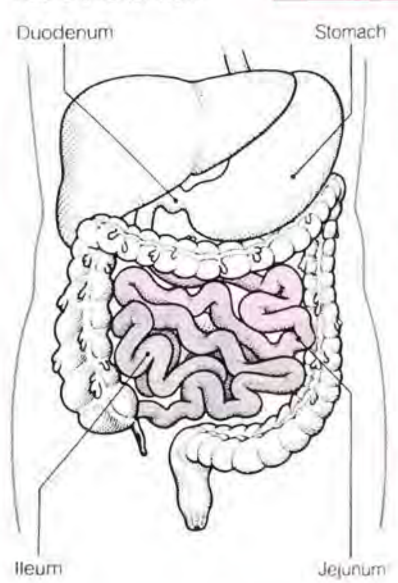
WHY IT IS DONE

The procedure is especially useful in the diagnosis of *Crohn's disease*, *celiac sprue*, *lymphoma*, and all other causes of *malabsorption* because these conditions are associated with recognizable changes in the small intestine.

HOW IT IS DONE

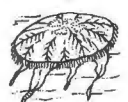


The patient may be sedated slightly before the procedure is started. A small device called a Crosby capsule is attached to a length of fine tubing; both are well lubricated and the patient is asked to swallow the capsule. The tube is guided down the esophagus through the stomach and duodenum until the capsule reaches the jejunum. An X ray is then performed to ensure that the capsule is in the correct position. A syringe is used to withdraw air from the tube, causing a minute piece of tissue to be sucked into the capsule, where it is sheared off. The tube and capsule are then withdrawn and the tissue is taken from the capsule for examination.



Jejunum

The middle, coiled section of the small *intestine*, joining the *duodenum* to the *ileum*. It is wider than the ileum and has a thicker wall, but its function is the same—the digestion of food and the absorption of nutrients from it. Among the few disorders that affect the jejunum are *celiac sprue*, *Crohn's disease*, and *lymphoma*.



ANATOMY OF THE JEJUNUM

This section of the small intestine joins the duodenum to the ileum. It is wider than the ileum and has a thicker wall.

Jellyfish stings

Jellyfish, together with corals, sea anemones, and Portuguese men-of-war, belong to a group of marine animals called the coelenterates. These animals have tentacles armed with stinging capsules that discharge when touched. Usually, the result of a sting is no more than an itchy or mildly painful rash, but some jellyfish and Portuguese men-of-war can cause a severe sting. In rare cases, venom entering the bloodstream may cause vomiting, sweating, shock, breathing difficulties, convulsions, and collapse. Dangerous species live mainly in tropical waters.

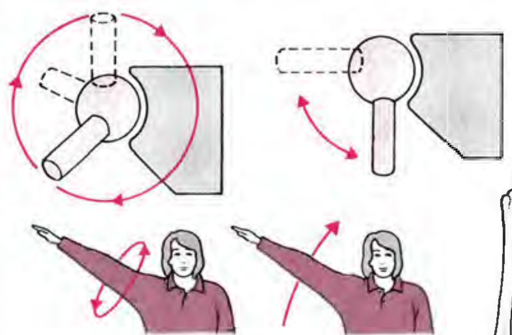
TREATMENT

If fragments of jellyfish tentacle remain attached to the skin after a sting, vinegar should be applied to inactivate the stinging capsules; the tentacle fragments should then be scraped off. Analgesics (painkillers) may be taken. A severe reaction requires hospitalization and sometimes *cardiopulmonary resuscitation*. Antivenoms effective against the more dangerous species of jellyfish may be available in areas where these species are common.

Jet lag

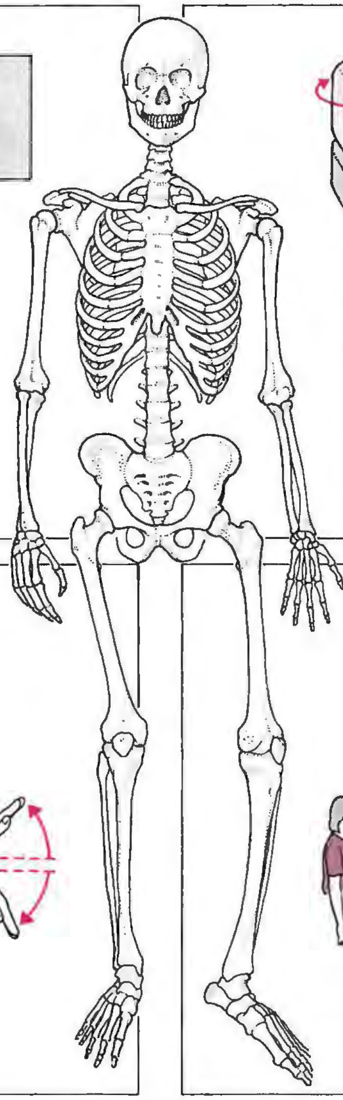
Interruption of the sleep/wake cycle, fatigue, and other symptoms caused by disturbance of normal body rhythms as a result of flying across different time zones.

CAUSES

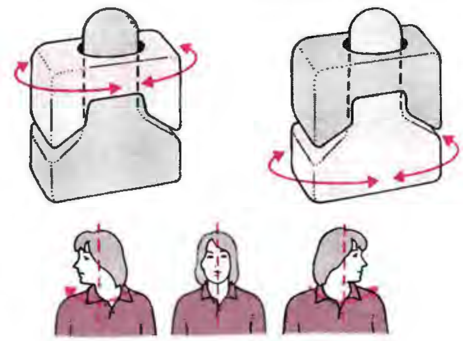


Each person has an "internal clock" that determines when the desire to sleep, wake, and eat, the release of various hormones, and many other bodily functions take place in every 24-hour period. The near 24-hour cycle of each activity is called a circadian rhythm. When an air traveler crosses several time zones, his or her day (as timed by an external clock) is longer or shorter than 24 hours, depending on the direction of the flight. Most of the traveler's circadian rhythms are unable to adjust to this shorter or longer day, resulting in jet lag when the flight is over. Jet lag is the desire to sleep during the local day, wakefulness at night, general fatigue, reduced physical and mental activity, and poor memory.

Jet lag tends to be worse after an eastward flight (which shortens the traveler's day) than after a westward one. It is most likely to affect people over 30 who normally follow an established daily routine.

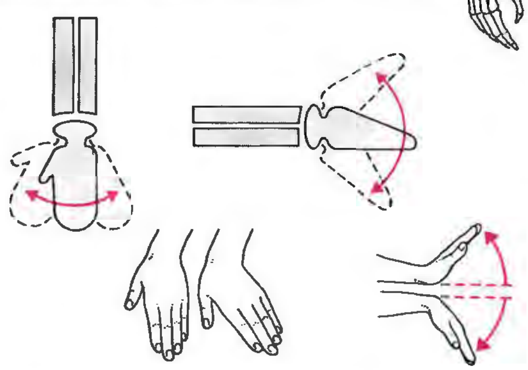


J

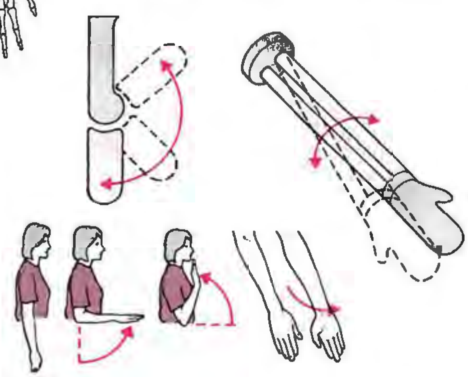


TYPES OF JOINTS

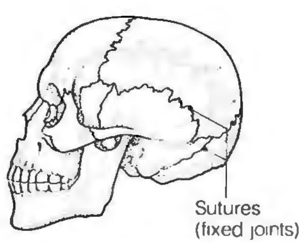
Some joints are fixed (e.g., the skull) and some allow a little movement (e.g., the vertebrae). Of the mobile joints, the hinge joint is the simplest. Pivot joints allow rotation only, while ellipsoidal joints allow all types of movement except pivotal. Ball-and-socket joints allow the widest range of movement.



Ball-and-socket joint
A ball-and-socket joint allows the widest range of movement—backward or forward, sideways, and rotation. Examples are the hip and shoulder joints.

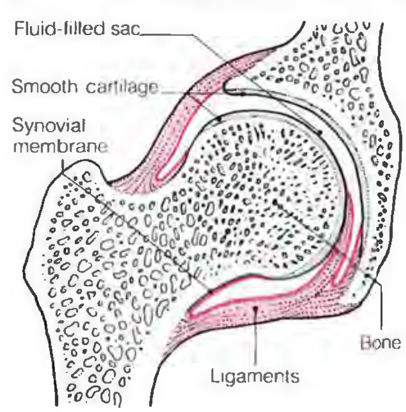


Pivot joint
In a pivot joint, movement is limited to rotation, either by means of a bony projection pivoting within a ring, or a ring pivoting around an axis (e.g., the joint between the first and second vertebrae).



Ellipsoidal joint
In an ellipsoidal joint, an oval-shaped part fits into an elliptic cavity, allowing all types of movement except pivotal (an example is the wrist joint).

Hinge joint
This is one of the simplest joints; it allows bending and straightening, as in the fingers. The knee and elbow are modified hinge joints that allow some rotation as well.



STRUCTURE OF A FIXED JOINT

Fixed joints are firmly secured by fibrous tissue. The joints between the bones of the skull are an example.

STRUCTURE OF A MOBILE JOINT

In mobile joints, the surfaces of the bones are coated with smooth and slippery cartilage to reduce friction during movement. The joint is sealed within a tough fibrous capsule lined with synovial membrane, which produces a clear, sticky fluid that lubricates the joint. Each joint is surrounded by strong ligaments that support it and prevent excessive movement. Movement of the joints is controlled by muscles that are attached to bone by tendons on either side of the joint.

PREVENTIVE MEASURES

The symptoms of jet lag can be minimized by drinking plenty of nonalcoholic fluids during the flight and avoiding heavy meals. Also, people flying east should go to bed earlier than usual for a few days before the journey; people flying west should do the opposite. If possible, try to arrive in the new time zone in the early evening and go to bed early.

It may take several days to adjust to a new time zone (about half a day to one day for each time zone crossed). The adjustment can be eased by breaking up a long journey with a stopover and by resting after the flight.

Jigger flea

See *Chigoe*.

Jock itch

See *Tinea*.

Joggers' nipple

Soreness of the nipple caused by the rubbing of clothing against it, usually during sports such as jogging or long-distance running. Joggers' nipple, which affects both men and women, can be prevented by applying petroleum jelly to the nipple before prolonged running. Wearing a clean shirt also helps because sweat can aggravate the condition. Treatment involves covering the nipple with a bandage to reduce rubbing.

Joint

The point at which two bones meet. At these junctions, the surfaces of the ends of the bones are covered with cartilage and the joint lined with a synovial membrane. Some joints are fixed (such as those between bones of the skull) and some allow a small amount of movement (those between the bodies—central areas—of the vertebrae, for example). Highly mobile joints are far more common; there are several types capable of different types of movement.

DISORDERS

Common joint injuries include *sprains*, ligament tears, cartilage damage, and tears of the joint capsule.

Dislocation of a joint is usually the result of injury, but is occasionally congenital. A less severe injury may cause *subluxation* (partial dislocation). Rarely, the bone ends are fractured, sometimes leading to *hemarthrosis* (bleeding into the joint) or *effusion* (accumulation of fluid in a joint) due to *synovitis* (inflammation of the lining of the joint).

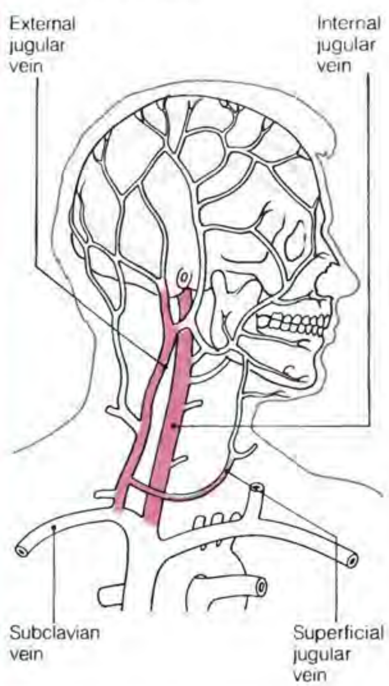
Joints are commonly affected by forms of *arthritis* (inflammation of a joint). *Bursitis* (inflammation of a bursa) may occur as a result of local irritation or strain.

Permanent joint deformities may be caused by severe injury or arthritis. Temporary deformities may occur in childhood, usually affecting a joint in the legs; they resolve later in life as growth continues. Surgery may be required to relieve certain deformities.

Joint replacement

See *Arthroplasty*.

Joule



The international unit of *energy*, work, and heat. Approximately 4,200 joules (symbol J), or 4.2 kilojoules (kJ), equal one kilocalorie (1,000 calories, or 1 C); 1 kJ equals about 240 C.

Jugular vein

One of three veins on each side of the neck that return deoxygenated blood from the head to the heart. Of the three (internal, external, and superficial) by far the largest is the internal jugular, which arises at the base of the skull, travels down the neck alongside the carotid arteries, and passes behind the clavicle (collarbone), where it joins the subclavian vein (the large vein that drains blood from the arms). The jugular is rarely injured because it lies deep in the structures of the neck.

ANATOMY OF THE JUGULAR VEIN

These three veins on each side of the neck return blood from the head to the heart.

Jumpers' knee

Inflammation of the tendon below the patella (kneecap) usually caused by repetitive exercise such as long-distance running (see *Overuse injury*). Jumpers' knee can also be caused by exercise that strains the kneecap.

Jungian theory

Ideas put forward by the Swiss psychiatrist Carl Gustav Jung (1875-1961). Originally an associate of Sigmund Freud, Jung broke away in 1913 to form his own school of analytical psychology, mainly because he did not believe that sexual drive was the only force behind all human activity. Instead, he theorized that certain ideas (called archetypes) inherited from experiences in our distant past were present in each person's unconscious and controlled the way in which each person viewed the world. Jung called these shared ideas the "collective unconscious."

Although Jung believed that each individual also had a "personal unconscious" containing experiences from his or her life, he regarded the collective unconscious as superior. Therapy was therefore aimed at putting people in touch with this source of profound ideas, particularly through interpretation of dreams.

Jung's therapeutic approach was also based on his theory of personality, which postulated two basic types, the *extrovert* and the *introvert*. He believed that one of these types dominates a person's consciousness and that the other must be brought into consciousness and reconciled with its opposite.

Junk food

The name commonly applied to refined or processed foods, such as candy, potato chips, and sweetened carbonated beverages. Junk food provides *calories* but few of the other *nutrients* needed for a healthy diet. Small amounts of junk food are not harmful, but people who consume large quantities may not eat enough other foods to provide a well-balanced diet. (See also *Nutrition*.)

Juvenile arthritis

See *Rheumatoid arthritis, juvenile*.

K

Kala-azar

A form of the insect-spread parasitic disease *leishmaniasis*. Kala-azar occurs in many parts of Africa, the Mediterranean area, and India.

Kaolin

An *aluminum* compound used as an ingredient in some *antidiarrheal drugs*. It is thought that kaolin helps treat *diarrhea* by adsorbing *bacteria*, *viruses*, and toxins (poisons) from the intestine and eliminating them from the body when the drug is excreted in the feces.

Kaposi's sarcoma

A condition, characterized by malignant skin tumors, that is a prominent feature of *AIDS*. In the past, Kaposi's sarcoma developed slowly and was seen almost exclusively in elderly Italian and Jewish men. In patients with AIDS, it is highly aggressive and tumors soon become widespread.

The tumors, consisting of blue-red nodules, usually start on the feet and ankles, spread further up the legs, and then appear on the hands and arms. In people with AIDS, tumors also commonly affect the gastrointestinal and respiratory tracts, where they may cause severe internal bleeding.

For mild cases of Kaposi's sarcoma, low-dose *radiation therapy* is usually effective. For more severe cases, *anticancer drugs* may be necessary to slow the spread of the tumors.

Kawasaki disease

An acute childhood illness that affects many systems in the body. It is also called mucocutaneous lymph node syndrome. The condition was first observed in Japan in the 1960s. It is becoming increasingly common in the US in all children, not only those of Japanese ethnic origin. It usually occurs in the first two years of life. The cause is unknown.

SYMPTOMS

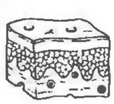
Fever is the first symptom; it usually persists for one or two weeks. Other characteristic symptoms are *conjunctivitis*, dryness and cracking of the lips, and swollen lymph nodes in the neck. Toward the end of the first week of illness, the palms and soles become red, the hands and feet swell, and a rash similar to that of measles appears over the body. By the end of the second week, the skin at the tips of the fingers and toes peels and the other symptoms subside.

TREATMENT AND OUTLOOK

There is no cure, but *aspirin* may help prevent possible heart complications. Most children make a complete recovery. In about 1 to 2 percent of cases, however, sudden death occurs after the acute phase of the illness, usually due to *coronary thrombosis*.

Keloid

A raised, hard, irregularly shaped, itchy scar on the skin. A keloid occurs because of a defective healing process in which an excess of *collagen* forms at the site of a healing scar. Keloids are more common in black people than in white people.



Keloids can occur anywhere on the body, but are most common over the sternum (breastbone) and over the shoulder. They often enlarge after developing and may be unsightly; after some months most flatten and cease to be itchy.

Injections of *corticosteroid drugs* directly into the keloid may reduce itchiness and cause some shrinkage. Surgical removal is of little use since the new scar that forms is almost always a keloid.

Crop of keloids over the breastbone
These overgrowths of scar tissue usually flatten out and become less noticeable over a period of months or years.

Keratin

A fibrous protein that is the main constituent of the outermost layer of the *skin*, *nails*, and *hair*. Keratin is a tough substance that is resistant to damage from a wide range of chemical and physical agents.

Keratitis

Inflammation of the *cornea* (the front part of the eyeball). The term is often used loosely to refer to corneal disorders that do not meet the strict definition of inflammation (since inflammation involves blood vessels and the normal cornea has none). A better general term for disorders of the cornea is *keratopathy*.

True keratitis is rare. One form is interstitial keratitis, which affects about 70 percent of children with congenital *syphilis*. Symptoms include eye pain, excessive watering, and photophobia (sensitivity to bright light); blood vessels grow into the cornea. Treatment with antibiotics usually restores vision.

Keratoacanthoma

A harmless skin nodule that generally occurs singly on the face or arm of elderly people. Initially resembling a small, round wart with a soft center, the keratoacanthoma grows rapidly over a period of about eight weeks. At this point it reaches its maximum size of about 0.8 inch (2 cm) across. The mature nodule has bulging sides and its center may have a whitish appearance. Without treatment, the keratoacanthoma slowly disappears after reaching its mature state.

The cause of the growth is unknown, but it tends to be more common in people who have had years of exposure to strong sunlight and in people taking long-term *immunosuppressant drugs*.

A *biopsy* (removal of a small piece of tissue for analysis) may be necessary to distinguish a keratoacanthoma from a *squamous cell carcinoma*, a form of skin cancer.

Keratoconjunctivitis

A disorder of the cornea associated with *conjunctivitis*. The most common form is epidemic keratoconjunctivitis, caused by a virus that usually causes painful swelling of a small lymph gland in front of the ear. It is highly infectious and is spread mainly by sharing towels or by unsterile instruments and eye drops.

The conjunctivitis is often severe, with notable redness, swelling, or destruction of the surface layer of the conjunctiva, leaving a whitish membrane. Seven to ten days after the onset, tiny opaque spots resembling

snowflakes develop in the cornea. The spots may persist for many months and sometimes interfere with vision.

There is no specific treatment for epidemic keratoconjunctivitis. The corneal opacities can sometimes be minimized with *corticosteroid drugs* in eye-drop form. (See also *Keratoconjunctivitis sicca*.)

Keratoconjunctivitis sicca

A condition of persistent corneal and conjunctival dryness caused by deficiency in tear production. Commonly referred to as "dry eye," keratoconjunctivitis sicca occurs in *autoimmune disorders* such as *rheumatoid arthritis*, *Sjögren's syndrome*, and systemic *lupus erythematosus*; all of these conditions can damage the tear-producing glands. Prolonged dryness may cause blurred vision, burning, itching, and grittiness. In severe cases, opacification or ulceration of the cornea may occur. The most effective treatment for dry eyes is artificial tears, which may require frequent use.

Keratoconus

A condition of abnormal corneal growth in which both corneas gradually become thinned and conical.

Keratoconus usually starts around puberty and affects more females than males. It causes increasing *myopia* (nearsightedness) and a progressive distortion of vision that cannot be fully corrected by glasses. Hard contact lenses improve vision in the early stages but are less effective as the condition progresses.

A *corneal graft* is usually performed when vision has seriously deteriorated and contact lenses no longer are helpful. The results of corneal grafting are generally excellent.

Keratolytic drugs

Drugs that loosen and remove keratin (the tough, outer layer of the skin). Keratolytic drugs, which include preparations of *sulfur* and *salicylic acid*, are used in the treatment of skin and scalp disorders, such as *warts*, callosities (see *Callus, skin*), *acne*, *dandruff*, and *psoriasis*.

Keratomalacia

The last stage of corneal damage due to *vitamin A* deficiency. Keratomalacia usually occurs only in severely malnourished children; it is very rare in developed countries.

Prolonged lack of vitamin A causes severe dryness of the eyes with a characteristic foamy patch on the corners of the conjunctiva. There may also be a gritty feeling in the eyelids and sensitivity to bright light. Until this point, the condition is easily reversible by taking large doses of vitamin A. If the deficiency is not treated, keratomalacia develops and the cornea becomes opaque and ulcerated. Perforation of the cornea is common, usually leading to loss of the eye from infection.

Keratopathy

A general term used to describe a wide variety of disorders of the *cornea* (the front part of the eyeball). The word also forms part of the name of certain specific disorders.

Actinic keratopathy is damage to the outer layer of the cornea by ultraviolet light, either from the sun or from artificial sources, such as sunlamps or arc welding torches. The corneal layer tends to strip off, exposing the nerve endings and causing severe pain. Skiers or mountaineers may suffer a similar effect known as snow blindness.

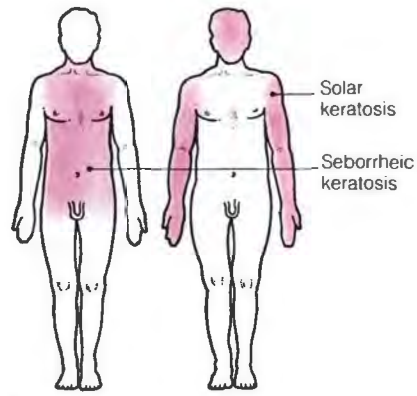
Exposure keratopathy is damage to the cornea caused by loss of the normal protection afforded by the tear film and the blink reflex. It may occur in a variety of conditions in which the lids cannot cover the cornea, including severe *exophthalmos*, *facial palsy*, and *ectropion*.

Keratoplasty

See *Corneal graft*.

Keratosis

A skin growth caused by an overproduction of *keratin* (the main skin protein). Keratoses occur mainly in the elderly.



TYPES

SEBORRHEIC KERATOSES Often called seborrheic warts, they range from flat, dark brown, rough patches to small, wartlike protrusions and are covered with a greasy, removable crust. Seborrheic keratoses are completely harmless, but can be unsightly.

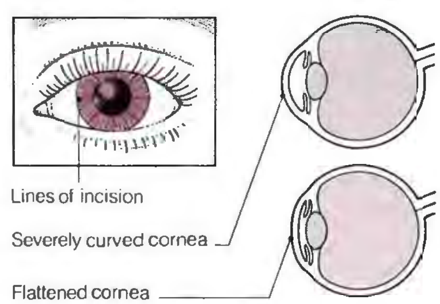
SOLAR KERATOSES Small, wartlike, red or flesh-colored growths that appear on exposed parts of the body as a result of overexposure to sun over a period of years. Solar keratoses may rarely develop into skin cancer, usually a *squamous cell carcinoma*.

TREATMENT

Unless they are large and unsightly, seborrheic keratoses require no treatment. However, solar keratoses must always be removed because of the risk of skin cancer. Removal is usually done as an outpatient procedure by *cryosurgery* (the destruction of tissue by extreme cold).

Sites of keratoses
Seborrheic keratoses occur mainly on the trunk; solar keratoses usually affect the face, arms, and hands.

Keratosis pilaris



A very common skin condition in which patches of raised, rough skin appear on the upper arms, thighs, and buttocks. The openings of the hair follicles become distended with hard plugs of *keratin* (the main skin protein) and the hairs that grow in them may be distorted.

The condition occurs most commonly in older children, adolescents, and obese people, and is often worse in winter. It is not serious and usually clears up on its own. In severe cases, symptoms can be improved by rubbing a mixture of salicylic acid and soft paraffin into the affected areas; scrubbing these areas with a loofah may also help.

Keratotomy, radial

A relatively new surgical procedure to reduce *myopia* (nearsightedness).

The results of radial keratotomy vary and the effect is not always per-

Procedure for keratotomy
Eight or more radial cuts are made in the cornea, avoiding the central zone. During healing, the scars contract, causing the cornea to become flatter and less powerful.

manent. Serious complications may develop. The procedure is not generally recommended for people whose vision can be corrected by glasses or contact lenses.

Kerion

A red, pustular swelling that develops as a reaction to a fungal infection, usually scalp ringworm (see *Tinea*). The inflammation gradually subsides over six to eight weeks but, if severe, may leave a scar and permanent loss of hair from the affected area. It is treated by applying ichthammol paste to the swelling and by taking the antibiotic griseofulvin.

Kernicterus

A rare disorder in which excess bilirubin (a pigment derived from the breakdown of red blood cells) causes brain damage in newborn (especially premature) infants, resulting in a form of mental retardation.

SYMPTOMS AND SIGNS

Excess bilirubin produces signs of *jaundice* in the first few days of life. In addition, the baby becomes more and more listless, sometimes adopting a characteristic posture with arched back and neck. Without treatment, the baby is likely to die at the end of the first week of life. Survivors may be deaf and may suffer from *athetosis* (uncontrollable, writhing movements) and *spasticity* (abnormal muscle stiffness). Mental retardation, bizarre eye movements, difficulty speaking, and a proneness to seizures may follow.

PREVENTION AND TREATMENT

Kernicterus is completely preventable if jaundice is treated promptly; there is no cure for the brain damage if kernicterus has occurred.

Ketoconazole

An *antifungal drug* used in the treatment of severe fungal infections of the lungs, brain, kidney, and lymph glands (see *Fungi*). Ketoconazole is also given to treat *candidiasis* (thrush) of the skin, mouth, or vagina when other antifungal preparations have proved ineffective.

Ketoconazole may cause nausea but it can sometimes be avoided if the drug is taken with food. Other possible adverse effects include rash and, rarely, liver damage.

Ketoprofen

A *nonsteroidal anti-inflammatory drug* (NSAID) prescribed as an *analgesic* (painkiller) in the treatment of injury to soft tissues, such as muscles and ligaments. Ketoprofen is also given to reduce joint pain and stiffness in people with types of arthritis, including *rheumatoid arthritis*, *osteoarthritis*, and *ankylosing spondylitis*.

Ketoprofen may cause abdominal pain, nausea, indigestion, and an increased risk of *peptic ulcer*.

Ketosis

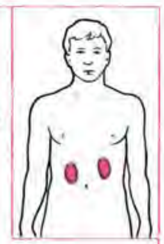
A potentially serious condition in which excessive amounts of ketones accumulate in the body. Ketones are substances chemically related to acetone, which is found in solvents such as nail polish remover. Ketosis results whenever glucose is not available to use as a source of energy, which forces the body to use fats instead. This, in turn, leads to fatty acids being released into the blood; they are then converted to ketones.

The underlying causes of ketosis include fasting or starvation, and untreated or inadequately controlled *diabetes mellitus*, in which the lack of insulin prevents glucose from being used as fuel.

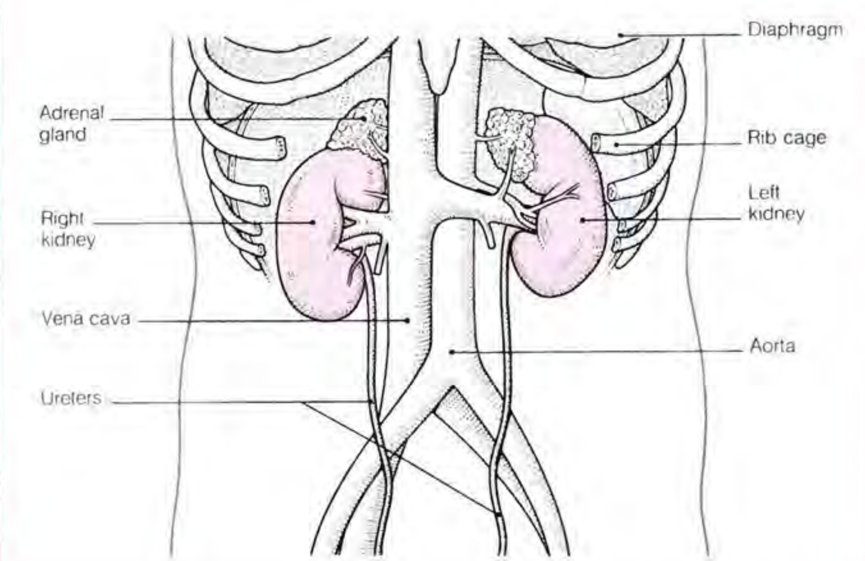
Symptoms and signs may include sweet, "fruity-smelling" breath, loss of appetite, nausea, vomiting, and abdominal pain. If the condition is not treated, confusion, unconsciousness, and death may follow.

Ketosis can be diagnosed by a test to detect ketones in the urine. Treatment is the same as for diabetes unless the cause is fasting or starvation, in which case gradual reintroduction of a nutritious diet is usually effective.

Kidney



The organ responsible for filtering the blood and excreting waste products and excess water in the form of urine. The kidney, ureter, bladder, and urethra make up the *urinary tract*.



STRUCTURE

There are two kidneys, each about 4 to 5 inches long and about 6 ounces in weight. They lie in the abdomen underneath the liver on the right and the spleen on the left. The arteries that supply the kidneys arise directly from the aorta (the main artery of the body leading from the heart). Once within the kidneys, the renal arteries divide into smaller and smaller branches, ending in capillaries in the glomeruli (the kidney's primary filtering units). Each kidney contains about 1 million glomeruli, which pass the filtered blood through long tubules into the medulla (the central collecting

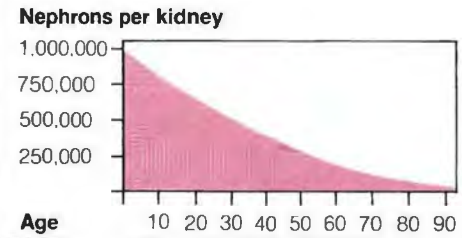
LOCATION OF THE KIDNEYS

The kidneys are situated at the back of the abdominal cavity, just above the waist, on either side of the spinal column. The kidney on the right lies below the liver, while the kidney on the left is situated below the spleen. The arteries that supply the kidneys arise directly from the aorta.

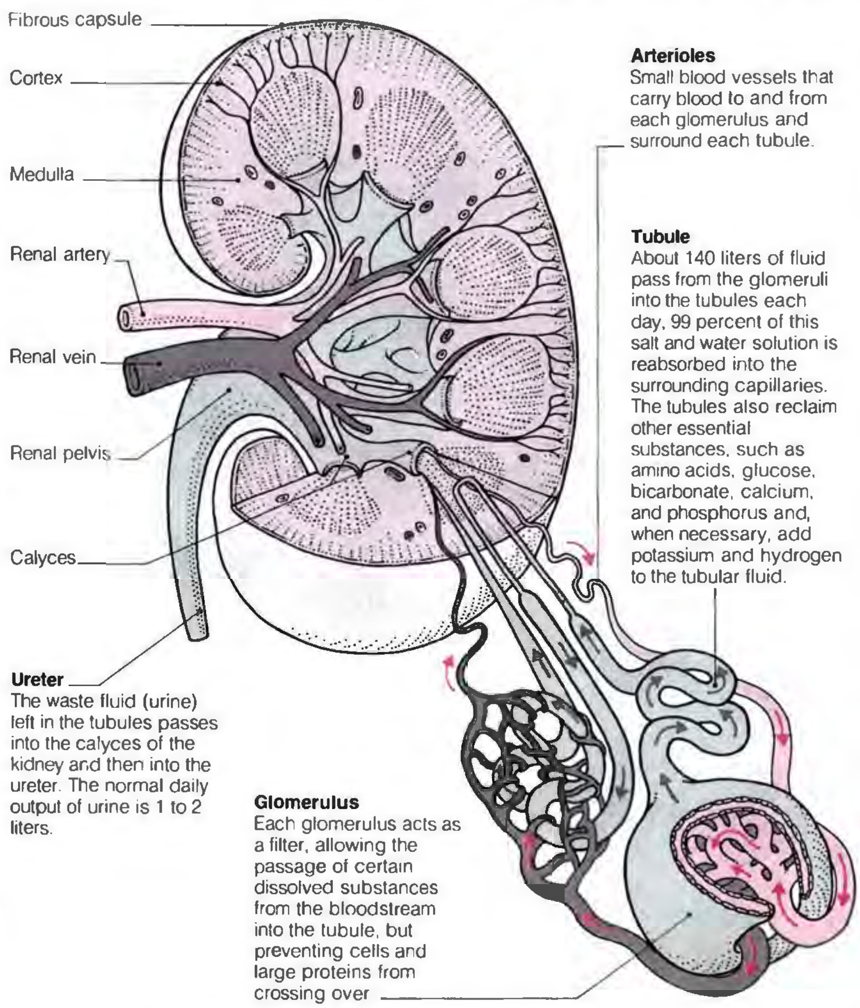
region of the kidney). The glomeruli and tubules make up the nephrons, the functioning units of the kidney. As people age, the number of functioning nephrons is reduced; this process may be speeded up by disease.

FUNCTION

The main functions of the kidney are to regulate blood and electrolytes and to eliminate waste products. The most important waste products are those generated by the breakdown of proteins. The kidneys also control the body's acid-base balance. When blood and body fluids become too acid or too alkaline, the urine acidity is altered to restore the balance. When excess water is ingested, the kidney excretes it; when water is lost (as a result of diarrhea or sweating), the kidney conserves it (see *ADH*).



The kidney also produces several hormones, including erythropoietin, which regulates the production and release of red blood cells from the bone marrow. *Vitamin D* is converted into active hormonal form by the kidney. Renin, an enzyme released by the kidney when blood pressure falls, acts on a protein in the blood to produce *angiotensin* (a powerful constrictor of small arteries that helps regulate blood pressure). Angiotensin also controls the release of *aldosterone*, an adrenal hormone that acts on the tubules to promote reabsorption of sodium and excretion of potassium.



THE FUNCTION OF THE KIDNEY

The kidney is essential to the regulation of the body's fluid balance and acid-base balance. The kidney contains about 1 million nephrons, each of which consists of a glomerulus and a tubule that drain urine into the renal pelvis. Capillaries feed each glomerulus and surround each tubule.

RENAL FUNCTION AND AGE

The efficiency of the kidney diminishes with age as the number of functional nephrons is reduced.

Kidney cancer

Cancers that have their origins in the kidneys themselves are not rare. Cancer that starts in other organs rarely spreads to the kidneys.

TYPES

There are three main types of cancer arising in the kidneys.

RENAL CELL CARCINOMA This is the most common type of kidney cancer, accounting for about 75 percent of all kidney growths. The tumor usually occurs after the age of 40 and affects twice as many men as women. The most common symptom is *hematuria* (blood in the urine). There may be pain in the loins, a lump in the abdomen, fever, or weight loss. About 25 percent of patients survive five years or more because the tumor often has spread to the lungs, bone, liver, and brain by the time treatment is started.

NEPHROBLASTOMA Also called Wilms' tumor, this cancer accounts for about 20 percent of all cancers in children. It is found mainly in children under the age of 4 years and occurs almost twice as often in males. Nephroblastoma grows rapidly and is often felt as a lump in the abdomen. This cancer occasionally causes abdominal pain. Nephroblastoma frequently spreads to the lungs, liver, and brain. If treatment is started early, about 50 to 80 percent of children survive.

TRANSITIONAL CELL CARCINOMA This type arises from cells lining the renal pelvis. It develops in tobacco smokers and in people who have consumed very large quantities of analgesics (painkillers) over the course of many years. Hematuria is a common symptom; *hydronephrosis* (distention of the kidney with urine) may occur due to blockage of the ureter. Survival rates vary greatly, depending in part on early detection and treatment of the tumor.

DISORDERS OF THE KIDNEY

The kidneys are susceptible to a wide range of disorders. However, only one normal kidney is needed for good health, so disease is rarely life-threatening unless it affects both kidneys and has reached an advanced stage.

Hypertension (high blood pressure) can be both a cause and effect of kidney damage. Other effects of serious disease or damage include the *nephrotic syndrome* (in which large amounts of protein are lost in the urine and fluid collects in body tissues) and acute or chronic *renal failure*.

CONGENITAL AND GENETIC DISORDERS

Congenital abnormalities of the kidneys are fairly common. In *horseshoe kidney*, the two kidneys are joined at their base. Some people are born with one kidney missing, both kidneys on one side, or a kidney that is partially duplicated and gives rise to two ureters (duplex kidney). These conditions seldom cause problems. In rare cases, a baby is born with kidneys that are so underdeveloped that they are barely functional.

Polycystic disease of the kidneys is a serious inherited disorder in which multiple cysts develop on both kidneys (see *Kidney, polycystic*). In *Fanconi's syndrome* and *renal tubular acidosis* (which are rare), there are subtle abnormalities in the functioning of the kidney tubules, so that certain substances are inappropriately lost in the urine.

IMPAIRED BLOOD SUPPLY

Various diseases may cause damage to, or lead to obstruction of, the small blood vessels within the kidneys, impairing blood flow. *Diabetes mellitus* and *hemolytic-uremic syndrome* are examples. In physiological *shock*, blood pressure and flow through the kidneys are seriously reduced; this can cause a type of damage known as acute tubular necrosis. The larger blood vessels in the kidney may be affected by *periarteritis nodosa* and systemic *lupus erythematosus*. In rare cases, there is a defect of the renal artery supplying a kidney, which may lead to hypertension and tissue damage.

AUTOIMMUNE DISORDERS

Glomerulonephritis refers to an important group of autoimmune disorders in which the glomerular filtering units of the kidneys become inflamed. It sometimes develops after infection with streptococcal bacteria.

TUMORS

Benign *kidney tumors* are rare. They may cause *hematuria* (blood in the urine), although most cause no symptoms. Malignant tumors are also rare. Renal cell carcinoma, the most common type, occurs mostly in adults over 40; nephroblastoma (Wilms' tumor) affects mainly children under 4 (see *Kidney cancer*).

METABOLIC DISORDERS

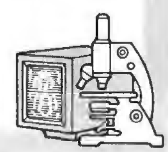
Kidney stones are common in middle age. They are usually caused by excessive concentrations of various substances (such as calcium) or lack of inhibitors of crystallization in the urine. In *hyperuricemia*, there is a tendency for uric acid stones to form (see *Calculi, urinary tract*).

INFECTION

Infection of a kidney is called *pyelonephritis*. An important predisposing factor is obstruction of the flow of urine through the urinary tract, leading to stagnation and subsequent infection spreading up from the bladder. The cause of the obstruction may be a congenital defect of the kidney or ureter, a kidney or ureteral stone, a bladder tumor, or, in a man, enlargement of the prostate gland.

Tuberculosis of the kidney is caused by infection carried by the blood from elsewhere in the body, usually the lungs.

DRUGS



Allergic reactions to certain drugs can cause an acute kidney disease, with most of the damage affecting the kidney tubules. Other drugs may directly damage the kidneys if taken in large amounts for prolonged periods. For example, renal failure can develop after many years of taking excessive amounts of analgesics. Some potent antibiotics can damage the kidney tubules, producing acute tubular necrosis.

OTHER DISORDERS

Hydronephrosis refers to a kidney swollen with urine as a result of obstruction further down the urinary tract. In the *crush syndrome*, kidney function is disrupted by proteins (released into the blood from severely damaged muscles) that block the filtering mechanisms.

INVESTIGATION

Kidney disorders are investigated by *kidney imaging* techniques such as *ultrasound scanning*, intravenous or retrograde *pyelography*, *angiography*, and *CT scanning;* by *renal biopsy* (removal of a small amount of tissue for analysis); by *blood tests;* and by *kidney function tests*, such as *urinalysis*.

DIAGNOSIS AND TREATMENT

Diagnosis is made by intravenous *pyelography* or by renal *angiography*. Treatment consists of *nephrectomy* (removal of the kidney) and sometimes removal of the ureter as well. In the case of a nephroblastoma, nephrectomy is followed by *radiation therapy* and *chemotherapy*.

Kidney cyst

A fluid-filled sac within the kidney. Most are noncancerous.

Simple kidney cysts are found in about half the people over 50; most of them develop for no known reason. The cyst usually produces no symptoms unless it becomes large enough to cause pain in the lower back due to pressure from a buildup of fluid. Multiple cysts sometimes occur in one or both kidneys.

Kidney cysts also occur in polycystic kidney disease (see *Kidney, polycystic*), a hereditary condition that often leads to *renal failure* before the age of 50.

DIAGNOSIS AND TREATMENT

Cysts are frequently discovered only when the person is being examined for some other reason. Treatment is not usually necessary. *Aspiration* of the cyst may be performed to ensure that there is no malignancy or to relieve severe pain. When the cyst is large, fluid often reaccumulates, requiring excision.

Kidney failure

See *Renal failure*.

Kidney function tests
Tests performed to investigate urinary symptoms and kidney disorders. Kidney function tests may also be performed as part of a routine investigation before major surgery, or before prescribing drugs that are eliminated by the kidney. The tests are also performed to determine the function of a transplanted kidney.

TYPES

Urinalysis is a simple kidney function test. Collected urine is examined under the microscope for blood cells, pus cells, and casts (cells and mucuslike material that accumulate within the tubules and pass into the urine). Urine may also be cultured to confirm the presence of infection. It also may be tested for substances that are present only when the kidneys are diseased or damaged.

Kidney function can be assessed by measuring the concentration of substances in the blood (such as *urea* and creatinine) normally eliminated from the body via healthy kidneys. The creatinine clearance test provides an assessment of kidney function by comparing the amount of creatinine in the blood with the amount excreted in the urine over a timed interval, usually 24 hours.

Kidney function may also be assessed by *kidney imaging* techniques, which can help identify whether one or both kidneys are diseased.

Kidney imaging
Techniques for visualizing the kidneys, usually performed for diagnostic purposes.

TYPES

Ultrasound scanning provides remarkably clear pictures of the kidney. It can show an enlarged kidney, indicate the site of any blockage, and show the presence of a cyst or other tumor.

Conventional *X rays* show the outlines of the kidney and most kidney stones. Intravenous *pyelography* (in which a radiopaque contrast material is injected into a vein) gives a good picture of the internal anatomy of the kidney and ureters, as well as the presence of stones. *Angiography* involves injecting a material similar to that used in intravenous pyelograms into the renal arteries or veins to demonstrate the blood supply of the kidneys. When the material is injected into the arteries, it is known as arteriography. Digital subtraction angiography permits imaging of the renal circulation with less contrast material and greater safety.

CT scanning provides a complete cross section of the kidney displayed as computerized X-ray pictures. It is particularly useful for showing abscesses or tumors.

Radionuclide scanning is cheaper than conventional X rays and exposes the patient to less radiation. The two types usually used for the kidney are the DMSA scan and DTPA scan. DMSA is a substance given by intravenous injection that binds to the cells of the kidney tubules and gives a single static picture of the kidneys, indicating their relative size, shape, position, and function. DTPA, also given intravenously, is filtered by the glomeruli and passes out in the urine. Pictures are taken at intervals to record its passage through the renal tract. DTPA provides similar information to that provided by the intravenous pyelogram, although the anatomical details are less clear.

Kidney, polycystic
An inherited disorder in which there are numerous cysts in both kidneys. The cysts gradually increase in size until most of the normal kidney tissue is destroyed; cysts may also occur in the liver and, rarely, in other organs. Polycystic kidney disease is distinguished from multiple simple cysts of the kidneys, which occur commonly with age (see *Kidney cyst*).

TYPES

ADULT POLYCYSTIC DISEASE This disorder shows an autosomal dominant pattern of inheritance (see *Genetic disorders*). Symptoms, which may appear at any time (but usually appear in middle age) include abdominal swelling, pain, *hematuria* (blood in the urine), and frequent *urinary tract infections*. As the disease progresses, *hypertension* and *renal failure* may result.

JUVENILE POLYCYSTIC DISEASE This rare disorder causes *renal failure* in infants and young children. It is usually diagnosed at birth because of massive enlargement of the kidneys.

TREATMENT

There is no effective treatment for preserving kidney function in polycystic kidney disease. Symptoms of renal failure can be treated by *dialysis* (artificial purification of the blood) and *kidney transplant*.

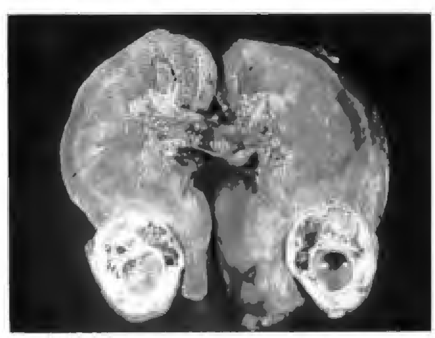
Kidney stone
See *Calculus, urinary tract*.

Kidney transplant
A transplant operation in which the diseased kidney of a person who has chronic *renal failure* is replaced by a transplanted healthy kidney, either from a living donor or a cadaver. One healthy donor kidney is sufficient to maintain the health of the recipient.

Kidney transplantation is more straightforward than the transplantation of any other major organ and is by far the most commonly performed. In addition, the failure of a kidney transplant is far less serious than an unsuccessful heart, liver, or lung transplant because kidney function can be taken over by *dialysis*.

HOW IT IS DONE

For a description of a kidney transplant, see box (next page).



OUTLOOK

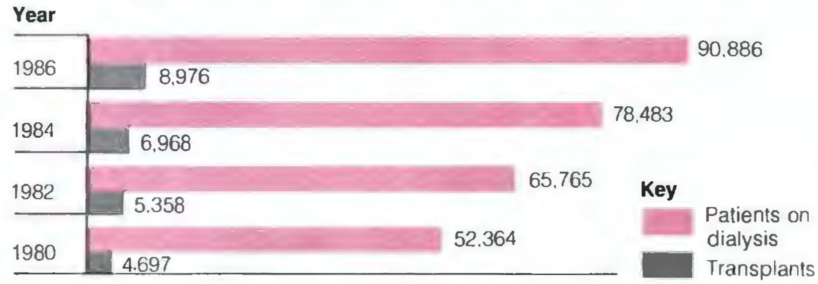
Kidney transplants are successful in more than 80 percent of cases. This figure climbs to more than 90 percent if the donor is a close blood relative. The primary danger is rejection of the donated kidney within the first month or two after transplantation. If the kidney is rejected, the patient returns to dialysis (artificial purification of the blood). However, more transplants may be attempted if the patient is in good health otherwise. All kidney transplant patients must take a lifelong course of *immunosuppressant drugs* to prevent rejection.

Kidney tumors
Growths of the kidney. Kidney tumors may be malignant (see *Kidney cancer*) or benign.

Fibromas, *lipomas*, and *leiomyomas* (which are benign) often cause no symptoms and may be discovered only during surgery on the kidney. Occasionally, a *hemangioma* grows very large and is mistaken for a cancer; it may also cause *hematuria* (blood in the urine).

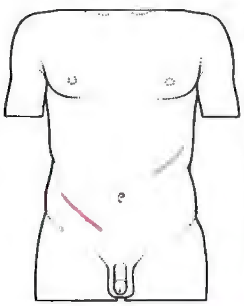
No treatment is necessary for benign tumors unless they are very large or cause pain or bleeding.

Example of a kidney tumor
A malignant tumor of one kidney (sliced in half). Surgical removal of a malignant kidney tumor is always necessary.



K

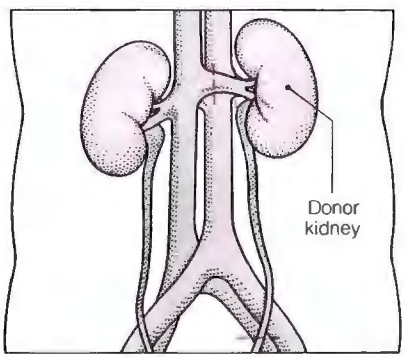
PROCEDURE FOR A KIDNEY TRANSPLANT



The donated kidney comes from a close (living) blood relative of the patient or from any person who consented to medical use of organs after death (cadaver transplant). To prevent rejection of the kidney by the recipient's *immune system,* the tissue type and blood group of recipient and donor must be a close match (see *Transplant surgery*).

DIALYSIS AND TRANSPLANTATION IN THE US

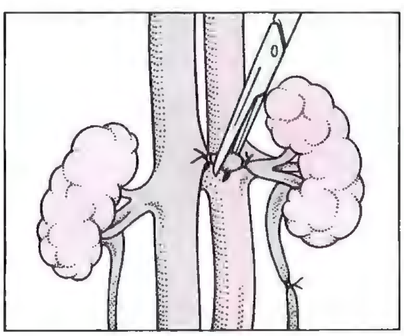
About one third to one half of new patients with end-stage kidney failure are suitable for a transplant, but many have to wait some time for a suitable donor kidney to become available; in the meantime they add to the growing number of patients undergoing dialysis.



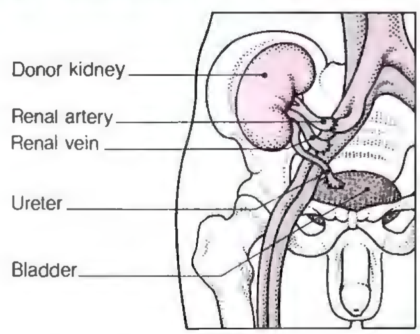
HOW IT IS DONE

Removal
The kidney is removed via an incision under the ribs.

Insertion
The donor kidney is inserted low in the pelvis.

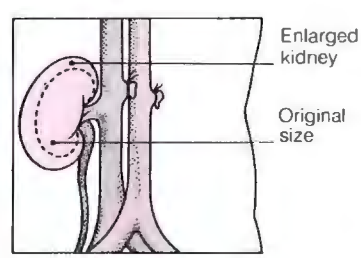


1 Usually the left kidney is removed from living donors because it has a longer vein than the right and is easier to remove safely. After removal, the kidney is flushed with saline solution.



Maintaining the kidneys
Kidneys from a cadaver can be maintained for transplantation by a simple machine that passes a cooling saline solution through them.

Inserting the kidney
The surgeon inserts the donated kidney in its new position in the pelvis.

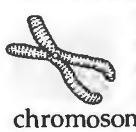


2 The surgeon may remove one or both of the patient's kidneys. Before removing a kidney, it is necessary first to clamp and cut the renal blood vessels that supply the kidney. The ureter must also be clamped and cut.

3 The donor kidney is usually placed in the pelvis. The renal artery and vein of the donor kidney are joined to the recipient's artery and vein and the lower end of the donor ureter is connected to the recipient's bladder. The clamps are then removed.

THE DONOR (AFTER THE OPERATION)

The health of the donor is not affected by losing one kidney; the remaining kidney enlarges to take over full function.



Kilocalorie
The unit of energy equal to 1,000 *calories*. In dietetics, a kilocalorie is often called simply a Calorie.

Kilojoule
The unit of energy equal to 1,000 *joules*, abbreviated kJ.

Kleptomania
A recurring inability to resist the impulse to steal objects that are not necessarily wanted or needed. The condition is rare, although it is often used by shoplifters and other thieves as an excuse.

In true kleptomania, the person experiences an increasing sense of tension before committing the act of theft and a sense of relief or pleasure while carrying it out. The act is not preplanned and little thought is given to the consequences, but later there may be anxiety and depression caused by the fear of being caught.

Kleptomania is usually a sign of an immature personality. It may also be caused by *dementia* and be the result of some forms of brain damage.

Klinefelter's syndrome

A *chromosomal abnormality* in which a male has one or more extra X *chromosomes* in his cells, giving him a chromosome complement of XXY or, more rarely, XXXY, XXXXY, and so on (instead of XY). About one in every 500 male infants born has the syndrome. The chances of a baby having the condition increase with age of the mother.

SYMPTOMS AND SIGNS
The features of Klinefelter's syndrome may pass unnoticed until puberty, when *gynecomastia* (breast enlargement) occurs and the testes remain small. Affected males are infertile due to *azoospermia* (absence of sperm production). They are usually tall and thin, and the body shape looks female rather than male. The incidence of mental retardation is higher in people with Klinefelter's syndrome than in the general population.

DIAGNOSIS AND TREATMENT
Diagnosis is confirmed by *chromosome analysis*. There is no treatment, although mastectomy may be performed if gynecomastia causes psychological distress; hormonal treatment may be used to induce secondary sexual characteristics, such as growth of facial hair. Parents who have had an affected child should receive *genetic counseling*.

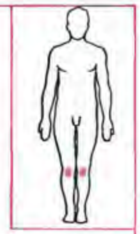
Klumpke's paralysis
Paralysis of the lower arm, with wasting of the small muscles in the hand and numbness of the fingers (excluding the thumb) and of the inside of the forearm.

Klumpke's paralysis is caused by injury to the first thoracic nerve (one of the *spinal nerves*) in the brachial plexus (the network of nerves behind the shoulder blade); injury to this nerve is usually the result of dislocation of the shoulder.

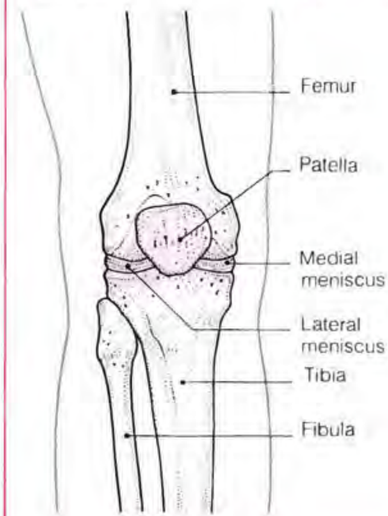
In some cases, there may also be drooping of the upper eyelid, constriction of the pupil, and loss of sweating on one side of the face and neck (a collection of symptoms known as *Horner's syndrome*).

The condition is usually permanent. The only treatment consists of exercises to maintain mobility of the joints.

Knee
The joint between the femur (thigh bone) and tibia (shin); the patella (kneecap) lies across the front of the joint. The knee is a modified hinge joint, capable of bending and straightening, and capable of slight rotation in the bent position.



STRUCTURE
Two disks of protective cartilage called menisci (see *Meniscus*) cover the surfaces of the femur and tibia; they reduce friction between the bones during movement. The joint is partly surrounded by a fibrous capsule lined with synovial membrane, which secretes a lubricating fluid that allows the cartilage to move freely.



Strong ligaments on each side of the joint provide support and limit side-to-side movement. *Cruciate ligaments* within the joint, which cross over each other as they run diagonally between the femur and tibia, provide additional support, prevent overbending and overstraightening of the knee, and limit sliding movement between the bones.

Bursas (fluid-filled sacs) are present above and below the patella and behind the knee. The *quadriceps muscles* (which run along the front of the thigh) straighten the knee; the *hamstring muscles* at the back of the thigh bend the knee.

DISORDERS
Sudden twisting of the knee may cause a ligament sprain or tear a meniscus. If a meniscus is torn and a fragment of the cartilage catches between the surfaces of the joint, the knee may become temporarily locked in one position.

LOCATION OF THE KNEE
The knee is the joint that is situated between the femur and the tibia. The patella lies across the front of the joint.

Severe damage to a joint, often as the result of a sports injury, may cause *hemarthrosis* (bleeding into the joint); minor injuries may lead to *synovitis* (inflammation of the joint lining). Repetitive activity, such as running, may cause inflammation of the tendon below the patella. In children, inflammation of the tibial tubercle (the bony prominence beneath the knee) may occur temporarily (see *Osgood-Schlatter disease*).

Bursitis (inflammation of a bursa) usually occurs in response to local pressure on the front of the knee. Fluid escaping from a bursa behind the knee causes a *Baker's cyst*.

Arthritic conditions most likely to affect the knee are *osteoarthritis*, *rheumatoid arthritis*, and retropatellar arthritis (inflammation of the undersurface of the patella). A condition similar to retropatellar arthritis, known as *chondromalacia patellae*, is common in adolescents.

Fractures of the lower femur, upper tibia, or the patella disrupt normal movement of the knee. A sharp blow to the knee may result in dislocation of the patella.

Knock-knee and *bowleg* are common in childhood as temporary deformities that resolve as growth continues; in adults, they may be caused by injury or disease.

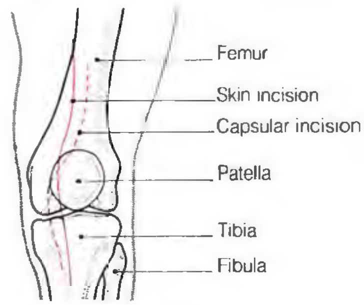
Knee joint replacement

A surgical procedure to replace a diseased knee joint with an artificial substitute. Early replacement knees were simply large hinges. Today, most artificial knees take the form of metal and plastic implants that cover the worn cartilage. The aim is generally to preserve as much of the original joint as possible.

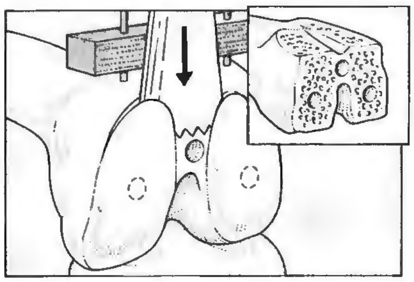
WHY IT IS DONE

Knee joint replacement is most often carried out in older people whose knees are severely affected by pain and impaired motion due to *osteoarthritis* or *rheumatoid arthritis*. An artificial knee is not normally recommended for younger patients because it does not restore the full range of movements and is unlikely to withstand vigorous activity.

RECOVERY PERIOD

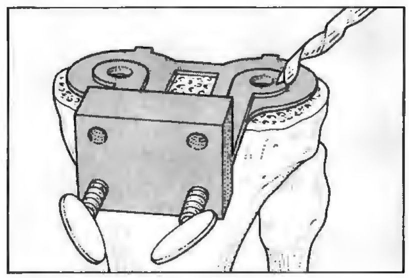


The plaster cast fitted after the operation is usually removed after five days and exercises are started to strengthen the quadriceps. The patient can normally put weight on the leg after two or three weeks.



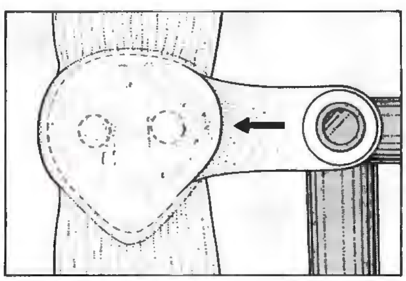
OUTLOOK

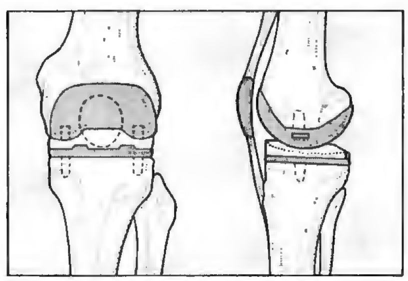
Although knee replacements can relieve pain and restore a degree of movement, results are often uncertain and the durability of the artificial parts is limited. However, research continues into the development of stronger materials, better cements (glues), and joint designs that more closely resemble natural joints.



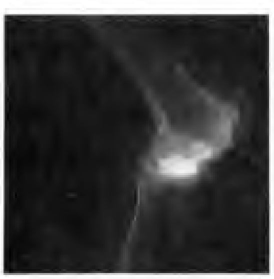
PROCEDURE FOR A KNEE REPLACEMENT

The surgeon usually makes one long incision, cuts through the joint capsule and synovial membrane, and then pushes aside the patella to reach the joint. Special instruments are used to make precise measurements and to cut away areas of bone so that the artificial components will fit and move correctly.

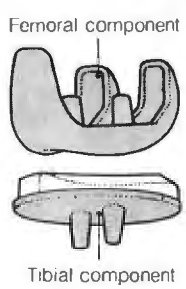




1 The lower end of the femur is shaped and holes are drilled into it to accept the femoral component of the prosthesis. Cutting and drilling are done using special instruments.



2 The upper end of the tibia is shaped and holes are drilled into it to accept the tibial component. The cutting and drilling are again carried out using special precision instruments.



3 The back part of the patella is cut away to leave a flat surface. Small holes are then drilled into this surface to accept the patellar component of the artificial joint.

4 Having achieved a satisfactory fit using trial components, the final prosthesis is cemented in place. Excess cement is then removed and a final check is made of the joint movements.

X ray of arthritic knee
Severe wear and tear of the bone and cartilage can easily be seen.

Knee prosthesis
The two main components fit over the femur and tibia.

X ray of artificial knee
The X ray shows the components of the prosthesis in position.

Knock-knee

Inward curving of the legs so that the knees touch, causing the feet to be kept farther apart.

CAUSES

Knock-knee is a part of normal development in some children and is common between the ages of 3 and 5 years. It may also be the result of injury or disease. Among the common causes are diseases that soften the bones (such as *rickets* or *osteomalacia*), *rheumatoid arthritis* or *osteoarthritis* of the knee, or a fracture of the lower femur (thigh bone) or upper tibia

The appearance of knock-knee
This condition is common in toddlers but nearly always disappears by age 7.

(shin) that has not healed in a straight, vertical line.

TREATMENT

In children, the condition usually requires no treatment unless it persists after the age of 10, when it may start to strain the joints of the lower leg. Wearing heel wedges in the shoes may help correct the line of the leg, but most people require *osteotomy* (an operation in which the tibia is cut and realigned to straighten the leg).

In adults, treatment consists of osteotomy, or, when the condition has been present for a considerable time, *knee joint replacement*.

Knuckle

The common name for a *finger* joint.

Koilonychia

A condition in which the nails are dry, brittle, and thin, eventually becoming concave (spoon shaped). Koilonychia may be caused by injury to the nail. Other causes include iron-deficiency *anemia* and *lichen planus*; rarely, the condition is inherited.

The appearance of koilonychia
In koilonychia, the nails are flattened and look fragile, bending where they protrude past the finger ends.

Koplik's spots

Tiny, gray-white spots within the mouth (on the inner lining of the cheeks) that appear during the incubation period of *measles*.

Korsakoff's psychosis

See *Wernicke-Korsakoff syndrome*.

Kraurosis vulvae

See *Vulvitis*.

Kuru

A progressive and fatal infection of the brain that affects some natives of the highlands of New Guinea. Kuru is caused by a virus spread by cannibalism. The condition is now rare.

The disease is caused by a "slow" virus (which causes no signs of disease until many months or years after entry into the body) and the incubation period may be as long as 30 years. Symptoms include progressive difficulty in controlling movements and, eventually, *dementia*.

Kuru has aroused special interest recently because of certain similarities between the causative virus and *HIV* (human immunodeficiency virus), which causes *AIDS*. It is known that HIV can cause brain changes similar to those in kuru.

Kwashiorkor

A severe type of malnutrition in young children, occurring mainly in poor rural areas in the tropics. It is chiefly confined to children between 1 and 3 years old. The term kwashiorkor is derived from a Ghanaian word meaning "disease suffered by a child displaced from the breast."

CAUSES

The illness starts when the child is suddenly weaned onto a poor diet low in calories, protein, and certain essential micronutrients such as zinc, selenium, and vitamins A and E. To obtain enough nutrients from the food that is available, the child would need to eat a larger amount than he or she is capable of taking in. The problem is often exacerbated by a poor appetite due to illness. In addition, the lacking micronutrients provide protection against certain chemicals that are produced during infections and which also lead to *edema* (accumulation of fluid in the tissues). Measles and other infections common in the tropics precipitate kwashiorkor in undernourished children.

SYMPTOMS AND SIGNS

Growth is stunted, but edema makes the child look puffy and generally less emaciated than a child with *marasmus*, another form of malnutrition. Affected children are apathetic, weak, irritable, and inactive. Their skin sometimes flakes off, leaving a raw, weeping area beneath, and their hair may lose its curliness, become sparse and brittle, and turn from dark to fair.

The liver often enlarges, dehydration may develop (despite the simultaneous presence of edema), and the child loses resistance against severe infection, which may be fatal. In its severe, advanced stage, the illness is often marked by jaundice, drowsiness, and a fall in body temperature.

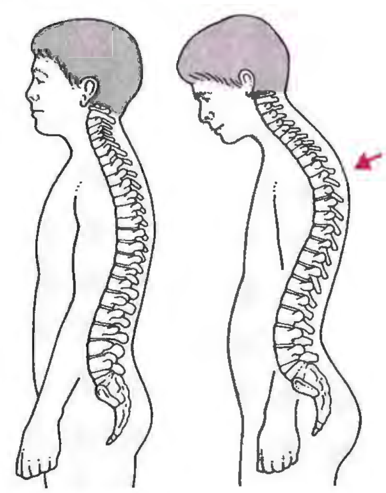
DIAGNOSIS AND TREATMENT

Diagnosis is based on a physical examination and the child's medical and dietary history.

The priorities in severe cases are to keep the child warm, replace lost fluids, and treat any infection. Initially, the child is fed milk (in frequent small amounts) and vitamin and mineral tablets, if possible. Zinc is given to prevent more flaking of the skin. When the edema has disappeared and the child's appetite has returned, a high-calorie, protein-rich diet is given.

OUTLOOK

Most children treated for kwashiorkor recover, but those less than 2 years old are likely to suffer permanent stunting of growth. Of the children ill enough to be admitted to a hospital, about 85 percent survive.



Kyphoscoliosis

A combination of *kyphosis* (abnormal backward curvature of the spine) and *scoliosis* (curvature of the spine to one side or the other).

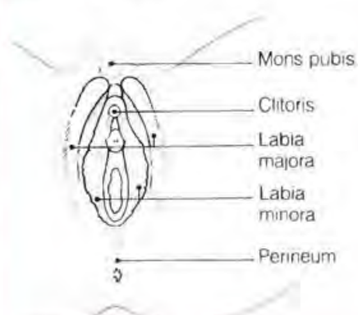
Kyphosis

The medical term for excessive backward curvature of the spine. Kyphosis usually affects the spine at the top of the back, resulting in either a hump or a more gradually rounded back. Less commonly, it affects normally forward-curving parts of the spine at the neck and lower back.

Kyphosis may be caused by any of a variety of spinal disorders, including *osteoporosis* (bone degeneration from softening due to calcium loss), fracture of a vertebra, or a tumor of a vertebra (see *Spine* disorders box). In the past, the main cause of kyphosis was spinal tuberculosis. Treatment, which is rarely successful, is of the underlying disorder.

The appearance of kyphosis
In kyphosis, the thoracic part of the spine is excessively curved, producing a humped (rounded) appearance.

K

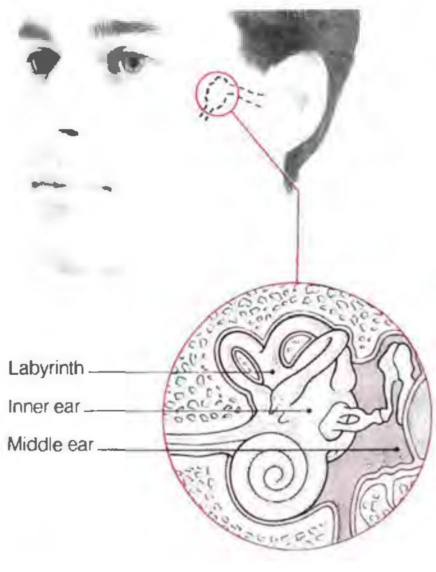


L

Labetalol
A *beta-blocker drug* used to treat *hypertension* (high blood pressure) and *angina pectoris* (chest pain caused by impaired blood supply to the heart).

Possible adverse effects include indigestion, nausea, and, in rare cases, depression and temporary impotence. Labetalol is less likely than some other beta-blocker drugs to cause cramping of the legs or coldness of the hands and feet.

Labia
The lips of the *vulva* (the female external genitalia) that protect the vaginal and urethral openings. There are two pairs of labia. The outer pair, called the labia majora, are fleshy folds that bear hair and contain sweat glands. They cover the smaller, hairless inner folds, the labia minora, which meet to form the hood of the *clitoris*.



LOCATION OF LABIA
The labia majora extend forward from the perineum and fuse at the front at the mons pubis. The labia minora lie within.

Labile
Unstable; likely to undergo change. Vitamins are labile because they are broken down easily by such factors as heat and excess acidity. Blood pressure that has a tendency to fluctuate may be described as labile. In psychiatry, the term is sometimes used to mean emotional instability.

Labor
See *Childbirth*.

Labyrinthitis
Inflammation of the labyrinth (the fluid-filled chambers in the inner ear that sense balance) that results in *vertigo*, a sensation that oneself or one's surroundings are spinning around.

Mechanism of labyrinthitis
In labyrinthitis, inflammation of the fluid-filled chambers (labyrinth) of the inner ear causes disruption of the individual's sense of balance. The inflammation is usually caused by viral or bacterial infection.

CAUSES
Labyrinthitis is almost always caused by bacterial or viral infection. Viral labyrinthitis may occur during a flulike illness or during illnesses such as measles or mumps. Bacterial labyrinthitis is commonly caused by inadequately treated *otitis media* (infection of the middle ear), particularly if a *cholesteatoma* (an infected collection of debris in the middle ear) has developed and eroded a pathway into the inner ear. Infection may also reach the inner ear (via the bloodstream) from elsewhere in the body. Less commonly, bacterial labyrinthitis results from a head injury.

SYMPTOMS AND TREATMENT
Apart from vertigo, labyrinthitis can cause nausea, vomiting, *nystagmus* (jerky eye movements), *tinnitus* (ringing in the ears), and deafness.

Viral labyrinthitis clears up on its own, but symptoms are relieved by antihistamines such as meclizine. Bacterial labyrinthitis requires immediate treatment with *antibiotic drugs* to eradicate the infection. Otherwise, the infection may lead to permanent deafness or may spread to the tissue covering the brain, causing *meningitis*.

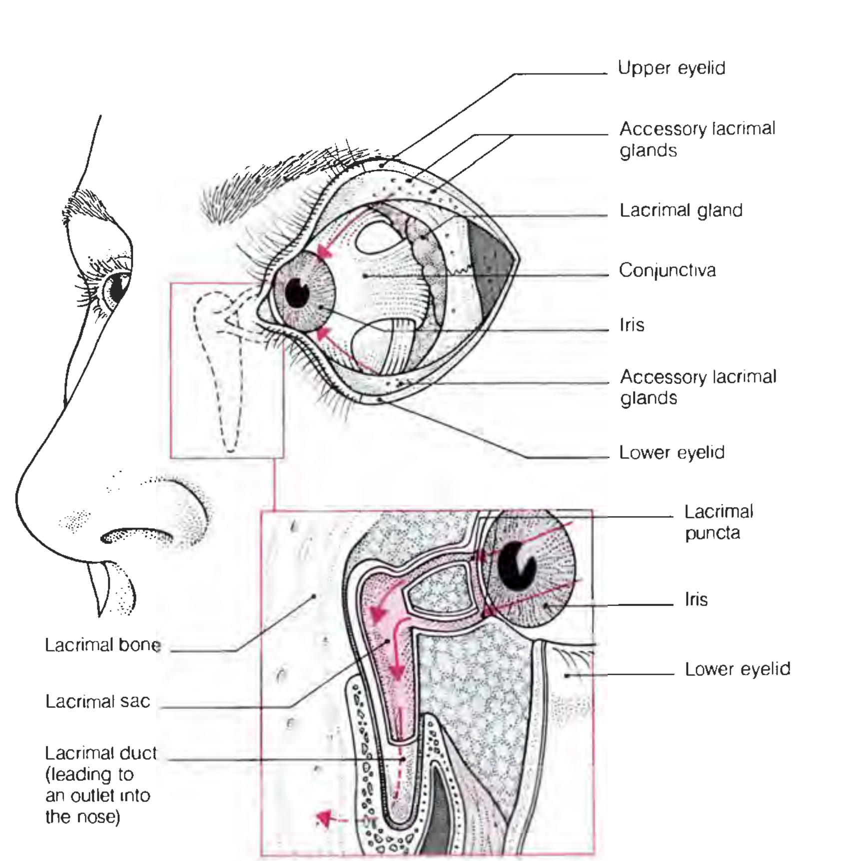
Surgery may be necessary to drain pus from the ear or to remove any cholesteatoma.

Laceration
A torn, irregular wound, as opposed to a straight cut, or *incision*. One example of a laceration is the tearing of the perineum (the area between the vagina and anus) that sometimes occurs during childbirth.

Lacrimal apparatus
The system that produces and drains tears. The lacrimal apparatus includes the main and accessory lacrimal glands and the nasolacrimal drainage ducts. The main glands secrete *tears* during crying and when the eye is irritated; the accessory glands maintain the normal tear film.

STRUCTURE
The main lacrimal glands lie just within the upper and outer margin of the orbit (socket) and drain into the *conjunctiva*. The accessory glands lie within the conjunctiva, secreting directly onto its surface.

Tears drain through the lacrimal puncta, tiny openings toward the inner end of each eyelid. The puncta are connected by narrow tubes to the lacrimal sacs, which lie in shallow hollows in the lacrimal bones. These bones are situated just within the inner margin of the orbit on either side of the nose. Overlying the lacrimal sacs are flat muscles that compress the sacs during blinking. Leading from the sacs are the nasolacrimal ducts, which run down through the bone to open inside the nose.



The action of blinking provides a suction effect to draw away excess fluid by compressing and releasing the lacrimal sacs.

FUNCTION
The principal function of tears is to keep the *cornea* and conjunctiva constantly moist. Moisture is essential to maintain transparency of the cornea and to prevent ulceration. By lubricating the surface of the eye, tears aid movement of the eyelid in blinking. Tears also wash away small foreign bodies and contain a natural antibiotic called lysozyme. Another function is their role in expressing emotion.

Lactase deficiency
A condition in which lactase, an enzyme that breaks down the lactose (milk sugar) present in the cells of the

FUNCTIONS OF THE LACRIMAL APPARATUS

Tear production must be sufficient to compensate for evaporation and maintain the tear film. Accessory lacrimal glands in the conjunctiva perform this function. The main lacrimal glands secrete when excess fluid is required. Surplus tears drain into the nose.

small intestine, is missing. Lactase deficiency causes lactose intolerance, an inability to digest lactose.

TYPES, INCIDENCE, AND SYMPTOMS

Lactase deficiency may be present at birth, may develop immediately after weaning, or may not become evident until puberty or later.

Congenital lactase deficiency is sometimes permanent, but is more often temporary. This type is caused by delayed enzyme maturation, especially in premature babies.

Permanent lactase deficiency develops in about 80 to 90 percent of blacks and Orientals and in about 5 to 15 percent of whites. Lactase deficiency may also occur as a complication of intestinal diseases (such as *celiac sprue* and *gastroenteritis*). In these cases, the deficiency frequently disappears as the disease improves.

Undigested lactose ferments in the intestine and causes severe abdominal cramps, bloating, flatulence, and diarrhea; weight loss and malnutrition may also occur.

DIAGNOSIS AND TREATMENT

The diagnosis can be confirmed by tests on blood and feces. Treatment is a lactose-free diet; milk must be avoided but fermented milk products, such as yogurt, can be eaten. Enzyme replacements (which partially or fully break down lactose) may be used.

Lactation

The production and secretion of milk after childbirth. (See *Breast-feeding*.)

Lactic acid

A weak acid produced by cells when they break down glucose to produce energy by anaerobic metabolism (chemical processes that do not require oxygen). This process occurs only when there is too little oxygen for the more usual aerobic metabolism. For example, lactic acid is produced by muscles during vigorous exercise and is one of the factors that contributes to *cramp*. Lactic acid is also produced in tissues when their blood supply (oxygen) fails due to a *myocardial infarction* (heart attack) or *shock*.

Normally, lactic acid is removed from the blood by the liver; if lactic acid accumulates, a condition called *acidosis* results.

Lactose

One of the sugars present in milk. Chemically, lactose is a disaccharide *carbohydrate*, a sugar made up of two monosaccharide (simple sugar) units.

Lactose is broken down by lactase (an enzyme released by the lining of the small intestine) into the monosaccharides glucose and galactose, which are then absorbed into the bloodstream. *Lactase deficiency* results in a reduced ability to digest lactose. If the diet contains milk, lactose accumulates and ferments in the feces, sometimes causing diarrhea.

Lactose intolerance

The inability to digest lactose, a sugar found in milk. It is usually caused by a deficiency of lactase, an enzyme found in the small intestine (see *Lactase deficiency*). Rarely, it occurs in a person who is not deficient in lactase.

Lactulose

A *laxative drug* used to treat *constipation* and *liver failure*. Lactulose causes water to be absorbed into the feces from the intestinal blood vessels, making the feces softer and easier to pass. It is used to treat liver failure because it helps eliminate ammonia from the bloodstream into the feces.

Lambliasis

Another name for *giardiasis*.

Laminectomy

Surgical removal of part or all of one or more laminae (the bony arches of the vertebrae that surround the spinal cord) to expose the spinal cord. Laminectomy is performed as the first stage of spinal canal decompression, an operation carried out to relieve pressure on the spinal cord or on a nerve root leading from it (see *Decompression, spinal canal*).

HOW IT IS DONE

An incision is made in the patient's back and the laminae are exposed. Enough of one or more adjacent laminae is then chipped away to give the surgeon access to the cord. Rarely, several complete laminae must be removed. In this case, *spinal fusion*

(immobilization of the spine with metal rods or bone grafts) is then necessary to prevent subsequent instability of the spine.

Lance
To incise (cut) using a *lancet* or a surgical scalpel.

Lancet
A small, pointed, double-edged knife used to open and drain lesions such as boils and abscesses.

Lanolin
A mixture of a yellow, oily substance obtained from sheep's wool and purified water, used as an *emollient* in the treatment of dry skin. Lanolin is a common ingredient of bath oils and hand creams; it is also used to treat mild *dermatitis*. Occasionally, lanolin may irritate the skin.

Lanugo hair
Fine, soft, downy hair that covers a fetus. Lanugo hair first appears in the fourth or fifth month and usually disappears by the ninth month. It can still be seen in some premature babies.

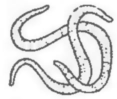
Lanugo hair sometimes reappears in adults who have cancer, particularly of the breast, bladder, lung, or large intestine. It may also occur with *anorexia nervosa* or be a side effect of drugs (especially *cyclosporine*).

Laparoscopy
A method of examining the abdominal cavity by means of a laparoscope, a type of *endoscope* (viewing tube).

WHY IT IS DONE

Laparoscopy is usually performed to determine the cause of pelvic pain or gynecological symptoms (such as *ectopic pregnancy* or *pelvic inflammatory disease*) that cannot be confirmed by physical examination. It is frequently used to examine the condition of the fallopian tubes when investigating cases of *infertility*. Laparoscopy can also be used to examine the appendix, gallbladder, and liver.

Laparotomy, exploratory
An operation in which the abdomen is opened to look for the cause of an undiagnosed illness. Laparotomy strictly describes any abdominal surgery because, even when the surgeon is operating to treat a known disorder, a thorough examination of the entire abdomen is carried out.



WHY IT IS DONE

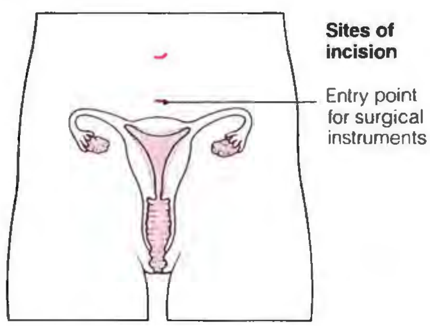
The primary reason for a laparotomy is to investigate symptoms and signs whose cause other tests have failed to discover. Common examples include recurrent abdominal pain and *peritonitis* (infection within the abdominal cavity). The operation may also be performed as an emergency procedure if the abdomen has been seriously injured in an accident.

HOW IT IS DONE

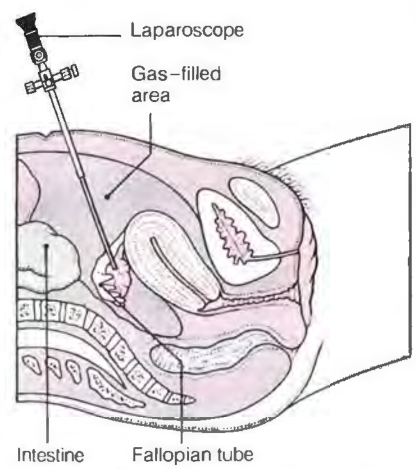
A vertical (or, less commonly, a crosswise or oblique) incision is made in the abdomen and the abdominal cavity is opened and explored for signs of disease. Any diseased organ is repaired or removed, after which the incision is sewn up.

The recovery period depends upon the nature and extent of the disease discovered and treated.

Larva migrans



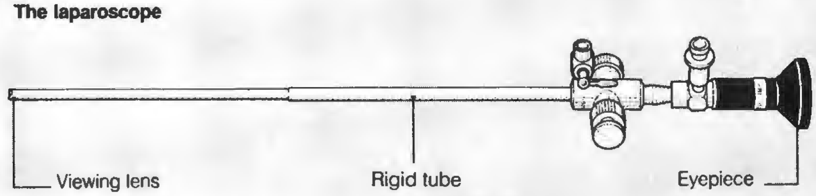
Infections characterized by the presence of the larval (immature) forms of certain worms in the body and by the symptoms caused by movement of the worms.



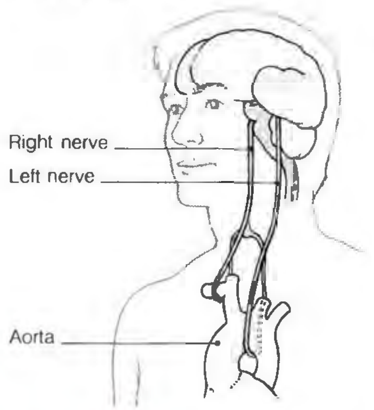
Visceral larva migrans, better known as *toxocariasis*, is caused by a type of worm that normally parasitizes dogs. Cutaneous larva migrans is caused by hookworm larvae that normally parasitize dogs, cats, or other animals. Also known as creeping eruption, it is contracted by walking barefoot on soil or beaches contaminated with animal feces. The larvae penetrate the skin of the feet and move randomly, leaving intensely itchy red lines sometimes accompanied by blistering.

Both types of larva migrans can be treated with *antihelmintic drugs*, such as thiabendazole.

Laryngeal nerve
One of a pair of nerves that carries instructions from the brain to the larynx (voice box) and sends sensations from the larynx to the brain. Each nerve leaves the brain through a hole in the base of the skull and passes down the neck. The right-hand nerve then hooks around an artery behind the clavicle (collarbone) before returning to the larynx. The other nerve travels farther, hooking around the



PROCEDURE FOR LAPAROSCOPY
A hollow needle is inserted into the abdomen just below the navel (using anesthesia), and carbon dioxide gas is pumped through the needle to expand the abdominal cavity. The laparoscope (see below) is then inserted through another incision to view the internal organs. The gas in the abdomen may cause discomfort for a day or two afterward.



Gynecological laparoscopy
Laparoscopy is used in diagnosis and for removing ova for in vitro fertilization. Laparoscopic sterilization is a common sterilization procedure for women.

The laparoscope

LOCATION OF LARYNGEAL NERVES

Both nerves exit the brain at the base of the skull and pass down the neck. One hooks around an artery behind the right clavicle, the other hooks around the aorta; both return to the larynx.

aorta (the major artery leaving the heart) before passing back to the larynx. Damage to one or both nerves causes *vocal cord* paralysis, resulting in loss of voice and sometimes obstruction to breathing.

Laryngectomy

Surgical removal of all or part of the larynx (voice box) to treat advanced cancer of the larynx (see *Larynx, cancer of*). After the operation, the patient is no longer able to speak in the usual fashion.

WHY IT IS DONE

If cancer of the larynx is detected early, the prospects of curing it with *radiation therapy* are good. However, tumors that have grown to a considerable size, and those that are not responding to radiation therapy, require surgical removal.

HOW IT IS DONE

An incision is made in the neck and the larynx is removed, using general anesthesia. The top of the trachea (windpipe) immediately below the larynx is then sewn to the skin around the surgical wound in the neck to form a permanent opening called a stoma, through which the patient will breathe from then on.

RECOVERY PERIOD

Immediately after the operation, a bell or buzzer and pen and paper are given to the patient so that he or she can communicate. A tube is left in the stoma for a few days so that, as the surrounding tissues heal, they do not close the opening. The air in the patient's room is humidified to reduce the production of mucus in the stoma, and any excess mucus is sucked away.

Initially, all food is passed through a thin tube running from the nose to the stomach. After about 10 days the feeding tube is removed and food (fluid or semisolid at first) can be taken normally again. Speed of recovery depends partly on age and health.

OUTLOOK

With persistence, the patient can learn from a speech therapist a new way of speaking (called esophageal speech). Air is swallowed, then expelled in a controlled way; this noise is modulated by the tongue, palate, and lips to form gruff, though distinguishable, words. The technique requires painstaking practice. Alternatively, patients may use an electronic larynx, a device that emits a buzzing noise and is held against the top of the throat. By mouthing words, the person converts the buzz to speech.

Swimming is not possible, and care must be taken when bathing.

Laryngitis

Inflammation of the larynx (voice box) usually caused by infection and resulting in *hoarseness*. Laryngitis may be acute, lasting only a few days, or chronic, persisting over a long period.

CAUSES

Acute laryngitis is usually caused by a viral infection, such as a cold, but it can also be due to an allergy to a drug, pollen, or some other substance.

Chronic laryngitis may be caused by overuse of the voice, by violent coughing, by irritation due to tobacco smoke, alcohol, or fumes, or by damage during surgery.

SYMPTOMS AND SIGNS

Hoarseness is the most common symptom, and it may progress to loss of voice. There may also be pain or a feeling of discomfort in the throat (especially during swallowing) and a dry, irritating cough. Laryngitis caused by a viral infection is often accompanied by fever and a general sick feeling.

TREATMENT

A person with laryngitis should rest in bed, avoid tobacco and alcohol, keep the throat lining moist with humidifiers, and take *antipyretic drugs* to reduce fever and *analgesic drugs* to relieve pain.

If the symptoms do not subside within four or five days, if sputum (phlegm) is coughed up, or if hoarseness persists for several weeks, a physician should be consulted. Antibiotic drugs will be prescribed if there is a bacterial infection. If the physician suspects a cause other than infection, diagnostic tests may be required, possibly to check for signs of cancer (see *Larynx, cancer of*), which can be cured if treated at an early stage.

Laryngoscopy

Examination of the larynx (voice box) using a mirror held against the back of the palate (indirect laryngoscopy), or a viewing tube called a laryngoscope (direct laryngoscopy). Either a rigid or a flexible laryngoscope may be required.

WHY IT IS DONE

The larynx is inspected when a person complains of persistent hoarseness or has other change in the voice, when there is persistent stridor (a harsh noise when breathing in), or when someone experiences difficulty inhaling. Laryngoscopy is also useful in examining people who have throat pain or difficulty swallowing.

INDIRECT LARYNGOSCOPY This technique is used to detect *epiglottiditis* (in adults), *laryngitis*, benign or malignant laryngeal tumors, and any reduction of movement in the vocal cords.

DIRECT LARYNGOSCOPY This procedure is used when a biopsy or more careful evaluation is needed (e.g., assessing the extent of a tumor). The laryngoscope also allows more elaborate procedures, such as complete excision of a benign *lesion*, foreign body removal, laser surgery, or injection of polytef into paralyzed vocal cords. Often, a microscope is used with the laryngoscope. Direct laryngoscopy is also done before *intubation*.

HOW IT IS DONE

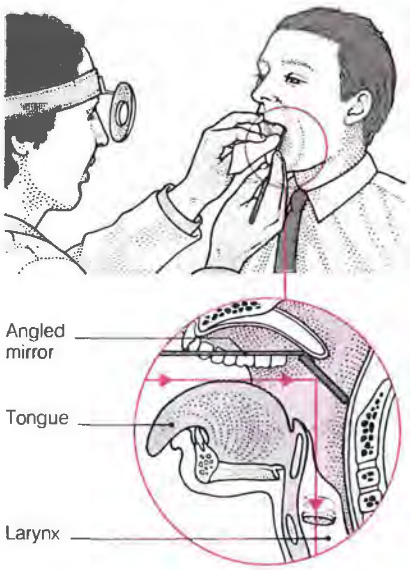
Indirect and direct laryngoscopy procedures are shown in the illustrated box, next page.

Laryngotracheobronchitis

Inflammation of the larynx, trachea, and bronchi. It is the most common cause of *croup*.

Larynx

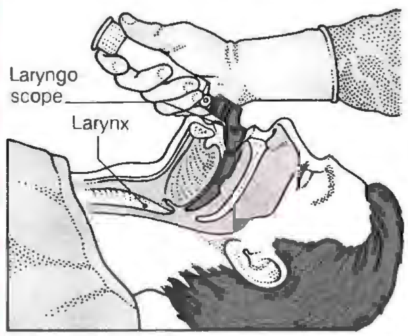
The organ in the throat responsible for voice production and for preventing food from entering the airway during swallowing. Its common name is the voice box.



STRUCTURE

The larynx, which lies between the *pharynx* (upper part of the airway) and the *trachea* (windpipe), forms part of the tube in the throat that carries air to and from the lungs. It consists of areas

PROCEDURE FOR LARYNGOSCOPY



There are two techniques. In indirect laryngoscopy, the patient's throat is examined with the use of a mirror. In direct laryngoscopy, the patient's throat is viewed with an instrument called a laryngoscope. If a rigid laryngoscope is used, general anesthesia is required. Only mild sedation is needed if a flexible laryngoscope is used.

INDIRECT LARYNGOSCOPY

The patient sticks out his or her tongue and the physician rests an angled mirror on the soft palate. A lamp or mirror on the physician's head illuminates the larynx, which is reflected in the mirror.

DIRECT LARYNGOSCOPY

A rigid laryngoscope is passed down the throat via the mouth; a flexible laryngoscope is passed via the nostril.

View of larynx This view was obtained with a laryngoscope. The vocal cords are at the center and the epiglottis forms the arc at the top.

of cartilage (tough but flexible tissue), the largest of which is the thyroid cartilage, which projects at the front to form the Adam's apple. Below it, connecting the thyroid cartilage to the trachea, is the cricoid cartilage, which is shaped like a signet ring with the seal at the back. Situated on top of the seal are the two pyramid-shaped arytenoid cartilages. Between these two cartilages and the interior surface of the Adam's apple stretch two fibrous sheets of tissue, the *vocal cords,* which are responsible for voice production.

Attached to the top of the thyroid cartilage at the entrance to the larynx is the *epiglottis*, a leaf-shaped flap of cartilage that prevents food from entering the larynx during swallowing. The entire larynx is lined with *mucous membrane*, which is of the squamous cell type.

FUNCTION

The most important function of the larynx is to prevent *choking*. When a person is not eating or drinking, the epiglottis stays upright, keeping the larynx open as part of the airway to the lungs; as soon as swallowing begins, the epiglottis drops like a lid over the larynx, directing food to either side. Closure of the true vocal cords and the false vocal cords just above them also helps protect the airway. The food or drink then passes down the *esophagus* to the stomach.

The secondary function of the larynx is voice production. Air from the lungs passes over the stretched vocal cords. The resultant vibrations are modified by the tongue, palate, and lips to produce *speech*.

Larynx, cancer of

A malignant tumor of the larynx (voice box), often causing persistent hoarseness. Laryngeal cancer represents about 2 percent of all cancers.

CAUSES AND INCIDENCE

The exact causes of this type of cancer are not known, but it occurs most commonly in heavy smokers. Laryngeal cancer is also associated with high alcohol consumption.

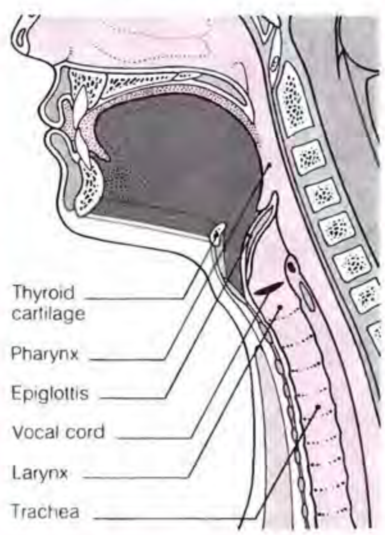
In the US, laryngeal cancer primarily affects people over age 60; it is more common in men than in women.

SYMPTOMS

Hoarseness is the main symptom, particularly when the tumor originates on the vocal cords. A tumor that develops elsewhere in the larynx often passes unnoticed until an advanced stage of the disease, when the tumor causes discomfort in the throat, difficulty breathing and swallowing, and coughing up blood.

DIAGNOSIS

Laryngoscopy (examination of the larynx indirectly with a mirror, or directly with an endoscope) reveals any tumor on the larynx. A *biopsy* (removal of a sample of tissue) is carried out in the hospital using local or general anesthesia to determine whether the growth is benign or malignant, and whether the lining of the larynx shows any signs of early cancerous change.



TREATMENT

If the tumor is discovered when it is still small, the outcome is usually favorable. A small cancer of the true vocal cords has about a 95 percent chance of cure, usually by *radiation therapy* alone.

For larger tumors (and for those that do not respond to radiation therapy) partial or total *laryngectomy* (removal of the larynx) is considered for all but frail or elderly patients. The cure rate of surgery varies according to the site and extent of the tumor. In all cases

LOCATION OF LARYNX

The larynx, commonly called the voice box, is situated deep in the throat between the pharynx and the trachea (windpipe).

DISORDERS OF THE LARYNX

Disorders affecting the larynx (voice box) are common. They usually cause *hoarseness* because they interfere with the functioning of the vocal cords. Other symptoms include difficulty breathing, stridor (a harsh noise on breathing in), a painful throat, and coughing. Persistent hoarseness should be reported to a physician.

CONGENITAL DEFECTS

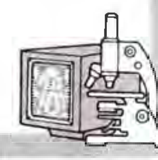
Rarely, a baby is born with a soft, limp larynx, a condition called laryngomalacia. The main signs are stridor and noisy breathing when feeding. The larynx usually attains a normal firmness by age 2.

INFLAMMATION

Laryngitis (inflammation of the larynx) is the most common laryngeal disorder in adults; symptoms are hoarseness, fever, and discomfort in the throat. In children, *croup* (inflammation and narrowing of the air passages) is very common up to age 4. Much rarer is *epiglottiditis* (inflammation of the epiglottis, the flap of cartilage that closes the larynx during swallowing). This is a life-threatening disorder in young children.

TUMORS

Various kinds of benign growth may develop on the vocal cords. The most common is a polyp, a smooth swelling usually caused by smoking, by an infection such as influenza, or by straining the voice. Warts occasionally develop on a child's vocal cords. Both polyps and warts require removal and microscopic analysis to exclude cancer. *Singers' nodes* are small benign growths that can occur on the vocal cords of people who strain their voices. They give the voice a hoarse tone.



Malignant tumors, which cause persistent hoarseness, are usually caused by smoking and/or alcohol use (see *Larynx, cancer of*).

OTHER DISORDERS

A tumor, an infection, or, rarely, throat surgery can damage one or both of the nerves supplying the larynx, causing *vocal cord* paralysis, which results in loss of voice and may interfere with breathing.

INVESTIGATION

Disorders of the larynx are investigated by *laryngoscopy*. Sometimes a *biopsy* sample is taken for pathologic analysis; X rays, especially *tomography*, may provide more information.

after losing part or all of the larynx, the patient must master new techniques for producing speech.

If the tumor has spread throughout the larynx, or to other parts of the throat (or, rarely, other parts of the body), the patient is treated with radiation therapy and *anticancer drugs*. This combination relieves symptoms and often temporarily arrests the progress of the disease.

Laser

A device that produces a concentrated beam of light radiation; laser is an acronym for light amplification by stimulated emission of radiation. A laser beam is parallel, of a single specific wavelength (or sometimes of a narrow band of wavelengths), and coherent (that is, all the crests of the individual waves coincide).

Laser treatment

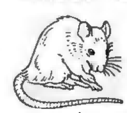
The use of a *laser* beam in a variety of medical procedures.

LOW-INTENSITY TREATMENT

Treatment with low-intensity beams stimulates tissue healing and reduces pain, inflammation, and swelling. It works by improving blood and lymph flow and by reducing the production of *prostaglandins* (hormonelike substances that stimulate inflammation and cause pain). Low-intensity beams are used in the treatment of muscle tears, ligament sprains, and inflamed tendons and joints.

HIGH-INTENSITY TREATMENT

High-intensity treatment destroys cells directly under the beam while leaving adjacent cells undamaged, making it useful in the treatment of some tumors. The beam cuts through tissue and, simultaneously, causes blood clotting, making it a useful surgical tool.



LASERS IN OPHTHALMOLOGY Lasers are used in the treatment of diabetic *retinopathy* (to prevent bleeding from abnormal blood vessels), to prevent and treat retinal detachment (by sealing small tears or areas of degeneration), and to destroy small tumors of the retina. The laser can also be used to make a central hole to restore vision if the lens capsule becomes opaque after *cataract surgery*.

LASERS IN GYNECOLOGY Laser beams are sometimes used to unblock fallopian tubes by removing scar tissue formed after an infection or a *sterilization* procedure. Lasers are used to destroy abnormal cells in the *cervix*.

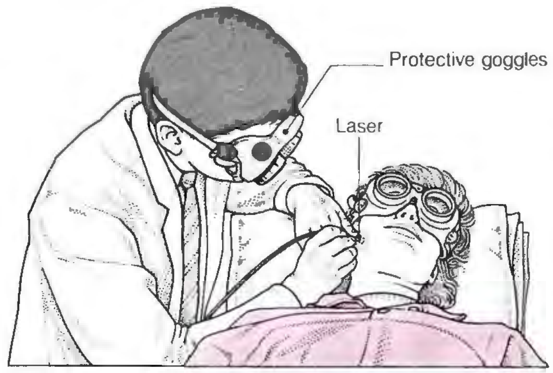
OTHER USES Lasers are commonly used to remove small birthmarks and tattoos; the results are variable. Early malignant tumors of the larynx can be successfully removed without damaging the vocal cords.

Many new applications are being investigated. Potential uses include the removal of atherosclerotic *plaque* from inside arteries. It may also be possible to use lasers to disintegrate bladder and kidney stones, and to remove otherwise inaccessible tumors of the brain and spinal cord. (See also illustrated box, overleaf.)

Lassa fever

A dangerous infectious disease, caused by a virus, that was first reported in 1969. The disease occurs in occasional outbreaks in West Africa; a small number of cases have been imported into the US and Europe.

In Africa, where the virus is harbored by a type of rat, infection may be acquired by inhaling droplets of the rat's urine. Medical and nursing staff are at risk of acquiring the virus from the blood of an infected person or from droplets coughed into the air. No one in the US has ever acquired the disease from an infected person.



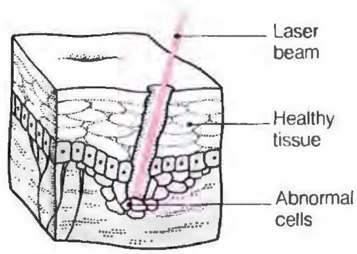
SYMPTOMS AND TREATMENT

After an incubation period of three to 17 days, the illness starts with fever, headache, muscular aches, and a sore throat. Later, severe diarrhea and vomiting develop. In extreme cases, the patient's condition deteriorates rapidly in the second week. About one quarter to one third of hospitalized patients die from the illness.

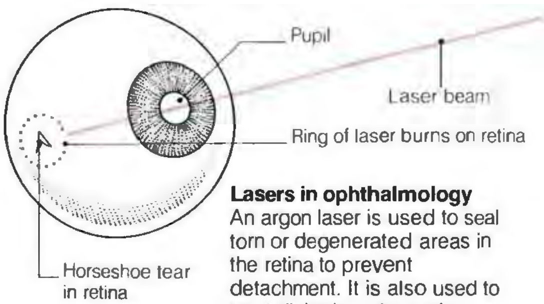
Lassa fever can be diagnosed by a blood test. Infected people must be isolated; they are treated by relief of symptoms and injections of the *antiviral drug* ribavirin and of serum containing *antibodies* that are active against the virus.

USE OF A LASER

The concentrated beam of light released by a laser has a variety of medical purposes. When set to low intensity, the laser works to stimulate tissue healing and reduces pain, inflammation, and swelling. At high intensity, the beam destroys cells on which it is focused while leaving adjacent tissue unharmed. It can also cut through tissues without causing bleeding.



Argon laser
Photocoagulation of blood vessels occurs when the blue-green light from this laser is absorbed by hemoglobin.



Removing skin blemishes
These photographs, taken before and after laser treatment, show removal of a port-wine stain. In some cases, treatment is less successful, leaving scars.

Focused carbon dioxide laser
This laser is ideal for precision cutting or for destroying abnormal cells because its focused beam leaves surrounding areas of tissue intact.

Lasers in ophthalmology
An argon laser is used to seal torn or degenerated areas in the retina to prevent detachment. It is also used to treat diabetic retinopathy.

Lassitude

A term describing a feeling of *tiredness*, weakness, or exhaustion.

Lateral

Relating to, or situated on, one side. Bilateral means on both sides.

Laudanum

A solution of *opium* once used as a sedative and painkiller and in the treatment of diarrhea.

Laughing gas

The popular name for *nitrous oxide*, a gas inhaled in combination with oxygen to produce general *anesthesia*. Laughing gas is so called because of the euphoric effects it produces.

Laurence-Moon-Biedl syndrome

A very rare inherited disorder characterized by increasing *obesity*, *retinitis pigmentosa* that may lead to blindness, mild to moderate *mental retardation*, *polydactyly*, and *hypogonadism*.

The condition is probably caused by a disorder of the hypothalamus (part of the brain that controls the hormone balance). There is no treatment; parents should seek *genetic counseling*.

LAV

Lymphadenopathy-associated virus, a name formerly given to the virus responsible for *AIDS*. The virus was renamed *HIV* (human immunodeficiency virus) in 1986.

Lavage, gastric

Washing out the stomach with water, usually to remove poisons.

HOW IT IS DONE

The patient is placed face down with his or her head below the level of the stomach and turned to one side. A lubricated tube is passed down the esophagus into the stomach and a funnel is attached to the top. (If the patient is not fully conscious, a tube is also passed down the throat into the windpipe to prevent regurgitated water and stomach contents from entering the lungs.) Water is poured into the funnel until the stomach is filled. The top of the tube is then lowered, allowing the fluid in the stomach to drain into a bucket. This process is repeated until the water returns clear. An early sample of fluid from the stomach is kept so that the poison can be analyzed. In certain cases, an antidote to the poison (or a substance that neutralizes the poison) is added to the water or is passed into the stomach after lavage is finished.

Lavage is not used if a corrosive poison has been swallowed because of the risk of the tube perforating tissues. Corrosive acids or alkalis may be diluted by giving large amounts of water or milk (see *Poisoning*).

Laxative drugs

COMMON DRUGS
Bulk-forming *Methylcellulose Psyllium*
Lubricant *Mineral oil*
Saline *Magnesium sulfate Sodium phosphate*
Stimulant *Bisacodyl Senna*
Others *Lactulose*

WARNING
If constipation lasts for more than a week, consult your physician; you may have a serious underlying disorder.

A group of drugs used to treat *constipation*. A high-fiber diet, plenty of liquids, and proper toilet habits may relieve constipation without use of laxative drugs. They may be given to prevent constipation when straining should be avoided (e.g., following childbirth, abdominal surgery, or a *myocardial infarction*). Laxatives are sometimes used to clear feces from the intestine before surgical or investigational procedures.

TYPES

BULK-FORMING LAXATIVES These drugs retain fluid drunk with the laxative, increasing bulk and stimulating propulsion. They increase the volume of feces, making them softer and easier to pass.

STIMULANT LAXATIVES These drugs stimulate the intestinal wall to contract and thus speed up the elimination of feces. Because the feces spend less time in the intestine, less water is reabsorbed into the blood vessels, which helps keep the feces soft.

LUBRICANT LAXATIVES These substances soften and thus facilitate the passage of feces.

SALINE LAXATIVES These drugs increase the concentration of salts within the feces, an action that draws fluids into the intestine from the surrounding blood vessels.

POSSIBLE ADVERSE EFFECTS

Used in excess, laxative drugs may cause diarrhea. Since prolonged treatment may cause dependence on the laxative drug for normal bowel action, laxative use should be stopped as soon as normal habits are reestablished.

Stimulant laxatives and lactulose may cause abdominal cramps and flatulence. Prolonged use of saline laxatives is likely to cause a chemical imbalance in the blood. Lubricant laxatives may coat the intestine and prevent vitamin absorption.

Lazy eye

An ambiguous name for the visual defect that commonly results from *strabismus*. (See *Amblyopia*.)

LD_{50}

The abbreviation for median lethal dose, the amount of a drug needed to kill 50 percent of a group of animals. This dose is determined during experiments carried out to assess the toxicity of new drugs.

Lead poisoning

Swallowing or inhaling lead or lead salts can damage the brain, nerves, red blood cells, and digestive system.

Acute poisoning, which is relatively rare but sometimes fatal, occurs when a large amount of lead is taken into the body over a short period. Chronic poisoning results from small amounts of lead being taken in over a longer period. The body excretes lead very slowly, so it accumulates in body tissues (primarily in the bones). There is evidence that lead poisoning may produce no detectable physical effects but can cause mental impairment, particularly in children.

CAUSES AND INCIDENCE

Lead poisoning is most common in children who have licked or eaten old paint that contains high levels of lead. Adults most at risk include workers in industries such as lead mining and smelting, soldering, demolition, and pottery glazing. Drinking liquor from illicit stills with lead piping or inhaling the fumes from burning battery casings containing lead may also cause lead poisoning. So, too, can eating acidic food or drink that is stored or cooked in lead-glazed or lead-soldered containers.

Almost everybody is exposed to lead from exhaust fumes. In recent years, atmospheric lead levels have decreased as a result of legislation requiring vehicles manufactured after 1975 to run on unleaded gasoline. There is also a legal limit to the amount of lead that paint may contain.

SYMPTOMS AND SIGNS

Acute lead poisoning causes severe, colicky, abdominal pain, diarrhea, vomiting, weakness or paralysis of the limbs, seizures, and sometimes death.

In addition to the symptoms of acute poisoning, chronic poisoning may cause mental disturbances ranging from loss of memory, emotional instability, abnormal behavior, incoordination, and headaches to hallucinations, seizures, blindness, and coma. Seizures, behavioral abnormalities, and coma occur chiefly in children. There may also be *anemia*, loss of appetite, and a blue, black, or gray line along the gum margins.

If symptoms progress as far as seizures and coma, the risk of death is high. Even if the person survives, there is a high probability of permanent brain damage.

DIAGNOSIS

Lead poisoning is diagnosed from the patient's condition and history, and from blood tests to measure lead levels, X rays of the bones and abdomen to reveal lead deposits, and urine tests to measure the level of lead breakdown products.

TREATMENT

Treatment consists of avoiding further exposure to lead. The physician will prescribe *chelating agents* to bind to the lead and help the body excrete it at a faster rate. In mild cases, the chelating agent penicillamine may be used alone. In more severe cases, it may be used in combination with other chelating agents, such as edetate calcium disodium (calcium EDTA) and dimercaprol (BAL).

Learning

A change in behavior as a result of experience. Committing facts to memory, often termed "learning by heart," is a separate process. True learning may not be immediately obvious. Whether or not a person has learned a skill or a fact can be judged only on the basis of his or her performance in a real-life situation.

THEORIES OF LEARNING

According to behavioral theories, all learning in humans and animals occurs by *conditioning*. The simplest form (as described by Ivan Pavlov) is classical conditioning, in which a particular stimulus becomes associated with a particular response. In Pavlov's experiments, a bell was rung every time dogs were presented with food; eventually the dogs salivated in response to the bell alone.

A more sophisticated version of learning, termed operant conditioning by B.F. Skinner, relies on a system of rewards, known as reinforcements. Skinner observed that, if a hungry rat wandering about a cage accidentally bumped into a lever that released a food pellet, it learned to press the lever purposefully. The reinforcement need not appear every time for the rat to continue trying. In the same way, an occasional win on a slot machine is often enough to make people continue to play the game.

Rewards can also be used to encourage the development of new forms of behavior. Behavior "shaping" is the basis of animal training, and is used in dealing with behavioral problems in children and the mentally retarded. It can also apply to family and marital difficulties; partners or family members give each other rewards for desirable behavior. (See *Behavior therapy*.)

Another theory of learning proposes that, with experience, an abstract "cognitive" structure is built on which future decisions and behavior is based. Cognitive theorists believe that the simple responses of

conditioning are not sufficient to explain the ability to cope with new situations or solve new problems. For these processes, the more abstract mental qualities of *memory*, insight, and understanding are necessary.

The behavioral and cognitive approaches are combined in the "social learning theory," which proposes that learning occurs as a result of observation and imitation of the behavior of others.

No one theory can account for the complexities of learning. It is probable that some things are learned automatically, by conditioning, and others by complex thought processes that take account of many facts. Different factors may be more important at different times in a person's life; trial and error and observational learning are particularly important in young children. The ability to learn is also affected by personal interest in a task or subject, past experiences, and anxiety levels. In general, people learn faster when they are given a little at a time to learn; learning slows down as skill improves.

Learning disabilities

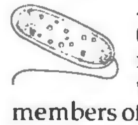
A range of physical and psychological disorders that interferes with learning. Learning disabilities include problems in learning caused by defects in mental activities (such as speech, hearing, and memory), but do not include those due to emotional or environmental deprivation or to poor teaching.

Children of borderline or retarded intelligence have general difficulty learning. So, too, do those with *hyperactivity*, which lowers the attention span. Others have specific problems, such as *dyslexia* (difficulty reading), dyscalculia (inability to perform mathematical problems), or dysgraphia (writing disorders). Some psychologists believe that specific learning difficulties in children of normal intelligence may be caused by forms of *minimal brain dysfunction*, which may be inherited. Attempts to assess and treat such children have so far not been very successful.

Leech

A type of blood-sucking worm with a flattened body and a sucker at each of its ends. Different types live on land or in water. Land leeches inhabit tropical forests. They can work their way through clothing and attach themselves to the ankles and lower legs. Aquatic, blood-sucking leeches live in warm water and attach themselves to swimmers, sometimes penetrating to the bronchi and the esophagus.

Use of a leech to drain blood
Leeches bite painlessly, introducing saliva into the wound before sucking blood. When they are satiated, they drop off. Here, a leech is being used to drain a hematoma (collection of blood) from a person's outer ear following an injury.



TREATMENT OF BITES
Attached leeches should be startled by applying a lighted match, alcohol, salt, or vinegar. They can then be pulled off gently to prevent the mouth parts from staying attached and becoming infected. A styptic pencil helps stop the bleeding after the leech has been removed. *Endoscopy* (use of an internal viewing tube) may be necessary to remove leeches from inside the body.

MEDICAL USES
Leeches were once attached to a patient's skin to "treat" many illnesses ascribed to excess blood. Today, leeches are sometimes used to drain a *hematoma* (a collection of partially clotted blood) from a wound.

Leg, broken

See *Femur, fracture of*; *Fibula*; *Tibia*.

Legionnaires' disease

A form of pneumonia (infection of the lungs) named after an outbreak that caused the death of 29 members of the American Legion who were attending a convention in a Philadelphia hotel in 1976. The bacterium responsible was isolated and the genus named *LEGIONELLA*. Tests identified the causative organism as a common contaminant of water systems that had been responsible for earlier epidemics of pneumonia (the cause of which had not been understood at the time).

CAUSES AND INCIDENCE
The bacterium breeds most readily in warm, moist conditions; in most outbreaks the source of infection has been the water or air-conditioning system in a large public building. Infection follows the inhalation of droplets of heavily contaminated water (from air-conditioning outlets and showers, for example). Elderly people, especially heavy smokers or drinkers, are particularly at risk.

The disease occurs both in localized outbreaks and as isolated cases. Over 700 diagnosed cases are reported in the US each year, but the true incidence is probably much higher. One to 2 percent of hospital cases of pneumonia may be caused by legionnaires' disease.

Control of the disease relies on the disinfection of water systems by chlorination or other means.

SYMPTOMS AND SIGNS
The first symptoms develop within a week of infection; they include headache, muscular and abdominal pain, diarrhea, and a dry cough. Over the next few days pneumonia develops, resulting in a high fever, shaking chills, the coughing up of thick sputum (phlegm), drowsiness, and sometimes delirium. Like other types of pneumonia, the illness usually becomes more severe unless treated. This phase lasts about a week, after which either a gradual recovery takes place or progressively serious breathing problems develop.

DIAGNOSIS AND TREATMENT
The patient is admitted to the hospital, where analysis of a sample of sputum (cultured on special media) or a lung biopsy reveals the microorganism responsible for the pneumonia. If it is *LEGIONELLA PNEUMOPHILA*, the patient is given the antibiotic erythromycin, often intravenously, which usually relieves symptoms quickly. Occasionally another antibiotic drug, rifampin, may be required.

OUTLOOK
The outcome of the disease depends on the age and general health of the patient. Younger people generally recover fully, but a substantial proportion of elderly, unfit people die from the illness. Death is usually due to irreversible lung damage.

Leg, shortening of

Shortening of the leg is usually caused by faulty healing of a fractured femur (thigh bone) or tibia (shin). Other causes are an abnormality present from birth, surgery on the leg, or muscle weakness associated with *poliomyelitis* or some other neurological disorder. Also, a deformity of the hip, knee, or spine may make one leg effectively shorter than the other even if the two are in fact of equal length.

If the difference in leg length exceeds 1.5 inches (4 cm), there is usually a noticeable limp; the resultant stress on the lower spine often causes *back pain*. Placing a raised heel on the shoe of the shortened side is a common remedy for a shortened leg.

Leg ulcer

An open sore on the leg that fails to heal, usually resulting from an inadequate arterial blood supply to or insufficient venous drainage from the area. Elderly people are most commonly affected.

Venous ulcer on leg
This type of ulcer, also known as a stasis ulcer, is caused by impaired drainage of blood from the leg by the veins. It is usually accompanied by edema (fluid accumulation) in the lower leg.

TYPES

Varicose ulcers, which occur mainly on the ankles and lower legs, are caused by valve failure in veins; these ulcers usually appear in conjunction with *varicose veins*.

Bedsores (also called decubitus ulcers) develop on pressure spots on the legs as a result of a combination of poor circulation, pressure, and immobility over a long period.

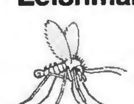
Leg ulcers may also be due to *peripheral vascular disease*, in which fatty deposits on or thickening of the walls of arteries restricts blood supply to the extremities.

Diabetes mellitus, which increases susceptibility to blood vessel disease and skin infection and impairs sensation, may lead to ulcers.

Ulcers may also develop through neglect of an infected small wound. In the tropics, infection with microorganisms can cause *tropical ulcers*.

PREVENTION AND TREATMENT

Prevention is always easier than cure. In general, anyone susceptible to leg ulcers should attempt to avoid obesity, leg injury, and immobility.



Treatment of leg ulcers, which depends on the cause, should be sought at the earliest sign of trouble. If an ulcer is exuding pus, a wet dressing may be applied under a bandage. This dressing should be changed only every three to seven days to avoid removing new skin from the area.

Leiomyoma

A benign tumor of smooth muscle (a type of muscle not under voluntary control). Leiomyomas usually occur in the smooth muscle of the uterus, where they gradually become replaced with fibrous tissue (hence their popular name, *fibroids*). More rarely, leiomyomas develop from smooth muscle in the wall of blood vessels in the skin, where they form tender lumps.

Leiomyomas are usually multiple and, although they are not malignant (cancerous), they may require surgical removal if they cause symptoms.

Leishmaniasis

Any of a variety of diseases affecting the skin, mucous membranes, and internal organs, caused by infection with single-celled parasites called leishmania. The parasites are harbored by dogs and rodents in various parts of the world, and are transmitted from infected animals or people to new hosts by the bites of sand flies.

About 12 million people worldwide are thought to be affected. Leishmaniasis is not contracted in the US, but travelers occasionally contract an infection abroad.

TYPES AND INCIDENCE

The most serious form of leishmaniasis, mainly affecting the internal organs, is called kala-azar or visceral leishmaniasis. It is prevalent in some parts of Asia, Africa, and South America, and also occurs in some Mediterranean countries.

In addition, there are at least three varieties of cutaneous leishmaniasis (mainly affecting the skin), one of which is prevalent in the Middle East, North Africa, and in the Mediterranean; the others occur only in parts of Central and South America.

Travelers can minimize the risk of infection by taking common-sense measures to discourage sand-fly bites (see *Insect bites*).

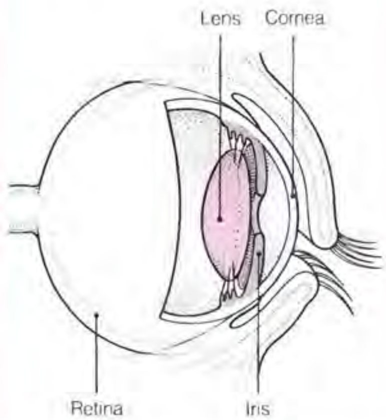
Leishmaniasis ulcer
This skin ulcer, which developed at the site of a sand-fly bite, is typical of the lesions found on the skin of people who are suffering from cutaneous leishmaniasis.

SYMPTOMS

Kala-azar causes a persistent fever, enlargement of the spleen, anemia, and, in the later stages, darkening of the skin. The illness may develop anytime up to two years after the initial infection, and, unless treated, is sometimes fatal.

The cutaneous forms cause the appearance of a persistent ulcer at the site of the sand-fly bite. The ulcer may eventually heal, but can leave an ugly scar. With the South American forms, more extensive tissue damage may occur, often on the face, causing severe disfigurement.

DIAGNOSIS AND TREATMENT



Kala-azar is diagnosed by a *bone marrow biopsy* and a blood test. The cutaneous forms are diagnosed by identifying parasites in scrapings taken from the edge of affected skin patches. All types of leishmaniasis are treated effectively with drugs, such as sodium stibogluconate, which are given by injection into a muscle or into a vein.

Lens

The internal optical component of the eye. Also called the crystalline lens, it is responsible for adjusting focus. This lens is one of two lenses in each eye; the other is the *cornea*, which provides most of the power needed to form an image on the *retina*.

The crystalline lens is situated behind the iris and is suspended on delicate fibers from the ciliary body. It is elastic, transparent, and slightly less

LOCATION OF THE LENS
This elastic and transparent organ is situated behind the iris and is suspended on delicate fibers from the ciliary body. Its full name—the crystalline lens—differentiates it from the cornea (another lens).

convex on the front surface than on the back. Changing degrees of curvature alter the focus of the eye so that an image remains sharp whether a near or a distant object is being viewed (see *Accommodation*).

Opacification of the crystalline lens, from any cause, is called *cataract*. (See also *Lens dislocation*.)

Lens dislocation

Displacement of the eye's crystalline *lens* from its normal position. Lens dislocation is almost always caused by an injury that ruptures some or all of the fibers that connect the lens to the ciliary body. In *Marfan's syndrome*, the fibers are particularly weak and lens dislocation is common.

A dislocated lens may slide downward, causing severe visual distortion or double vision in the affected eye, or it may slip backward into the vitreous humor. A lens dislocated forward usually causes a form of *glaucoma* because of closure of the drainage angle of the eye. If the glaucoma is severe, the lens may be removed. (See also *Aphakia*.)

Lens implant

A plastic prosthesis used to replace the removed opaque lens in *cataract surgery*. There are many different designs, which may be positioned in front of the iris, clipped to the pupil, or held in place behind the pupil by delicate plastic loops.

A lens implant usually provides excellent distance vision without glasses. However, most people need reading glasses or bifocal lenses for close vision after the implant.

Lentigo

A flat, discolored area of skin similar to a freckle. Lentigines (the plural of lentigo) are usually light brown and may occur singly or in groups. Unlike freckles they are as common on covered as on exposed parts of the body, and they do not fade in winter. Lentigines are more common in middle-aged and elderly people, especially those who have been exposed to a lot of sun.

Lentigines are harmless and no treatment is necessary. If raised, darker brown areas appear within them, a physician should be consulted; there is a danger that these areas could develop into malignant melanomas (see *Melanoma, malignant*).

Leprechaunism

A very rare congenital disorder in which affected infants have elfin faces, with wide-set eyes, large lips, and large, low-set ears; they also have large hands and feet. Hormonal imbalances cause enlargement of the penis in males and the clitoris and breasts in females, as well as hirsutism (hairiness). Most babies who have leprechaunism die in the first weeks or months of life.

Leprosy

A chronic bacterial infection, also known as Hansen's disease, that damages nerves, mainly in the limbs and facial area, and may also lead to skin damage. Untreated leprosy can have severe complications, which include blindness and disfigurement. Contrary to popular belief, it is not highly contagious.

Performing a lens implant
The photograph shows an operation in which the plastic lens implant is being inserted immediately behind the iris into position over the pupil of the eye.

CAUSES

Leprosy is caused by a bacterium, *MYCOBACTERIUM LEPRAE*, spread in droplets of nasal mucus. A person is infectious to others only during the first stages of the disease. Only people living in prolonged close contact with the infected person are at risk of infection. This, along with the fact that only 3 percent of the population is susceptible to leprosy, means that there is no justification for the practice (still prevalent in some countries) of isolating people with the disease.

INCIDENCE

Worldwide, there are about 20 million sufferers from leprosy, mostly in Asia, Central and South America, and Africa. Probably fewer than 20 percent of these have access to treatment. In the US, there are now more than 4,000 known cases, mainly in California, Florida, Hawaii, Louisiana, New York, and Texas; three quarters of the people affected were born outside the US.

SYMPTOMS AND SIGNS

Leprosy has a very long incubation period—about three to five years. Most of the destructive effects of the bacteria on nervous tissue are caused not by bacterial growth but by a reaction of the body's *immune system* to the organisms as they die. There are two main types of the disease. In lepromatous leprosy, damage is widespread, progressive, and severe. Tuberculoid leprosy is milder.

Initially, damage is confined to the peripheral nerves (those supplying the skin and muscles). There is lightening or darkening of skin areas, with associated reduced sensation and reduced sweating. As the disease progresses, the peripheral nerves swell and become tender. Hands, feet, and facial skin eventually become numb and muscles become paralyzed.

Complications include loss of all sensation in the hands and feet, so that accidental burns or injuries are not noticed, leading to extensive scarring or even to loss of fingers or toes. Muscle paralysis can lead to further deformity. Damage to the facial nerve means that the eyelids cannot be closed; the cornea dries and ulcerates, leading to blindness. Alternatively, direct invasion by bacteria may lead to inflammation of the eyeball, again leading to blindness. The disability caused by the combined effects of blindness and loss of touch sensation is extremely severe.

Cartilage and bone in the nose are often eroded, and bones elsewhere in

the body may be destroyed. In addition, the testes may atrophy, leading to sterility.

DIAGNOSIS AND TREATMENT

Early diagnosis of the disease is essential to prevent permanent disfigurement and disability. A provisional diagnosis is made from a physical examination of the patient; the presence of the bacteria is confirmed by a skin *biopsy* (removal of a sample of tissue for analysis).

Treatment is with the drug dapsone, which kills most of the causative bacteria within a few days. Any damage that has already occurred, however, is irreversible. Patients cease to be infectious soon after treatment starts. To prevent a relapse, use of the drug needs to be continued for at least two years after the last signs have disappeared.

Prevention of damage to the feet and other insensitive areas—through the use of proper footwear and health education—is very important. Plastic surgery may be helpful for facial deformities. Nerve and tendon transplants may improve the function of damaged limbs.

In the US, patients are eligible for treatment by the Public Health Service. There are special clinics and hospitals in different areas.

OUTLOOK

Resistance to dapsone is becoming more common worldwide; other curative drugs, such as rifampin and clofazimine, are much more expensive. With no vaccine and so many sufferers in poor countries, the battle against leprosy has only just begun.

Leptospirosis

A rare disease caused by a spirochete (spiral-shaped) bacterium harbored by rodents and excreted in their urine. It is also known as Weil's disease. About 100 cases of leptospirosis, leading to a few deaths, are reported in the US each year.

SYMPTOMS

After an incubation period of one to three weeks, there is an acute illness with fever, chills, an intense throbbing headache, severe muscle aches, eye inflammation, and a skin rash. In most cases, the kidneys are affected, often severely. Liver damage leading to jaundice is also common.

TREATMENT

Antibiotics are effective against the spirochetes. In about one third of all cases the condition improves promptly. However, many patients suffer a more persistent illness in which kidney and liver function recover only slowly. In these cases, the nervous system may also be affected, often producing signs of *meningitis* (inflammation of the membranes covering the brain and spinal cord).

Lesbianism

Female homosexuality. According to Alfred Kinsey's studies carried out in the 1940s, about 5 percent of women are entirely lesbian in their sexual activity, although some 15 percent have had, by the age of 45, a homosexual experience. Lesbianism is less common than male homosexuality (see *Homosexuality, male*), but relationships tend to be more stable and often are lifelong. Masturbation, oral sex, and mutual rubbing of the clitoris are the usual means of reaching orgasm.

Lesion

An all-encompassing term for any abnormality of structure or function in any part of the body. The term may refer to a wound, infection, tumor, abscess, or chemical abnormality.

Lethargy

A feeling of *tiredness*, drowsiness, or lack of energy.

Leukemia

Any of several types of cancer in which there is usually a disorganized proliferation of white *blood cells* in the bone marrow (from which all blood cells originate). The production of red blood cells, platelets, and normal white blood cells is impaired as they are crowded out from the marrow by the leukemic cells.

Other organs, such as the liver, spleen, lymph nodes, testes, or brain, may cease to function properly as they become infiltrated by the leukemic cells. The number of leukemic cells circulating in the blood may be high.

Leukemias are classified into acute and chronic types; acute leukemia generally develops more rapidly than chronic leukemia. They are also classified according to the type of white cell that is proliferating abnormally. If the abnormal cells are derived from lymphocytes or their immature precursors (lymphoblasts), the leukemia is called lymphocytic or lymphoblastic leukemia. If the abnormal cells are derived from other types of white blood cells or their precursors, it is called myeloid, myeloblastic, or granulocytic leukemia.

There are about 13 new cases of leukemia per 100,000 annually in the US, leading to about six to seven deaths per 100,000. (See also *Leukemia, acute*; *Leukemia, chronic lymphocytic*; *Leukemia, chronic myeloid*.)

Leukemia, acute

A type of leukemia in which the white blood cells produced in excess within the bone marrow are immature cells called blasts. Untreated, acute leukemia can be fatal within a few weeks to months. Treatment today can often prolong life and may even provide a complete cure.

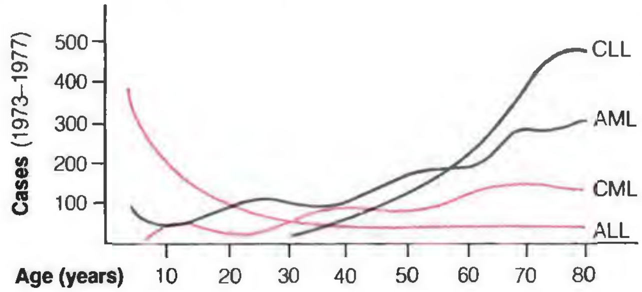
The abnormal cells may be of two types: lymphoblasts (immature *lymphocytes*) in acute lymphoblastic leukemia, and myeloblasts (immature forms of other types of white cell) in acute myeloblastic leukemia. Various subtypes are recognized according to the nature of the abnormal cells.

INCIDENCE AND CAUSES

About six or seven new cases of acute leukemia are diagnosed annually per 100,000 people in the US. The incidences of the two main types (acute lymphoblastic leukemia and acute myeloblastic leukemia) at different ages are shown on the next page.

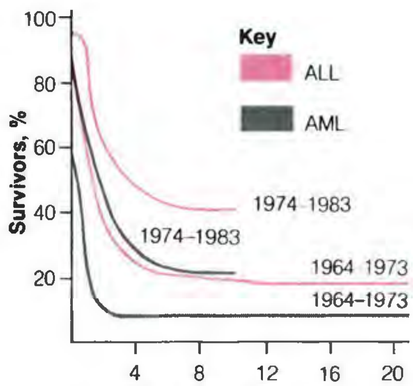
Both types seem to result from a single white cell mutating (altering in its genetic structure). The cell undergoes an uncontrolled series of divisions until billions of copies of the abnormal cell are present in the bone marrow, blood, and other tissues.

There are a number of possible causes for the original mutation. One type of acute lymphoblastic leukemia is thought to be caused by a virus similar to the one that causes *AIDS*. Exposure to certain chemicals (such as benzene and some anticancer drugs) and to atomic radiation or radioactive leaks from nuclear reactors can be a cause. Inherited factors may play a part; there is an increased incidence in people with certain genetic disorders (such as *Fanconi's anemia*) and chromosomal abnormalities (such as *Down's syndrome*). People with certain other blood disorders, such as chronic myeloid leukemia and primary *polycythemia*, are also at increased risk.



SYMPTOMS AND SIGNS

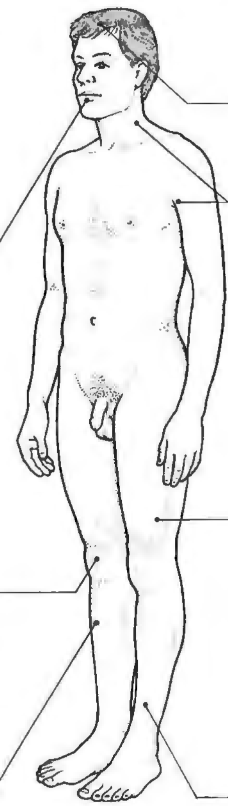
The symptoms and signs of both types of acute leukemia are caused by overcrowding of the bone marrow by blasts and by infiltration of various organs by the abnormal cells. The overcrowding causes the marrow's failure to produce normal blood cells of all types (see box, next page).



LEUKEMIA

In all forms of leukemia, abnormal white cells proliferate in the bone marrow. There are four main types—acute lymphoblastic leukemia (ALL), acute myeloblastic leukemia (AML), chronic lymphocytic leukemia (CLL), and chronic myeloid leukemia (CML). Their incidence varies with age (see right). The acute types have a rapid onset. There is a risk of death from overwhelming infection or blood loss, but modern treatment has greatly improved survival rates (below) and may bring a cure.

The chronic forms of leukemia progress much more gradually but are essentially incurable.



Incidence
The graphs show how the four main types of leukemia vary in incidence with age. Acute lymphoblastic leukemia (ALL) is the common type in children, chronic lymphocytic leukemia (CLL) is the most common after 40.

Survival rates for acute leukemia
The graphs show survival rates for acute lymphoblastic leukemia (ALL) and acute myeloblastic leukemia (AML) for cases diagnosed in the years 1964 to 1973 and 1974 to 1983. The improved survival rates are the result of better treatment.

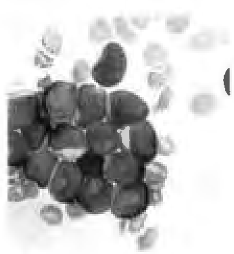
Symptoms of acute leukemia
Symptoms are caused partly by the abnormal white cells crowding out the bone marrow (so that it fails to produce sufficient normal blood cells of all types) and partly by the invasion of other body organs by abnormal cells.

Headache
Headache may be caused by anemia or by abnormal white cells affecting the nervous system

Gum bleeding
This results from insufficient production of platelet cells by the bone marrow; platelets are needed for the arrest of bleeding.

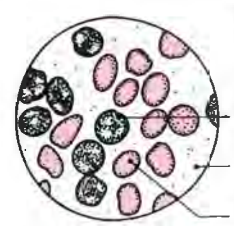
Enlarged lymph nodes
The lymph nodes in the neck, armpits, and groin may be swollen with huge numbers of immature white cells. The liver, spleen, and testes may also be swollen

Anemia
Anemia develops if there is insufficient production of red blood cells by the bone marrow. Anemia causes tiredness, breathlessness on exertion, and pallor.



Bone tenderness
This may be felt as the bone marrow becomes packed with immature white cells

Infections
White blood cells play a major part in the defense against infection. However, in acute leukemia, only immature, nonfunctioning white cells are made, so the patient may suffer from repeated chest or throat infections, herpes zoster, or skin and other infections.

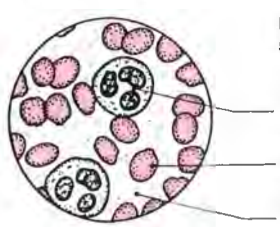


Frequent bruising
Reduced numbers of platelets may lead to bleeding points in the skin and bruising after mild trauma

HOW LEUKEMIA ATTACKS THE BODY

Leukemia is a form of cancer, but with the abnormally growing cells—mutated white blood cells—scattered throughout the body in bone marrow, rather than grouped into a single tumor. The abnormal cells may spill into the blood and may infiltrate and interfere with the function of other organs. But worse, the abnormal cells "take over" the marrow and prevent it from making enough normal blood cells—including normal white cells, red cells, and platelets. This leaves the sufferer highly susceptible to serious infections, anemia, and bleeding episodes.

Cell photograph
Shown is blood in acute leukemia. The large cells are abnormal, immature white cells; the smaller, paler cells are red blood cells.



Blood smear in leukemia

Abnormal white cells—susceptibility to infection

Fewer platelets—bleeding tendency

Fewer red cells—anemia

Appearance of blood in leukemia
In leukemia (above), the blood usually contains many abnormal white cells, and fewer red cells and platelets.

Normal blood smear

White cells fight infection

Red cells transport oxygen

Platelets help blood clot

Normal appearance of blood
In a normal blood smear (left), there are large numbers of red cells, many platelets, and a few white cells.

DIAGNOSIS
The diagnosis of acute leukemia is based on a *bone marrow biopsy* that confirms an abnormal number of blast cells. The blast cells are sometimes also seen in the blood. When acute lymphoblastic leukemia is diagnosed, a *lumbar puncture* is usually performed to examine the cerebrospinal fluid for the presence of blast cells.

TREATMENT
Treatment includes giving the patient transfusions of blood and platelets, and the use of *anticancer drugs* to kill the leukemic cells. These drugs tend to make the patient even more susceptible to infection, so powerful antibiotics may also be given.

From the beginning of treatment, it is common for the patient to have inserted into a large vein near the heart a catheter (tube) through which all drugs and transfusions are given. Treatment of leukemic cells in the cerebrospinal fluid is accomplished by the direct injection of drugs into the fluid and by subsequent *radiation therapy* to the head and spinal cord. Radiation therapy is more commonly given in the treatment of acute lymphoblastic leukemia than for acute myeloblastic leukemia.

The course of drug treatment may last for many weeks. When there is no evidence of leukemic cells in the blood or bone marrow, a state of remission is said to have been achieved. However, without repeated courses of treatment, the leukemia often relapses (returns). For this reason, the use of drugs is usually continued for many weeks after remission.

If the leukemia relapses after the first remission, *bone marrow transplantation* may be considered.

OUTLOOK
The outlook for people with acute lymphoblastic leukemia is generally better than it is for acute myeloblastic leukemia, and it is better for children than for adults. Survival rates are shown in the illustrated box.

Leukemia, chronic lymphocytic

A type of leukemia caused by proliferation of mature-looking *lymphocytes* (a type of white *blood cell* important in the body's *immune system*). Although incurable, the disease is not invariably fatal.

INCIDENCE AND CAUSES
There are about four new cases of chronic lymphocytic leukemia annually per 100,000 people in the US. Nearly all patients are over 50. The cause of the disorder is unknown.

SYMPTOMS AND SIGNS
Symptoms develop slowly, often over many years. Many cases are discovered by chance when a blood test is performed. In addition to features common to acute forms of leukemia (see opposite), symptoms and signs may include an enlarged liver and spleen, persistent raised temperature, and night sweats.

DIAGNOSIS AND TREATMENT
Chronic lymphocytic leukemia is diagnosed by finding large numbers of lymphocytes, all of the same type, in the blood and on a *bone marrow biopsy*. The severity of the disease is assessed by the degree of liver and spleen enlargement, anemia, and lack of platelet cells in the blood. Often, no treatment is required if the disease is mild. If more severe, *anticancer drugs* are given by mouth, sometimes combined with *radiation therapy*. Other measures include transfusions of blood and platelets, antibiotics to combat infection, and injections of *immunoglobulins* to boost the patient's immune system.

OUTLOOK
The progression of chronic lymphocytic leukemia is slow. More than half of the patients survive for five years from the time of diagnosis. Eventually, death usually results from overwhelming infection.

Leukemia, chronic myeloid

Also known as chronic granulocytic leukemia, chronic myeloid leukemia results from uncontrolled proliferation of the class of white *blood cell* called granulocytes. Large numbers of these cells, in various stages of maturity, appear in the blood.

INCIDENCE AND CAUSES
There are about two new cases of chronic myeloid leukemia diagnosed per 100,000 people in the US each year. Cases occur mainly among middle-aged to elderly people.

The cause of chronic myeloid leukemia is not known. However, in most cases, the patient's cells contain a specific *chromosomal abnormality* known as the Philadelphia chromosome. Part of one chromosome is attached to another chromosome.

SYMPTOMS
The disease usually has two phases—a chronic phase that may last several years and a more malignant phase in which large numbers of immature granulocytes are produced.

During the chronic phase, symptoms develop slowly; they may include tiredness, fever, night sweats, and weight loss. If the number of white cells in the blood rises very high, the blood may become excessively viscous (sticky), impairing the supply of oxygen to various organs. The effects can include visual disturbances and abdominal pain due to death of tissues within the spleen. *Priapism* (persistent, painful erection of the penis) is sometimes a feature.

The symptoms of the second phase are like those of acute forms of leukemia (see opposite).

DIAGNOSIS AND TREATMENT
The disease is sometimes not apparent until the patient has a blood test for some other reason. The diagnosis is made from the increased numbers of granulocytes in the blood and in the bone marrow (as detected by *bone marrow biopsy*). The presence of the Philadelphia chromosome, found by *chromosome analysis*, may help establish the diagnosis.

Treatment of the chronic phase includes the use of *anticancer drugs*. When the disease transforms into the acute phase, treatment is similar to that given for acute leukemia. If the number of white cells rises very high, the cells may be removed from the patient using a machine known as an apheresis machine.

Treatment of the acute phase is seldom successful; the patient usually dies of bleeding or infection. *Bone marrow transplantation* is now being used in an attempt to cure patients while the condition is still in the chronic phase.

OUTLOOK
The average survival time from first diagnosis is about three years. However, about one fifth of patients survive for 10 years or more. A successful bone marrow transplantation may improve the outlook, but is not without its own risks.

Leukocyte

Any type of white *blood cell*.

Leukodystrophies

A rare group of inherited childhood diseases in which the *myelin* sheaths that form a protective covering around many nerves are destroyed.

Diseases included in this group are metachromatic leukodystrophy (which causes impaired speech, blindness, paralysis, dementia, and death within a few years), Krabbe's disease (which results in blindness, deafness, seizures, paralysis, and death within one year), and Merzbacher-Pelizaeus disease (which causes progressive

incoordination, speech difficulties, paralysis, and mental deterioration from infancy until death, which occurs in early childhood).

Leukoplakia

Raised, white patches on the mucous membranes of the mouth or the vulva (the area around the opening to the vagina). Leukoplakia is due to the thickening of tissue and is most common in elderly people.

CAUSES

Leukoplakia in the mouth, which is most common on the tongue, is usually due to tobacco-smoking (particularly pipe-smoking) or to the rubbing of a rough tooth or denture. It is not known what causes the condition to develop on the vulva.

SYMPTOMS AND TREATMENT

The patches, which develop slowly, cause no discomfort and are usually harmless. Occasionally, they result from a malignant change in the affected tissue. For this reason, leukoplakia should always be reported to a physician.

Leukoplakia in the mouth may clear up once the cause has been treated. If the condition persists, the patches are removed using a local anesthetic. Leukoplakia of the vulva is treated in the same way. The removed tissue is examined microscopically for any signs of malignant change. (See also *Mouth cancer*; *Vulva, cancer of*.)

L

Leukorrhea

See *Vaginal discharge*.

Levodopa

A drug used in the treatment of *Parkinson's disease*, a neurological disorder caused by deficiency of the chemical dopamine in part of the brain.

HOW IT WORKS

Levodopa is absorbed into the brain and converted into dopamine. The drug is usually given with an enzyme (such as carbidopa) that reduces the amount of levodopa broken down by the liver before it can reach the brain. This allows a lower dose of levodopa to be given and thereby reduces the risk of adverse effects.

POSSIBLE ADVERSE EFFECTS

Adverse effects include nausea, vomiting, nervousness, and agitation. Prolonged use often impairs the effectiveness of treatment or increases the severity of adverse effects.

Levonorgestrel

A *progesterone drug* used in some *oral contraceptive* preparations.

Levothyroxine

A synthetic drug preparation related to thyroxine, the most important of the *thyroid hormones*.

LH

The abbreviation for luteinizing hormone—a *gonadotropin hormone* produced by the *pituitary gland*.

LH-RH

The abbreviation for *luteinizing hormone-releasing hormone*. This hormone is released by the *hypothalamus*.

Liability insurance, professional

A protection against lawsuits, traditionally purchased by physicians. As a result of the tremendous growth in the number of suits and size of awards in the 1970s and 1980s, coupled with less stringent interpretation of negligence, insurance companies have dramatically raised premiums, restricted policies to low-risk medical specialties, and, in some cases, stopped providing liability insurance.

Libido

Sexual desire. Libido is a healthy, normal feeling, especially strong in youth and gradually fading with age. Loss of libido is a symptom of numerous physical illnesses, and of *depression*, *drug abuse*, and *alcohol dependence*.

The libido theory of Sigmund Freud describes sexual development in childhood in terms of oral, anal, and genital stages (representing the areas of the body toward which a child's attention is directed at different ages). Freud believed that certain neurotic disorders and abnormal sexual behaviors were due to fixation of libido at one of these stages. By contrast, directing the libido (or "love energy") away from oneself to other people or objects was seen as a sign of maturity. (See also *Narcissism*; *Sexual desire, inhibited*.)

Lice

Small, wingless insects that feed on human blood. There are three species: *PEDICULUS HUMANUS CAPITIS* (the head louse), *PEDICULUS HUMANUS CORPORIS* (the body louse), and *PHTHIRUS PUBIS* (the crab, or pubic, louse). All lice have flattened bodies and measure up to one eighth of an inch (3 mm) across.

HEAD LICE

These lice live on and suck blood from the scalp. They leave red spots that itch intensely, leading to scratching, *dermatitis* (skin inflammation), and *impetigo* (a bacterial infection of the skin). The females lay a daily batch of tiny, pale eggs (nits) that are attached to hairs close to the scalp; the nits hatch in about seven days. The adults may live for several weeks.

Head lice affect all social classes. Children are most affected, women occasionally, and men rarely. The lice are spread by direct (although not necessarily head-to-head) contact.

Lotions containing malathion or carbaryl kill lice and nits rapidly. The lotion should be washed off 12 hours after application, and a fine-toothed comb run through the hair to remove dead lice and nits. Shampoos containing malathion or carbaryl are also effective if used repeatedly over several days. Combs and hairbrushes should be treated with very hot water to kill any attached eggs.

BODY LICE

These lice live, and lay eggs, on clothing next to the skin. The lice visit the body only to feed. Body lice transmit epidemic *typhus* and *relapsing fever*, which are rare today, but, in the past, were common in areas affected by war or natural disaster.

Body lice affect only people who rarely change their clothes. These lice can be killed by placing infested clothes in a hot dryer for five minutes, by washing them in very hot water, or by burning them.

CRAB LICE

These lice live in pubic hair or, more rarely, armpits or beards. They are usually passed from one person to another during sexual contact. (See *Pubic lice*.)

Licensure

Physicians must be licensed by the state in which they practice. The qualifications for licensure vary from state to state. In general, however, a physician must graduate from an accredited medical or osteopathic school, complete one year of residency training (internship), and pass a state's licensing examination. Graduates of foreign medical schools may be licensed if they meet the state's requirements for residency training and pass its licensing examination. Only a state licensing board has the legal power to restrict or suspend a physician's license to practice.

Lichenification

Thickening and hardening of the skin caused by repeated scratching. Lichenification is often the result of

trying to relieve the intense itching of disorders such as atopic *eczema* or *lichen simplex*.

Lichen planus
A common skin disease of unknown cause that usually affects middle-aged people. Small, shiny, extremely itchy, pink or purple raised spots appear on the skin of the wrists, forearms, or lower legs. There is often a lacy network of white spots covering the inside lining of the cheeks.

Treatment is with *corticosteroid drugs*. Creams, sometimes supplemented by injections in severe cases, are used to treat the skin rash and tablets are used to treat lichen planus in the mouth. Most cases clear up within 18 months.

Lichen simplex
Patches of thickened, itchy, and sometimes discolored skin caused by repeated scratching. Typical sites are the neck, wrist, arm near the elbow, and ankles. Lichen simplex is most common in women and is psychological in origin; sufferers often rub the patches (without being aware of what they are doing) when agitated or under stressful circumstances.

A cycle is established in which repeated scratching to relieve itching leads to more skin thickening and itching, which in turn requires yet more scratching.

Treatment is with *antihistamine* tablets and *corticosteroid* creams to relieve the itching and thus break the cycle. This permits the disorder to subside and the drug treatment to be effective.

Lid lag
A momentary delay in the normal downward movement of the upper eyelids that occurs when the eye looks down. A characteristic feature of *thyrotoxicosis*, lid lag usually occurs in conjunction with *exophthalmos* (protrusion of the eyeball).

Lidocaine

ANTIARRHYTHMIC LOCAL ANESTHETIC

Liquid Injection Cream Ointment

Ointment available over-the-counter

Available as generic

A local anesthetic (see *Anesthesia, local*). Lidocaine is used to relieve the pain and irritation caused by *sunburn* or *hemorrhoids*. It is given to numb tissues before minor surgical procedures and as a *nerve block* (to numb the area supplied by a particular nerve). Lidocaine is also used topically to relieve discomfort during the insertion of a *catheter* or an *endoscope*.

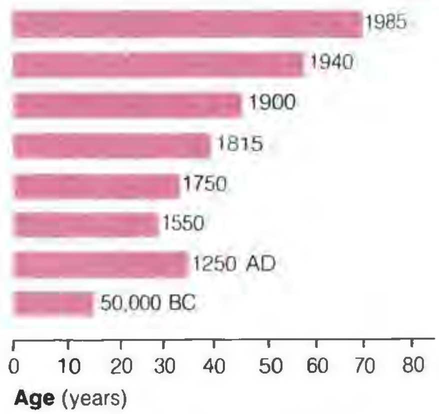
Lidocaine is given by intravenous injection after *myocardial infarction* to reduce the risk of *ventricular fibrillation* (an irregularity of the heart beat).

POSSIBLE ADVERSE EFFECTS

High doses given by injection occasionally cause nausea and vomiting.

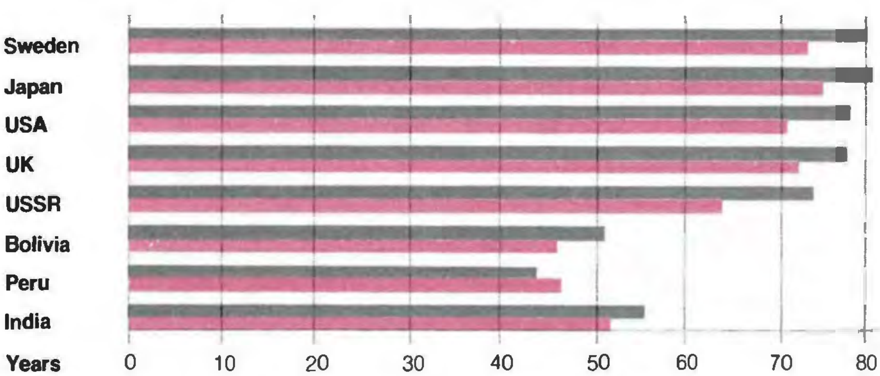
Life expectancy
The number of years a person can expect to live. In most Western countries, life expectancy at birth is about 70 years for men and 75 years for women. This sex difference is thought to be due to the fact that many more men than women smoked in the first half of this century. However, since then, the smoking sex ratio has evened out and there has been an increase in deaths from lung cancer in women. As a result, the sex difference in life expectancy is narrowing.

The expected age of death becomes greater the longer a person lives, so someone aged 70 may have a life expectancy of 15 years; even a 100 year old can expect to live a year or two.



LIFE EXPECTANCY AND LIFE SPAN

Life expectancy should be distinguished from life span. Since records began, some old people have lived well beyond 70 years. Gerontologists agree that, in the absence of disease, the average normal life span is about 85 years (see *Aging*).



The natural life span is determined largely by genetic factors. People whose parents and grandparents lived to be 90 are likely to live to about this age. However, the extent to which individuals fulfill their genetic potential is affected by environmental factors, such as nutrition and accidents, as well as by disease.

The proportion of the population that attains its natural life span depends on the general health of that population, so life expectancy is a good means of comparing the state of health in different countries or in different parts of the same country.

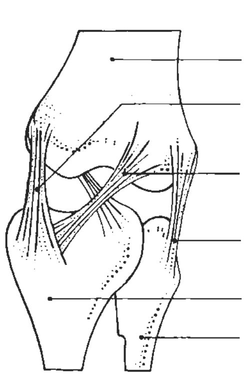
Life expectancy at birth may be as low as 35 years in some developing countries. However, although statistically accurate, this figure is misleading because it reflects the high mortality during infancy in these countries. Records show that life expectancy at age 40 is not greatly different around the world.

Life expectancy through history
Advances in medicine have dramatically increased life expectancy at birth. Life expectancies in England fluctuated around age 30 to 35 for many centuries, before reaching 40 in the early 19th century and climbing to over 70 in recent decades. Most developed countries follow a similar pattern.

Gender and life expectancy
In rich and poor countries, life expectancy at birth is generally higher for females (gray bars) than males (red). India is an exception.

Nationality and life expectancy
Average life expectancy at birth in most developed countries is now 70 or more; in developing countries it is 40 to 55.

Life support



The process of keeping a person alive by artificially inflating the lungs (see *Ventilation*) and, if necessary, maintaining the heart beat with a *pacemaker*.

Ligament

A tough band of white, fibrous, slightly elastic tissue. Ligaments are important components of joints, binding together the bone ends and preventing excessive movement of the joint. Ligaments also support various organs, including the uterus, bladder, liver, and diaphragm, and help maintain the shape of the breasts.

FUNCTION OF LIGAMENTS

These tough, fibrous bands of tissue bind bone ends together.

Torn ligament
A common injury of football and soccer players, torn knee ligaments usually result from twisting stress when the knee is turned while weight is on that leg.

INJURY

Ligaments, especially those in the *ankle joint* and *knee*, are sometimes damaged by injury. Minor sprains are treated with ice, bandaging, and sometimes physical therapy. If the ligament is torn, the joint is either immobilized by a plaster cast to allow healing or repaired surgically.

Ligation

The surgical process of ligating (tying off) a blood vessel to prevent bleeding, or a duct to close it, with a length of thread or other material. The term is used in *tubal ligation*, a form of sterilization in which the fallopian tubes are tied off.

Ligature

A length of thread or other material used for *ligation* (tying off) of a blood vessel or duct.

Lightening

A feeling experienced by many pregnant women when the baby's head drops into the pelvic cavity. Lightening usually occurs in the last three weeks of pregnancy, leaving more space in the upper abdomen and relieving pressure under the ribs, making breathing easier.

Light treatment

See *Phototherapy*.

Limb, artificial

Most artificial legs and arms, known medically as limb prostheses, are fitted to replace all or part of a limb amputated because of disease or severe injury (see *Amputation*). In some cases, however, they are required as a substitute for limbs missing from birth (see *Limb defects*).

To be acceptable, an artificial limb must restore as much as possible the function of the lost limb, be light enough to be worn comfortably, be easy to put on and take off, and look as natural as possible.

CONSTRUCTION AND MATERIALS

Artificial limbs can be obtained ready-made. However, for the best results, they should be constructed by a prosthetist (a specialist in making and fitting artificial limbs) to suit the individual's needs. A mold taken from the stump of the missing limb is used to make a socket for the top of the prosthesis into which the stump can fit closely and comfortably. The socket, made from wood, leather, or plastic, is attached to the stump by suction or by straps.

Each main part of an artificial limb replacing the natural lower leg, thigh, forearm, or upper arm is called an extension. The extension consists of an inner strut made of various materials; it is covered by foam rubber shaped to match the corresponding part of the natural limb. This unit is enclosed by an outer shell of metal, wood, or leather.

Artificial joints are usually made of plastic and metal and today incorporate sophisticated mechanisms that rotate the wrist, stabilize the knee joint, and control the length of stride.

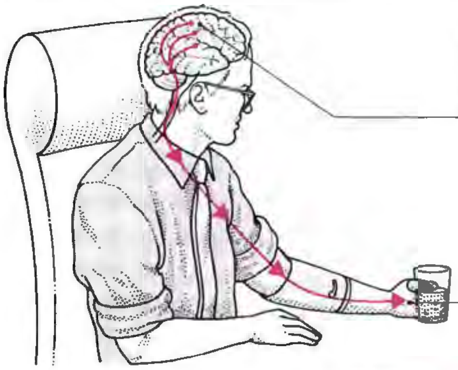
Generally, artificial legs are more useful than artificial arms because the straightforward movements of the natural leg are easier to duplicate than the wide-ranging, often intricate, movements of the arm (especially the hand). Even so, the design of artificial hands is now extremely advanced. Electronic circuitry has been developed to pick up muscle and nerve impulses reaching the stump from the spinal cord. The circuitry transforms the impulses into movements of the prosthesis. People with an artificial arm or hand may have several prostheses (e.g., one with a glove for social use and others with a claw or powered attachments for working).

Limb defects

Incomplete development of one or more limbs at birth. Sometimes an entire limb is missing, sometimes only the hand or foot, or the upper or lower half of a limb, is missing. In other people, hands, feet, or tiny fingers or toe buds are attached to limb stumps or grow directly from the trunk (a condition called phocomelia). Any combination of limbs may be affected.

Limb defects are rare; the incidence in the US is only about one in every 2,000 live births. The sedative drug *thalidomide* is known to have caused phocomelia when taken during pregnancy. (This drug was never sold in the US.) Otherwise, apart from those cases in which limb defects are inherited or part of a syndrome, their cause remains unknown.

MANAGEMENT

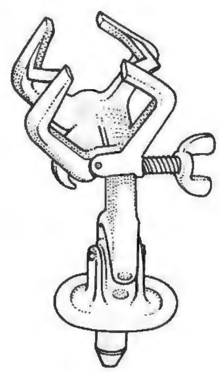


A child with a limb defect usually needs to attend a specialized center. Pediatricians, occupational therapists, psychologists, social workers, and other experts will treat the condition and advise on the child's development. A prosthetist will fit an artificial limb (see *Limb, artificial*) and teach the child how to use it.

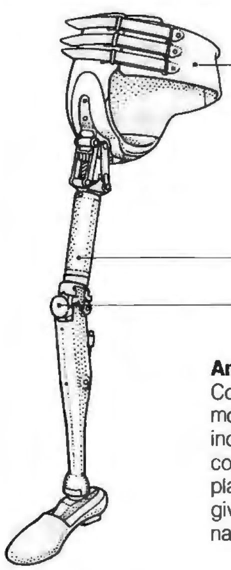
Limbic system

A ring-shaped area in the center of the brain that consists of a number of connected clusters of nerve cells. The limbic system plays a role in the *autonomic nervous system* (which automatically regulates body functions), in the emotions, and in the sense of smell. The limbic system is extensive, and the different substructures within it

TYPES OF ARTIFICIAL LIMBS

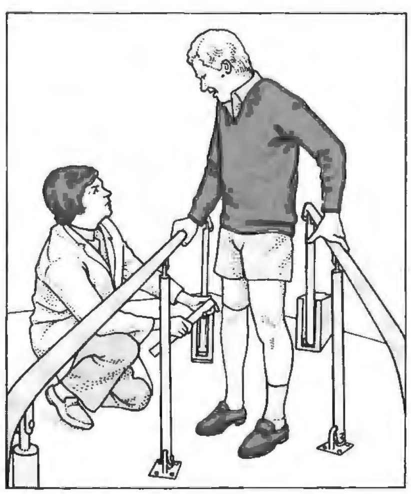


Different types of artificial limbs must restore as much as possible the function of the lost limb, be light enough to be worn comfortably, be easy to put on and take off, and look as normal as possible. Although ready-made prostheses are available and can be quite effective, the best artificial limbs are constructed by specialists and specially adapted to meet an individual's particular needs.



Initiating movement
The nerve impulses that move the prosthesis originate in the brain and pass via the spinal cord to the stump

Prosthetic movement
Electronic circuitry in the prosthesis picks up nerve impulses in the stump and causes the prosthesis to move in a near-normal way



Artificial hands
Many devices are available. The prosthesis on the left is servo-mechanism-controlled and battery-operated; it allows finger and wrist movements. The shovel grip is a prosthesis designed to meet a specific need, as are precision tweezers and golf-club grips.

An artificial leg
Components can be modified for each individual. They are covered with a plastic material to give the limb a natural appearance.

Training with prostheses
Special walking classes enable patients to adjust to their new limbs.

have been named (for example, the hippocampus, the cingulate gyrus, and the amygdala).

Much of our knowledge of the limbic system comes from the observation and investigation of the behavior of animals and people known to have damage to or disease in the limbic area of the brain. The most commonly observed effects are abnormalities of emotional response, such as inappropriate crying or laughing, easily provoked rage, unwarranted fear, anxiety and depression, and excessive sexual interest.

Limp

An abnormal, uneven pattern of *walking* in which the movements of one leg (or of the pelvis on one side of the body) are different from those of the other. A limp may involve dipping of the pelvis to one side, or failure to straighten the leg fully when the foot is placed on the ground.

Lincomycin

An *antibiotic drug* used to treat serious infections of the lungs, skin, bones, joints, and pelvis that are resistant to commonly prescribed antibiotic drugs such as *penicillin*. Lincomycin may rarely cause a type of *colitis* (inflammation of the intestine) called pseudomembranous enterocolitis.

Lindane

A drug used to treat infestation by *scabies* or *lice* and available in the form of a lotion, cream, or shampoo. Lindane sometimes irritates the skin and scalp and causes itching.

Linear accelerator

A device for accelerating subatomic particles, such as electrons, to a speed approaching that of light so that they have extremely high energies. A linear accelerator can also be used to generate high-energy X rays.

In medicine, high-energy electrons or X rays are used in *radiation therapy* to treat certain cancers. This method causes less damage to the healthy tissue around a tumor than does low-energy radiation therapy.

Lip

One of two fleshy folds around the entrance to the mouth. Externally the lips are covered with skin and internally with mucous membrane, the relative transparency of which allows the red-pink of the underlying capillaries to show through.

The main substructure of the lips is a ring of muscle; its functions include keeping food in the mouth, helping to produce speech and other sounds (like whistling), and kissing. Smaller muscles at the corners of the lips are responsible for facial expression.

DISORDERS

These include chapping (see *Chapped skin*), *cheilitis* (inflammation, cracking, and dryness), *cold sores* (blisters on the lips), syphilitic ulcers (see *Chancre, hard*), and *lip cancer*.

Lip cancer

A tumor, usually on the lower lip. Lip cancer is largely confined to older people, especially those exposed to a lot of sunlight through working outdoors and those who have smoked cigarettes or a pipe for many years. Lip cancer is the most common form of mouth cancer, but represents only about 1 percent of all cancers.

SYMPTOMS

A white patch develops on the lip and soon becomes scaly and cracked with a yellow crust. The affected area grows, eventually becoming ulcerous; the cancer may spread to the lymph nodes in the jaw and then the neck.

DIAGNOSIS AND TREATMENT

Any lip sore that persists for longer than a month should be seen by a physician. Lip cancer (usually a *squamous cell carcinoma*) is diagnosed by *biopsy* (microscopic examination).

Treatment is surgical removal, *radiation therapy*, or a combination of both. If the tumor has spread to the lymph nodes in the neck, *neck dissection* and more radiation may be necessary.

L

Lipectomy, suction

A type of *body contour surgery* in which excess fat is suctioned out through a small incision made in the skin.

Lipid disorders

Disorders of metabolism that cause abnormal amounts of *lipids* in the body. The most common of these disorders are the *hyperlipidemias*, which may be inherited or brought on or aggravated by diet or a disorder. In addition, there are also some very rare lipid disorders that are due solely to heredity, such as *Tay-Sachs disease*.

Lipid-lowering drugs

COMMON DRUGS
Drugs that act on the liver *Clofibrate Gemfibrozil Lovastatin*
Drugs that act on bile salts *Cholestyramine Colestipol Neomycin*

A group of drugs used to treat *hyperlipidemia* (abnormally high levels of one or more types of *lipid*, such as *cholesterol*, in the blood). Lipid-lowering drugs are given to reduce the risk of severe *atherosclerosis* (narrowing of the arteries causing impaired blood flow), usually when dietary measures have not worked.

HOW THEY WORK

Some lipid-lowering drugs alter enzyme activity in the liver to prevent the production of one or more types of lipid from fatty acids. This action reduces the level of lipids in the blood.

Other lipid-lowering drugs interfere with the absorption of bile salts from the intestine into the blood. Bile salts contain large amounts of cholesterol; a decrease in their concentration in the blood stimulates the liver to convert more cholesterol into bile salts, thus reducing the amount of cholesterol in the blood.

POSSIBLE ADVERSE EFFECTS

Lipid-lowering drugs that act on the liver cause increased susceptibility to gallstones. Those that act on bile salts may cause nausea and diarrhea.

Lipids

Often called structural *fats*, lipids are a group of fatty substances that includes triglycerides (the principal forms of fat in body fat), phospholipids (important constituents of cell membranes), and sterols such as *cholesterol*.

Lipoatrophy

Loss of *adipose tissue* (body fat). Patchy lipoatrophy may be caused in diabetics by repeated injections of insulin into one area of skin. Other causes include *malabsorption* of fat from the intestine and lipodystrophies (disorders of fat metabolism).

Lipoma

A common benign tumor of fatty tissue. Lipomas give rise to soft swellings that are slow-growing and often occur in multiples. They may develop anywhere in the body, but occur most commonly on the thigh, trunk, or shoulder. Lipomas are painless and harmless and do not need treatment, although they may be surgically removed for cosmetic reasons.

Liposarcoma

A rare malignant tumor of fatty tissue that usually develops during late middle age. Liposarcomas usually occur in the abdomen or on the thigh, where they produce firm swellings. They can generally be removed by surgery, but have a tendency to recur.

Lipreading

A way of understanding words or conversation through the use of visual clues rather than hearing. Lipreading is invaluable in helping people who are deaf understand more of what is said to them (see *Deafness*).

HOW IT IS DONE

The basis of lipreading is that certain speech sounds are produced by characteristic movements, positions, and relationships of the jaw, lips, and tongue. Because there are more than 40 clearly distinct sounds in the English language, facial expression and context are also important. However, many of the language sounds are produced by similar mouth patterns ("p," "b," and "m" all share the same pattern). There are only about 14 visibly distinguishable mouth patterns; of these, only four or five can be consistently recognized under normal viewing conditions.

EFFECTIVENESS

Tests have shown that the proportion of identified words can rise from 20 to 60 percent after training. Anyone speaking to a deaf person can help improve the effectiveness of lipreading by speaking slightly more slowly than usual, by not covering the mouth when speaking, and by looking directly at the deaf person.

Liquid petrolatum

See *Mineral oil*.

Lisp

The most common form of *speech disorder*. A lisp is due to protrusion of the tongue between the teeth so that the "s" sound is replaced by "th." Most children with a lisp have completely normal structures of the mouth and lips. However, sometimes the speech defect is caused by a cleft palate (see *Cleft lip and palate*).

In most children, lisping disappears without treatment. If it persists after the age of about 4, *speech therapy* may be considered.

Listeriosis

An infection common in animals, including cattle, pigs, and poultry, that also occurs very rarely in humans. It is caused by the bacterium *LISTERIA MONOCYTOGENES*. Possible causes include eating improperly cooked, infected meat or direct spread of the bacteria from an infected live animal.

A fever and generalized aches and pains are the only symptoms that most affected adults develop, but, in the elderly or infirm, the disease can be life-threatening. If an unborn child is infected through its mother's blood, it may be stillborn. *Pneumonia*, *septicemia*, and *meningitis* may develop in a newborn with the disease.

Listeriosis is diagnosed from blood tests and cultures of other fluids obtained from the infected person. Treatment with antibiotics usually clears up the infection.

Lithium

A drug used in the long-term treatment of *mania* and *manic-depressive illness*. Lithium helps prevent mood swings in mania and reduces their frequency and their severity in manic-depressive illness.

HOW IT WORKS

Lithium reduces excessive nerve activity in the brain. It is thought to work by altering the chemical balance within certain nerve cells.

POSSIBLE ADVERSE EFFECTS

High levels of lithium in the blood may cause nausea, vomiting, diarrhea, blurred vision, tremor, drowsiness, rash, and, in rare cases, kidney damage. Regular blood tests are carried out to monitor the level of lithium in the body.

Too much tea and coffee increases the risk of adverse effects. Too much sodium in the diet reduces the effectiveness of treatment.

Lithotomy

Surgical removal of a *calculus* (stone) from the urinary tract, especially from the bladder.

The operation of "cutting for stone" is one of the oldest known surgical procedures. Until the discovery of antiseptic surgical techniques, bladder stones were removed by approaching the organ through incisions between the thighs rather than via the abdomen. The patient would lie back with hips and knees bent and the legs open. Today, this *lithotomy position* is used primarily for gynecological examinations.

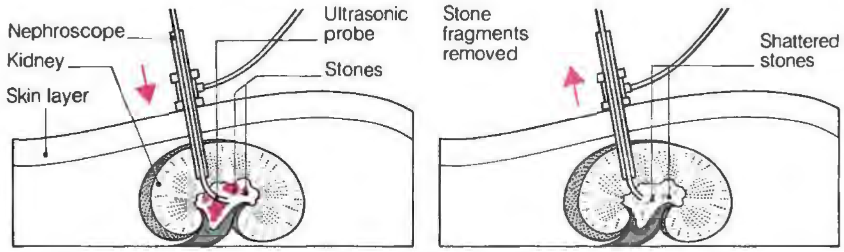
The operations of ureterolithotomy and *pyelolithotomy* (removal of ureteral and kidney stones, respectively, by incision) are still occasionally performed. In developed countries, surgical removal of bladder stones is rarely performed, and then only for large stones. Today, bladder stones are usually crushed and dissolved by use of a cystoscope (see *Cystoscopy*) or by *lithotripsy*.

Lithotomy position

Position in which a patient lies on his or her back with knees bent and wide apart. Originally used for *lithotomy* (surgical removal of stones), the position is still used for *pelvic examinations*, childbirth, and many types of pelvic surgery. Stirrups are usually used to support the feet and legs.

Lithotripsy

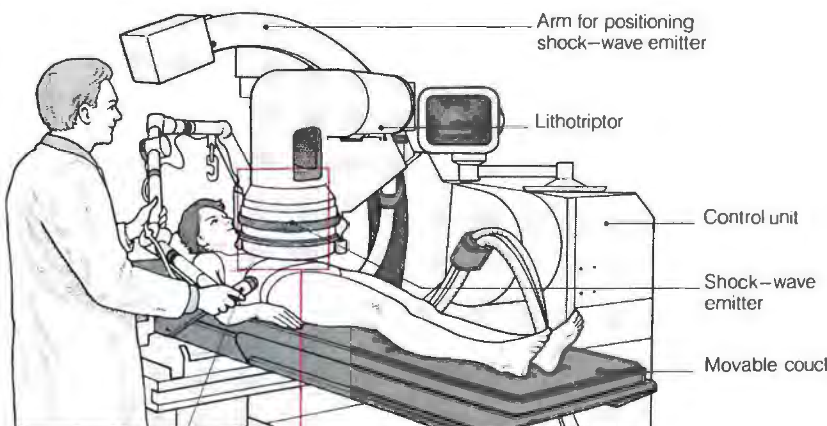
The process of using shock waves or ultrasonic waves to break up *calculi*



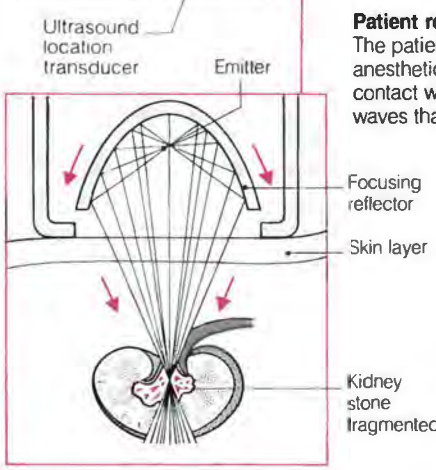
LITHOTRIPSY PROCEDURES

Calculi can sometimes be removed without major surgery. Lithotripsy uses ultrasonic or shock waves to break up the calculi. In percutaneous lithotripsy, the stones are easily removed through a small incision. After extracorporeal shock-wave lithotripsy (ESWL), stone fragments are passed in the urine.

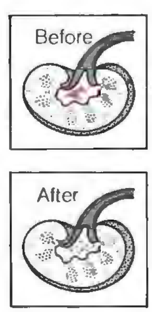
Abdominal calculi
This X ray shows two staghorn calculi in the kidneys. Before lithotripsy, stones such as these could be removed only by major surgery.



PERCUTANEOUS LITHOTRIPSY



1 The surgeon first makes a small incision in the flank and inserts a nephroscope (a type of viewing tube) into the kidney.



2 A probe is passed through the nephroscope to direct ultrasound waves at the stones, causing them to shatter. Stone fragments are then removed.

EXTRACORPOREAL SHOCK-WAVE LITHOTRIPSY (ESWL)

Patient receiving ESWL
The patient is given a general or epidural anesthetic. The lithotriptor, placed in contact with the abdomen, produces shock waves that are focused on the stone.

Effects and side effects
Nearly all the shock-wave energy is dissipated in the stone, causing it to shatter. The patient then drinks liberally to clear stone fragments from the urinary system. There may be blood in the urine and abdominal bruising, but serious complications are uncommon.

(stones) for excretion. There are two different procedures—extracorporeal shock wave lithotripsy (ESWL) and percutaneous lithotripsy.

WHY IT IS DONE

Lithotripsy is used to break up kidney and upper ureteral stones (see *Calculus, urinary tract*) into tiny pieces so that they can be excreted in the urine. It is also being investigated as a treatment for gallstones.

ESWL is used to break up smaller stones; percutaneous lithotripsy is used to break up larger stones. Very large stones may be treated with a combination of the two.

HOW IT IS DONE

Both procedures are performed using a general or epidural anesthetic. In some cases, more than one treatment is required.

ESWL This technique uses a machine called a *lithotriptor* to produce external shock waves to break up stones. X-ray imaging systems are used to show the position of the stone and to monitor its destruction into a fine sand, which is passed out of the body in the urine or the bile over the following few weeks. ESWL has radically changed the treatment of kidney stones by eliminating the need for most surgery. The technique may also change the treatment of gallstones.

PERCUTANEOUS LITHOTRIPSY A nephroscope (type of *endoscope*) is inserted into the kidney via a small flank incision. An ultrasonic probe is directed through the nephroscope to break up the stone; fragments are removed through the nephroscope.

RECOVERY PERIOD

There may be hematuria (blood in the urine) for about 12 hours after the treatment. After ESWL there may be some bruising of the skin at the entry and exit points of the shock wave. Most people can return to full activity within a week.

COMPLICATIONS

Renal colic, a sudden, severe pain in the side due to obstruction of the ureter by small fragments of stone, may occur after ESWL. Patients treated for gallstones may need drug treatment to aid the final elimination of stone residue.

Lithotriptor

The machine used in extracorporeal shock wave *lithotripsy* (ESWL) to disintegrate small *calculi* (stones).

Livedo reticularis

A netlike purple or blue mottling of the skin, usually on the lower legs. It is caused by the enlargement of blood vessels beneath the skin and tends to be worse in cold weather.

Though harmless, the condition is present for life. Livedo reticularis may appear in healthy people, but is more common in those who are abnormally sensitive to cold or in people who have suffered damage to blood vessels just beneath the skin (see *Vasculitis*).

Liver

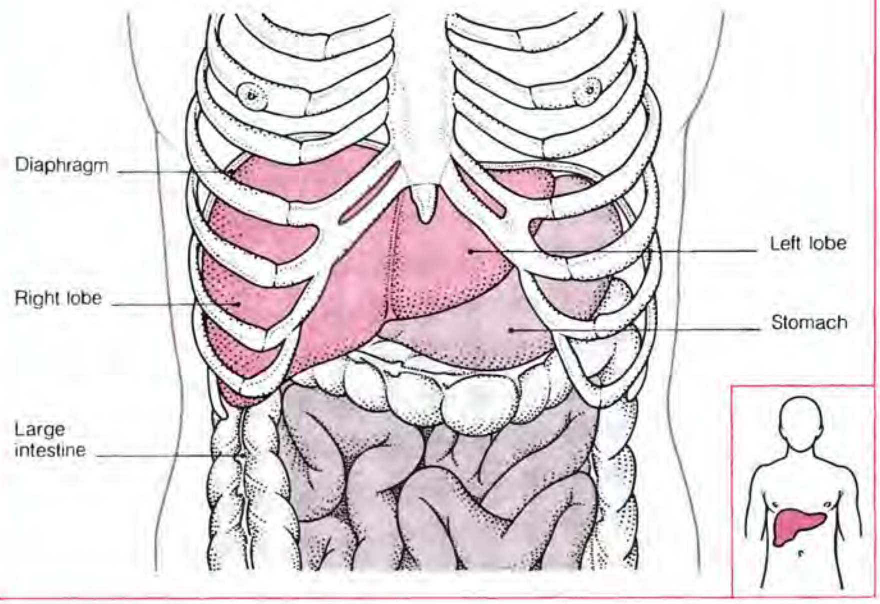
The largest and one of the most important internal organs, which functions as the body's chemical factory and regulates the levels of most of the main chemicals in blood. Weighing 2.5 to 3.3 pounds (1.1 to 1.5 kg), the liver is a roughly cone-shaped, red-brown organ that occupies the upper right abdominal cavity.

STRUCTURE

The liver lies immediately beneath the diaphragm; it has two main lobes.

The liver receives oxygenated blood from the hepatic artery and nutrient-rich blood via the portal vein (see illustration). The blood drains into the hepatic veins. The liver cells secrete *bile*, a fluid that leaves the liver through a network of ducts, the bile ducts. Within the liver, the small bile ducts and branches of the hepatic artery and the portal vein form a kind of conduit system known as the portal tracts.

FUNCTION



The liver has many functions vital to the body. One is to produce important proteins for blood plasma. They include albumin (which regulates the exchange of water between blood and tissues), complement (a group of proteins that plays a part in the *immune system's* defenses against infection), coagulation factors (which enable blood to clot when a blood vessel wall is damaged), and globin (a constituent of the oxygen-carrying pigment *hemoglobin*). The liver also produces *cholesterol* and special proteins that help carry fats around the body.

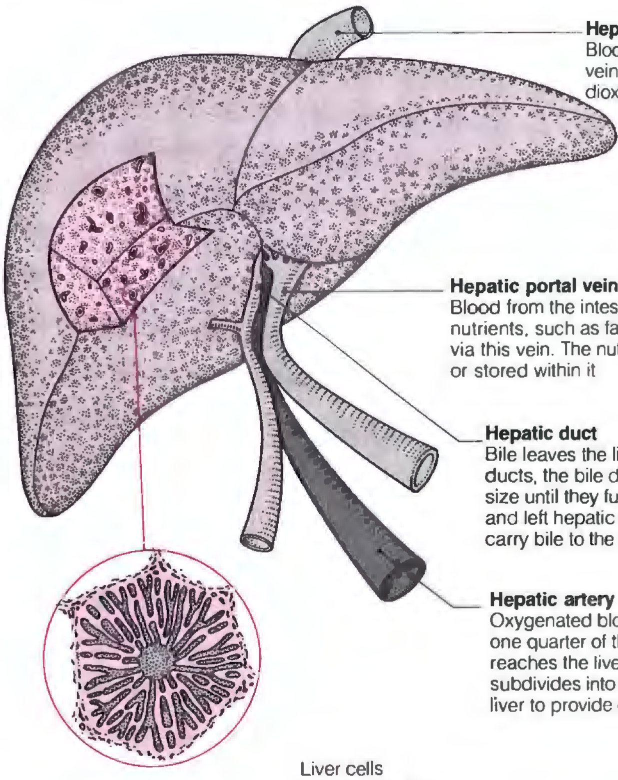
Another function of the liver is to take up glucose that is not required immediately by the body's cells, and store it as glycogen. When the body needs to generate more energy and heat, the liver (under the stimulation of hormones) converts the glycogen back to glucose and releases it into the bloodstream.

The liver also regulates the blood level of amino acids, chemicals that

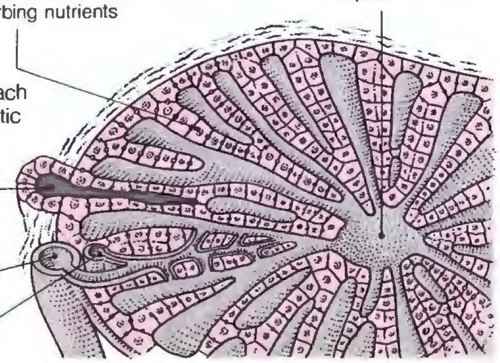
LOCATION OF THE LIVER

The liver is a roughly cone-shaped, red-brown organ that occupies the upper right-hand portion of the abdominal cavity. It lies immediately beneath the diaphragm, to which its upper side is attached. Its base is in contact with the stomach, right kidney, and intestines. Tucked within a depression on the underside of the liver is the gallbladder.

form the building blocks of proteins. When the blood contains too high a level of amino acids (such as after a meal), the liver converts some of them into glucose, some into proteins, some into other amino acids, and some into urea, which is passed to the kidney for excretion in the urine.



Along with the kidneys, the liver acts to clear the blood of drugs and poisonous substances that would otherwise accumulate in the bloodstream. The liver absorbs the substances to be removed from the blood, alters their chemical structure, makes them water soluble, and excretes them in the bile.



Bile carries waste products away from the liver and helps in the breakdown and absorption of fats in the small intestine (see *Biliary system*).

Although extremely complex in its functions, the liver is a remarkably resilient organ. Up to three quarters of its cells can be destroyed or surgically removed before it ceases to function.

LIVER STRUCTURE AND FUNCTION

The liver is a large organ with numerous functions. It absorbs oxygen and nutrients from the blood, and regulates the blood's glucose and amino-acid levels. It helps break down drugs and various toxins, and manufactures important proteins, such as albumin and blood coagulation factors. The liver also produces bile, which removes waste products and helps process fats in the small intestine.

Section through a liver lobule
Blood passes to the central vein via pathways between cells.

Liver abscess

A localized collection of pus in the liver. The most common causes are a spread of bacteria from intestines inflamed by *diverticular disease* or *appendicitis* and invasion of the liver by amebae (single-celled animal parasites) in people infected with *amebiasis*. In some cases, the source of infection cannot be identified.

An affected person is obviously sick, has a high fever and pain in the upper right abdomen, and (especially if elderly) may be confused.

DIAGNOSIS AND TREATMENT

Ultrasound scanning usually shows the abscess. The responsible microorganisms can sometimes be grown in *culture* from a blood sample or direct needle aspiration of the liver.

If possible, the abscess may be drained through a needle inserted through the abdominal wall and guided by ultrasound. Otherwise, abdominal surgery is needed.

Liver biopsy

A diagnostic test in which a small sample of tissue is removed from the liver. The procedure is relatively safe, and complications are rare.

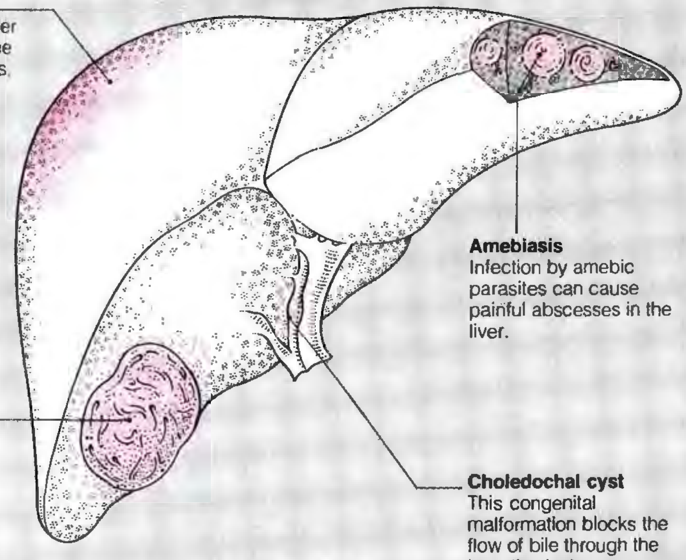
WHY IT IS DONE

The main function of the test is to diagnose liver diseases, such as *cirrhosis* and different types of *hepatitis*. A liver biopsy can also help diagnose diseases such as tumors and *lymphomas*, which spread throughout the body and affect many organs. In addition, the test can provide an important check on the efficacy of treatment of diseases such as chronic active hepatitis.

HOW IT IS DONE

Most liver biopsies are performed using a local anesthetic. While the patient holds his or her breath, a slim needle is inserted into the liver via a very small incision made over the right lower ribs. The needle is removed with a small sample of liver tissue, the structure and cells of which are examined by a pathologist.

A liver biopsy is sometimes performed during the course of another abdominal operation.



DISORDERS OF THE LIVER

By far the most common cause of liver disease in the US and other developed countries is excessive consumption of alcohol (see *Liver disease, alcoholic*). Alcohol-related disorders, which include alcoholic *hepatitis* and *cirrhosis*, outnumber all other types of liver disorder by at least five to one.

Worldwide, the pattern of liver disease is different. In parts of Africa and Asia, up to 20 percent of the population are carriers of the *hepatitis B* virus; in these parts of the world, the most important liver disorders are virus-induced cirrhosis and primary *liver cancer*.

Apart from alcohol- and virus-induced liver disease, the liver may be affected by congenital defects, bacterial and parasitic infection, circulatory disturbance, metabolic disorders, poisoning, and autoimmune processes.

Liver failure (complete loss of liver function) may occur as a result of acute hepatitis, poisoning, or cirrhosis. Enlargement of the liver (hepatomegaly) and *jaundice* are two common signs of liver disease.

L

CONGENITAL DEFECTS

Defects of liver structure at birth principally affect the bile ducts. A choledochal cyst is a malformation of the hepatic duct (formed from the union of all the small bile ducts in the liver) that may obstruct the flow of bile in infants (causing jaundice); it requires removal. In *biliary atresia*, the bile ducts are absent, again causing jaundice.

INFECTION AND INFLAMMATION

Hepatitis is a general term for inflammation in the liver; it may be caused by viruses such as the hepatitis A, B, and non A, non B viruses (see *Hepatitis, viral*). Bacteria may spread up the biliary system toward the liver to cause *cholangitis* or *liver abscess*. Parasitic diseases that may affect the liver include *schistosomiasis, liver fluke*, and *hydatid disease* (caused by various types of worm or fluke) and *amebiasis* (caused by a single-celled parasite).

POISONING AND DRUGS

Apart from alcohol, many drugs and toxins are broken down by the liver, damaging liver cells in the process. Suicidal overdose with the painkilling drug acetaminophen causes severe liver damage, which may not be obvious until up to two days after the overdose. Some medications, even in normal doses, can cause acute or chronic hepatitis by a direct toxic effect or through drug allergy.

Poisoning by certain types of mushrooms can cause acute liver failure (see *Mushroom poisoning*).

AUTOIMMUNE DISORDERS

Liver cells and bile ducts can be targets for autoimmune reactions (in which the body's immune system attacks its own tissues). A gradual destruction of liver cells is the main problem in autoimmune chronic active hepatitis (see *Hepatitis, chronic active*). The slowly progressive bile duct damage that occurs in primary *biliary cirrhosis* and sclerosing cholangitis possibly also has an autoimmune basis.

METABOLIC DISORDERS

The two main metabolic disorders affecting the liver are *hemochromatosis* (in which there is too much iron in the body) and *Wilson's disease* (in which there is too much copper).

TUMORS

The liver is a common site of malignant tumors that have spread from cancers of the stomach, pancreas, or large intestine. Enlargement of the liver and spleen is a common feature of *leukemias* and *lymphomas*. Primary tumors of the liver are much less common. (See *Liver cancer*.)

OTHER DISORDERS

In *Budd-Chiari syndrome*, the veins draining the liver become blocked by blood clots, causing painful swelling of the liver and severe *ascites* (collection of fluid in the abdomen). Obstruction of the portal vein is one cause of *portal hypertension* (high blood pressure in the portal vein), which can lead to *esophageal varices* (swollen veins in the esophagus) and ascites. Portal hypertension is also one of the usual complications of cirrhosis.

INVESTIGATION

Disorders of the liver may be investigated by physical examination, *liver biopsy, liver function tests, ultrasound scanning,* and *CT scanning.*

Liver cancer

A malignant tumor in the liver. The tumor may be primary (originating within the liver itself) or secondary (spread from elsewhere). There are two main types of primary tumor—a hepatoma, which develops in the liver cells, and a *cholangiocarcinoma*, which arises from cells lining the bile ducts.

CAUSES AND INCIDENCE

Hepatomas are the most common form of cancer worldwide. They are closely linked to hepatitis B (see *Hepatitis, viral*), common throughout Africa, the Middle East, and the Far East. In the US, hepatitis B is a relatively uncommon infection, so hepatomas are rare. There are only about three or four new cases per 100,000 people annually. When a hepatoma does occur, it is usually a complication of *cirrhosis* of the liver.

Secondary liver cancer is relatively common in the US (about 20 times more common than primary cancer); it often originates from cancers in the stomach, pancreas, or large intestine, where the primary tumor may have been small and caused no symptoms.

SYMPTOMS AND SIGNS

The most common symptoms of any liver cancer are weight loss, loss of appetite, and lethargy. In addition, there is often pain in the upper right abdomen. The later stages of the disease are marked by *jaundice* and *ascites* (fluid in the abdomen).

DIAGNOSIS

Liver tumors are usually detected as a result of *ultrasound scanning* that reveals abnormal areas in the liver. The diagnosis is confirmed by *liver biopsy* (removal of a small sample of liver for analysis).

About 80 percent of hepatomas raise the production by the liver of a substance called *alpha-fetoprotein*; measurement of the blood level of this protein is used as a screening test in areas where the cancer is common. *Angiography* is also used to detect hepatomas too small to be seen by other imaging techniques.

TREATMENT

A hepatoma usually remains confined to the liver for a long time. In cases where cirrhosis is not also present (which is rare in the US), complete removal of the tumor, leading to cure, is sometimes possible. In other cases, *anticancer drugs* can help the patient survive longer. A *liver transplant* may occasionally be considered.

There is no cure for secondary liver cancer, but anticancer drugs can help slow the progress of the disease. Tying off or blocking the hepatic artery or one of its branches to deprive the tumor of its blood supply has been attempted, as has placing a catheter into the artery for continuous administration of anticancer drugs.

Liver, cirrhosis of

See *Cirrhosis*.

Liver disease, alcoholic

Damage to the liver caused by persistent heavy alcohol consumption, with progression to *cirrhosis* (severe structural damage and loss of liver function) and death.

TYPES

Excess fat accumulation in the liver affects almost everyone with a moderate to high alcohol consumption. It is completely reversible through abstinence and, with the reversal, carries a low risk of progression to cirrhosis.

Acute or chronic *hepatitis* can sometimes develop in the persistent drinker. Individual liver cells are destroyed and there is inflammation of the liver with scarring. In people who continue to drink, there is a high risk (about 90 percent) of progression to cirrhosis; in most of those who stop drinking the liver returns to normal. Cirrhosis is irreversible, but abstinence often leads to a notable improvement in liver function.

CAUSES AND INCIDENCE

Until the 1960s, alcoholic liver damage was thought to be caused mainly by the malnutrition associated with alcohol dependence rather than by alcohol itself. It is now accepted that alcohol is directly toxic to the liver.

There is a clear relationship between the total amount of alcohol consumed in a population and the *incidence* of cirrhosis. The *prevalence* of alcoholic liver disease has been rising rapidly in most developed countries since about 1960, and the increase has been particularly steep in women. In the US, the death rate from cirrhosis has risen by about 70 percent since 1960. In New York, alcoholic cirrhosis is now one of the most common causes of death in people 25 to 44.

A person who consumes 7 ounces of alcohol on average per day (contained in about three quarters of a bottle of whisky or two and a half bottles of wine) has a 50 percent chance of cirrhosis within 20 years. A much lower average daily intake of 1.5 ounces (contained in two double shots of whiskey or four glasses of wine) in a man, or half that consumption in a woman, still carries a substantial risk.

SYMPTOMS AND DIAGNOSIS

The first symptoms or signs of liver damage are the same as those of hepatitis or cirrhosis. *Liver function tests* show a characteristic pattern of abnormalities, and *liver biopsy* may be recommended to define the type of damage precisely.

TREATMENT AND OUTLOOK

Abstinence from alcohol is the only method of returning the liver to normal or improving its function and prolonging life expectancy. Treatment methods are as for *alcohol dependence*.

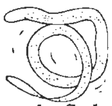
Liver failure

A complication of acute *hepatitis* (inflammation of the liver) in which there is such a severe impairment of liver function that it affects other organs, particularly the brain. Liver failure may also refer to a critical stage in *cirrhosis* of the liver.

SYMPTOMS

The principal symptoms of acute liver failure are those of the underlying hepatitis; later, symptoms of brain dysfunction develop. The brain dysfunction probably occurs because the liver fails to break down certain substances that build up in the blood (such as ammonia), which then poison or alter the transmission of nerve messages in the brain. The symptoms may include agitation and restlessness, followed by drowsiness, confusion, and coma—a condition known as hepatic *encephalopathy*.

When liver failure accompanies cirrhosis, other complications, such as *ascites* (fluid collection in the abdomen) and internal bleeding, may develop in addition to hepatic encephalopathy. The symptoms of brain dysfunction develop more slowly, with recurrent episodes of drowsiness or confusion. These episodes are frequently precipitated by bacterial infections or changes in drug treatment or diet.



DIAGNOSIS AND TREATMENT

A diagnosis is made from the patient's history, physical examination, *liver function tests*, and tests for viruses that can cause acute hepatitis.

Treatment of acute liver failure consists of skilled intensive care. There is no specific cure, although the use of antibiotics and enemas can reduce the number of intestinal bacteria, which are one of the main sources of toxic ammonia entering the bloodstream. A *liver transplant* is occasionally possible and suitable for certain patients. Only about one quarter of patients survive acute liver failure.

When brain dysfunction complicates cirrhosis, treatment of precipitating causes (such as infection) often leads to an improvement.

Liver fluke

Any of various species of flukes (small, flattened, worms) that infest the bile ducts within the liver. The only fluke of any importance in the US is *FASCIOLA HEPATICA*, which causes the disease fascioliasis. The adult flukes normally infest sheep and produce eggs that are passed in the sheep's feces. The eggs are eaten by snails, from which immature forms of the fluke emerge. They then become encysted (enclosed in a sac) on aquatic vegetation, particularly watercress. In the US the disease is confined to some western and southern states.

The disease has two stages. During the first stage, young flukes migrate through the liver, causing liver tenderness and enlargement, fever, night sweats, and sometimes a rash. In the second stage, adult worms are present in the bile ducts. This may lead to *cholangitis* (inflammation of the bile ducts) and *bile duct obstruction*, which can cause *jaundice*. In light infections, there may be no symptoms.

The disease is diagnosed from the presence of fluke eggs in the patient's feces. Treatment with the antihelmintic drug praziquantel may be effective.

A different species, *CLONORCHIS SINENSIS*, is common in the Far East. Infection is acquired from eating raw or uncooked freshwater fish. The symptoms and treatment are broadly similar to those for fascioliasis.

Liver function tests

A series of tests of blood chemistry that can detect changes in the way the liver is making new substances, breaking down and/or excreting old ones, and whether liver cells are healthy or being damaged. The tests are widely used to help in the diagnosis of liver disease, and to assess responses to treatment. They are particularly useful in distinguishing between acute and chronic liver disorders and between *hepatitis* (liver inflammation) and *cholestasis* (failure of bile flow). The most commonly performed tests are shown in the table.

TABLE OF LIVER FUNCTION TESTS

Test	Significance
Serum bilirubin	Bilirubin is the yellow breakdown product of red blood cells that is passed to the liver and excreted in bile. It is the substance that gives the yellow color to the skin in jaundice A high bilirubin level in the blood may indicate defective processing of bile by the liver or obstruction to bile flow.
Serum albumin	Albumin is one of the main proteins in blood Made by the liver, one of its actions is to hold fluid inside the blood vessels. A low level is found in many chronic liver disorders and is often associated with ascites and ankle edema (fluid collection in the abdomen and around the ankles).
Serum alkaline phosphatase	Alkaline phosphatase is an enzyme found in bile. The blood level of this enzyme rises when there is obstruction to the flow of bile (cholestasis).
Serum aminotransferases (transaminases)	The aminotransferases are enzymes released from liver cells into the blood when the liver cells are damaged. The levels will be raised in acute and chronic hepatitis.
Prothrombin time	A normal result in this test of blood clotting depends on the presence in the blood of a protein made by the liver from a fat-soluble vitamin, vitamin K. The test result can be abnormal in two kinds of disorders—when the protein is not made because of liver cell damage, and when there is a blockage to bile flow in the liver, causing a lack of bile in the intestines (which interferes with fat and vitamin K absorption).

Liver imaging

A technique that produces images of the liver, gallbladder, bile ducts, and blood vessels supplying the liver to detect abnormality or disease.

TYPES

CONVENTIONAL X-RAY TECHNIQUES *Cholecystography* and *cholangiography* are techniques in which a contrast medium (iodine-containing substance opaque to X rays) is introduced to show up gallstones, tumors, and blockages. *ERCP* (endoscopic retrograde cholangiopancreatography) is an alternative method of examining the biliary system by means of a contrast medium; it is especially useful in detecting blockage or narrowing of a bile duct or a pancreatic duct by a stone or tumor.

Angiography shows up the blood vessels within the liver that supply the liver. It also may be used to confirm the diagnosis of a hemangioma or to plan the treatment of liver tumors and other disorders.

SCANNING TECHNIQUES *Ultrasound scanning* is the most widely used of all liver imaging techniques. It is simple, safe, noninvasive, and produces excellent images, particularly of gallstones. *CT scanning* also provides good images and may be used if ultrasound has proved inconclusive.

Radionuclide scanning can indicate the presence of a cyst or a tumor. It is also useful in recording the progress of radioactive isotopes as they are excreted from the liver in bile.

Liver transplant

Replacement of a diseased liver with a healthy organ removed from a donor who has been declared brain dead. Liver transplantation is a technically difficult procedure, but is now accepted as a feasible and appropriate treatment for some types of advanced liver disease. The chances of surviving for many years with a transplanted liver are improving, but they are not yet as high as the chances of surviving with a kidney transplant.

WHY IT IS DONE

Transplantation is worth considering only for people with life-threatening or severely debilitating liver disease. However, if the disease process is too advanced, the person is unlikely to survive the operation. An assessment must be made of the likely length of survival and the quality of life with and without the operation.

In adults, the best results are obtained in the treatment of advanced liver *cirrhosis* in people with long-standing chronic active *hepatitis* or primary *biliary cirrhosis*. In acute *liver failure*, there can be difficulty in obtaining donor organs at an appropriate time, but people with a slightly less acute illness and those with *Budd-Chiari syndrome* have been successfully treated. People with primary *liver cancer* are rarely considered for transplantation because there is a high risk that the tumor will recur.

In children, congenital *biliary atresia* is the most common reason for transplantation.

HOW IT IS DONE

The donor organ is obtained from someone who has suffered *brain death* but whose liver is still healthy. The organ can be stored in cold salt solutions for a few hours.

A general anesthetic is given and the recipient's abdomen is opened. The diseased liver is removed, the donor organ is inserted in its place, and the major blood vessels and common bile duct are reconnected.

RECOVERY PERIOD

The first few days after the operation are spent in an *intensive-care* unit. *Immunosuppressant drugs* (particularly cyclosporine) are given to reduce the risk of rejection.

OUTLOOK

In some cases rejection occurs and a second transplant operation provides the only hope. There is now a 60 to 80 percent chance of surviving one year, which may mean that more than half of the people now receiving liver transplants will survive for five years. The quality of life is generally excellent, with most people returning to near normal activity within a few weeks of the operation.

Living will

See *Will, living*.

Lobe

One of the clearly defined parts into which certain organs, such as the brain, liver, lungs, and thyroid gland, are divided. The term may also be used to describe any projecting, flat, pendulous part of the body, such as the earlobe.

Lobectomy

An operation to cut out a lobe in the brain (see *Lobotomy, prefrontal*), liver (see *Hepatectomy, partial*), lungs (see *Lobectomy, lung*), or thyroid gland (see *Thyroidectomy*).

Lobectomy, lung

An operation to remove one of the lobes of the lung. Lobectomy is usually performed to remove a malignant tumor, but may also be used to treat localized *bronchiectasis* that has not responded to medical treatment. In the past, lobectomy was carried out to treat tuberculosis, which is treated today by drugs.

After lobectomy, the remaining lobes expand to fill the pleural space.

HOW IT IS DONE

A curved incision is made (using a general anesthetic), starting under the armpit and extending across the back, following the line of the lower edge of the shoulder blade. The muscles are cut through and the ribs are gently spread apart (or one is removed) to expose the lung. The blood vessels and bronchus (air passage) leading to the diseased lobe are then tied off and divided, and the lobe is removed. Before the incision is sewn up, a tube is inserted into the pleural space surrounding the lung to drain off fluid. It is usually removed after 24 hours.

Lobotomy, prefrontal

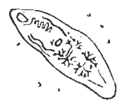
The cutting of some of the fibers linking the frontal lobes to the rest of the brain. Prefrontal lobotomy was widely used in the 1940s and 1950s to treat serious psychiatric disorders. However, the operation often resulted in harmful personality changes and is now used only as a last resort to treat people with severe, chronic depression. (See also *Psychosurgery*.)

Lochia

The discharge after childbirth of blood and fragments of the lining of the uterus where the placenta was attached. Lochia is bright red for the first three or four days and then becomes paler. The discharge decreases as the placental site heals and usually ceases within six weeks.

Locked knee

See *Knee*.



Lockjaw

A painful spasm of the jaw muscles that makes it difficult or impossible to open the mouth. Lockjaw is the most common symptom of *tetanus*.

Locomotor

Relating to movement of the extremities, as in locomotor *ataxia*, the incoordinated movements and lurching gait that occur in the later stages of untreated syphilis.

Loiasis

A form of the tropical parasitic disease *filariasis* that is caused by an infestation by the worm *LOA LOA*. The worm travels beneath the skin, producing areas of inflammation known as Calabar swellings.

Loin

The part of the back on each side of the spine between the lowest pair of ribs and the top of the pelvis.

Loose bodies

Fragments of bone, cartilage, or capsule linings that are free to move within a joint. They may occur whenever there is any damage to a joint, as in *osteoarthritis* (degeneration due to wear and tear), fracture, or *osteochondritis dissecans* (inflammation of bone and cartilage due to disrupted blood supply).

SYMPTOMS AND SIGNS

Loose bodies can sometimes be felt. They are troublesome only if they lodge between joint surfaces, where they cause the joint to lock (usually only briefly), resulting in severe pain. The joint usually swells several hours later. Though the swelling subsides, further locking and swelling can recur at any time.

DIAGNOSIS AND TREATMENT

X rays or *arthroscopy* (examination of the interior of the joint through a viewing tube) show whether loose bodies are present.

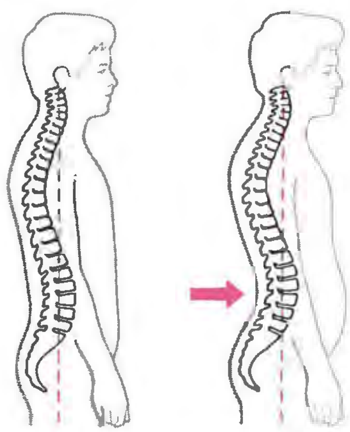
Occasionally, gentle manipulation of the joint is required to unlock it. If locking occurs frequently, the loose bodies are removed during arthroscopy or by an open operation.

Loperamide

An *antidiarrheal drug* used in the treatment of recurrent and sudden bouts of diarrhea. Loperamide is also given to help regulate bowel action in people who have had an *ileostomy*.

POSSIBLE ADVERSE EFFECTS

Loperamide occasionally produces a rash. Other rare adverse effects, such as fever, abdominal cramps, and bloating, are often difficult to distinguish from symptoms of the disorder causing the diarrhea.



Lorazepam

A *benzodiazepine drug* used to treat *insomnia* and *anxiety*. If use of lorazepam is suddenly stopped after it has been taken regularly for more than three weeks, there may be withdrawal symptoms (see *Drug dependence*).

L

Lordosis

Inward curvature of the spine, which is normally present to a minor degree in the lower back. Lordosis in the lower back can become exaggerated by poor posture (especially in someone who is overweight and has weak abdominal muscles) or by *kyphosis* (backward curvature of the spine) above the lower back.

Normal and abnormal lordosis
The normal inward curvature of the spine (left) is exaggerated in abnormal lordosis (right).

Once pronounced lordosis has developed, it is usually a permanent condition and can lead to *disk prolapse* or *osteoarthritis* of the spine.

Loss of normal lordosis in the lower back or neck can occur when the back or neck muscles are in spasm. The condition corrects itself once the cause is successfully treated.

Lotion

A liquid drug preparation applied to the skin. Lotions have a cooling, soothing effect and are useful for covering large areas. Examples of drugs prepared as a lotion include *calamine* (used to treat skin inflammation) and *lindane* (used in the treatment of scabies and lice infestations).

Lou Gehrig's disease

A name used commonly by the public for amyotrophic lateral sclerosis (see *Motor neuron disease*).

Lovastatin

A lipid-lowering drug approved in 1987 that lowers serum cholesterol levels by inhibiting cholesterol-producing enzymes. Lovastatin should not replace standard diet therapy; it is recommended when dietary measures and other nondrug therapy have been ineffective. Long-term effects are yet to be ascertained.

LSD

A synthetic *hallucinogenic drug* (drug that produces hallucinations) derived from ergot (a type of fungus). LSD is the abbreviation for lysergic acid diethylamide. The drug has no medical role. Its distribution and manufacture are governed by the Controlled Substance Act because of the drug's high potential for abuse.

LSD sometimes produces "bad trips" in which a person experiences panic, fear, and physical symptoms, such as nausea, dizziness, and weakness. In severe cases, sedation in the hospital may be necessary for several days. There may also be "flashbacks" to previous trips months or years afterward. Although there is no evidence that LSD causes *psychosis* (mental illness characterized by a loss of contact with reality), it may act as a trigger in a person predisposed to mental illness. There is evidence that LSD damages chromosomes.

Ludwig's angina

A bacterial infection of the floor of the mouth that becomes life-threatening as it spreads to the throat. The tissues become inflamed, swell, and harden.

The disorder is usually caused by an infected tooth or gum and is most common in people with poor *oral hygiene*. It generally results in fever, pain in the mouth and neck, and difficulty opening the mouth and swallowing. If not treated immediately with antibiotics, the swollen tissues of the throat may cause difficulty breathing. *Tracheostomy* (making a hole in the windpipe and inserting a tube through it) may be necessary to prevent asphyxiation.

Lumbar

Relating to the part of the back between the lowest pair of ribs and the top of the pelvis. The lumbar region of the spine consists of the five lumbar vertebrae between the lowest (12th) thoracic vertebra and the sacrum.

Lumbar puncture

A procedure in which a hollow needle is inserted into the lower part of the spinal canal to withdraw *cerebrospinal fluid* (the watery liquid that surrounds the brain and spinal cord) or to inject drugs or other substances.

WHY IT IS DONE

The main use of the lumbar puncture is to examine cerebrospinal fluid to diagnose and investigate disorders of the brain and spinal cord (such as *meningitis* and *subarachnoid hemorrhage*). The procedure is also used to inject drugs into the fluid (such as *anticancer drugs* to treat *leukemia* and other malignant diseases of the central nervous system). Another use of lumbar puncture is to inject a dye that will show up on X ray (see *Myelography*) to produce images of the spinal cord. Finally, lumbar puncture can be used to inject a local anesthetic to achieve extensive anesthesia without causing loss of consciousness.

HOW IT IS DONE

The patient lies on his or her side, chin on chest and knees drawn up, to pull the vertebrae (bones of the spine) apart; the area of skin overlying the lumbar vertebrae at the base of the spine is anesthetized with a local anesthetic. A hollow needle is then inserted between two of the vertebrae and into the spinal canal and is used to withdraw cerebrospinal fluid or to inject drugs, dye, or anesthetic.

After the needle is removed, the puncture site is covered with sterile tape. The procedure takes less than 20 minutes. It usually causes no discomfort; a headache that soon wears off may occur in some people.

Lumbosacral spasm

Prolonged, excessive tightening of the muscles that surround and support the lower part of the spine. Lumbosacral spasm is a cause of *back pain* and may occasionally result in temporary *scoliosis* (curvature of the spine to one side). Treatment may include bed rest, *analgesic drugs* (painkillers), and *muscle-relaxant drugs*.

Lumen

The space within a tubular organ. The term is most commonly used to refer to the cavity of the intestine.

Lumpectomy

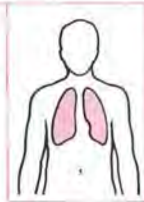
An operation to treat breast cancer (see *Mastectomy*).

Lunacy

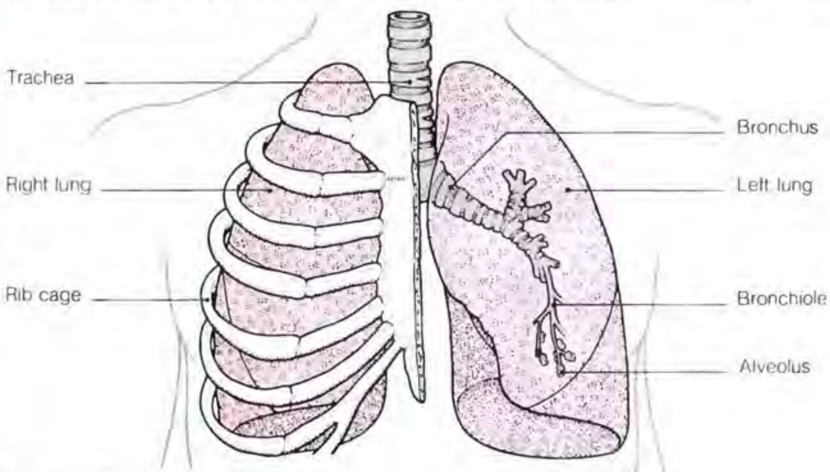
An outdated term for insanity. It was coined because of the belief that phases of the moon ("luna" in Latin) could bring on mental illnesses, especially illnesses that seemed to come and go. Patients were called lunatics and mental hospitals were known as lunatic asylums.

Lung

The main organ of the *respiratory system*. The two lungs supply the body with oxygen and eliminate carbon dioxide from the blood.



STRUCTURE



The *trachea* (windpipe) branches in the chest into two main *bronchi* (air passages), which supply the left and right lungs. The main bronchi divide again into smaller bronchi and then into bronchioles, which lead to air passages that open out into grapelike air sacs called alveoli. It is through the thin walls of the alveoli that gases diffuse into or out of the blood.

Each lung is enclosed in a double membrane called the *pleura*, which allows the lungs to slide freely as they expand and contract during *breathing*. (See also *Respiration*.)

LOCATION AND STRUCTURE OF THE LUNGS

The lungs lie in the chest within the rib cage. Air entering the body via the nose and mouth travels down the trachea to the main bronchi, which divide into smaller bronchi and then into bronchioles. These in turn lead to alveoli, where the oxygen/carbon dioxide exchange takes place. During expiration (breathing out), air leaves the body by the same routes.

Blood vessels in a lung
The tiniest "twigs" of this extensive blood vessel "tree" form into capillaries that surround the alveoli (air sacs) in the lung. Oxygen and carbon dioxide are exchanged between the alveoli and the capillaries.

Lung cancer

One of the most common forms of *cancer* in the US, lung cancer is the leading cause of cancer deaths in men and the second most common cause (after breast cancer) in women. There were about 160,000 deaths from lung cancer in 1986 in the US. The peak age for lung cancer is 65 years for men and 70 years for women. The disease is uncommon before age 40.

CAUSES

Cigarette smoking is the main cause of lung cancer. The more cigarettes smoked per day and the lower the age at which smoking started, the greater the risk of lung cancer. Cigar or pipe smokers have a lower risk of having lung cancer than cigarette smokers, but still have a significantly higher risk than nonsmokers (see *Tobacco smoking*). Passive smoking (the inhalation of tobacco smoke by nonsmokers) has been shown to increase the risk.

Living in an environment with a high level of air pollution or working with radioactive minerals or asbestos may cause some cases of lung cancer.

TYPES

There are several types of lung cancer, the most common being squamous cell carcinoma, small (oat) cell carcinoma, adenocarcinoma, and large cell carcinoma; each has a different natural history (growth pattern) and response to treatment. The squamous cell, small cell, and large cell types are all strongly associated with tobacco abuse; the relation between adenocarcinoma and tobacco use is less clear.

SYMPTOMS AND SIGNS

The first and most common symptom is a cough, occurring in about 80 percent of people with lung cancer. About half of all people with lung cancer have a chronic cough from *bronchitis*. Other symptoms include coughing up blood, shortness of breath, chest pain, and wheezing.

Lung cancer can spread locally to affect tissues immediately surrounding the lungs, or can spread to other parts of the body, especially the liver, brain, and bones. Pain may occur in these sites, and weight loss is a frequent symptom. Local spread may cause the collapse of a lung or *pneumonia*, or affect the pleura (membrane covering the lung), causing *pleural effusion* (a collection of fluid between the lung and the chest wall).

DIAGNOSIS

Lung cancer may be suspected during *history-taking* or a physical examination but, most often, it is discovered when a chest X ray shows a characteristic shadow on the lung.

To confirm the diagnosis, tissue must be examined cytologically for the presence of cancerous cells (see *Cytology*). The simplest test is to examine samples of sputum (phlegm), because cancer cells may have been shed into the airways and occur in the sputum. A *bronchoscopy* may be performed to examine the condition of the lungs or to take a biopsy (small sample of tissue) for analysis or examination. Sometimes biopsy of the suspected tumor is necessary. Cells are obtained through a needle inserted into the chest or by performing an operation to expose the tumor for a direct biopsy (excision of part of the tumor).

TREATMENT

If lung cancer is diagnosed at an early stage, *pneumonectomy* (surgical removal of the lung) or *lobectomy* (removal of part of the lung) may be performed. Surgery is usually possible only when the cancer is still fairly small and confined to one lung, and when the patient's general condition enables a major operation to be performed. *Anticancer drugs* and *radiation therapy* may be used to contain the spread of the tumor or destroy cancerous cells; they are the usual treatment for small cell lung cancer.

OUTLOOK
Overall, less than 10 percent of lung cancer patients survive for five years after the disease is diagnosed. After surgery, the five-year survival rate is between 15 and 30 percent; there have been cases of long-term survival in patients treated with chemotherapy for small cell carcinoma.

The highest chance of cure is obtained when the cancer is discovered and treated early. If the cancer has spread beyond the chest, a cure is highly unlikely.

Lung, collapse of
See *Atelectasis; Pneumothorax.*

Lung disease, chronic obstructive
The combination of chronic *bronchitis* and *emphysema,* in which there is persistent disruption of airflow into or out of the lungs.

Lung imaging
A technique that provides images of the lungs to aid in the diagnosis of abnormalities or disease.

TYPES

CONVENTIONAL X-RAY TECHNIQUES A *chest X ray* provides an excellent image of the lungs, from which almost every type of lung disorder can be detected. *Tomography* produces a sharp image of a cross section of an organ at a particular depth and is sometimes used to visualize the interior of a lung that is obscured by an overlying diseased area or to more clearly identify a nodule in the lung.

In pulmonary *angiography,* a contrast medium (a substance opaque to X rays) is injected into the pulmonary artery to detect *pulmonary embolism* (blockage by a blood clot). *Bronchography* (in which the contrast medium is injected into the bronchi) was once widely used to examine bronchi damaged by chronic infections; it has now been largely replaced by *bronchoscopy.* Other imaging techniques are also used.

SCANNING TECHNIQUES *CT scanning* provides a more detailed image of the lungs than is possible with standard X rays and plays an important role in detecting the presence and spread of *lung tumors. Ultrasound scanning* is sometimes used to reveal *pleural effusion* (fluid around a lung).

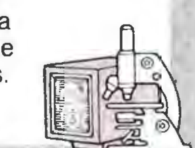
Other less commonly employed imaging techniques involve the use of *radionuclide scanning* to aid in detecting pulmonary embolism. Digital radiography uses a computer to process a standard X-ray film. The computer removes all unwanted elements (such as the bones of the chest) from the image, leaving a clearer view of the structures to be examined.

Lung tumors
Growths in the lung that may be malignant (see *Lung cancer*) or benign. Benign lung tumors are less common than malignant tumors and, unlike malignant tumors, typically affect younger adults and are unrelated to cigarette smoking.

The most common benign tumor is a bronchial *adenoma,* which arises in the lining of a bronchiole. Adenomas often cause partial bronchial obstruction; hemoptysis (coughing up blood) may also occur. Treatment involves surgical removal of the tumor.

DISORDERS OF THE LUNG
The lungs are continuously exposed to airborne particles, such as bacteria, viruses, and allergens, all of which can cause lung disorders. Most of these disorders do not interfere with oxygen supply; those that do are a major threat to health.

INFECTION
Infective disorders are common, especially *tracheitis* (inflammation of the lining of the windpipe) and *croup* (a virus infection of young children). *Bronchitis* (inflammation of the bronchi), *bronchiectasis* (swelling of the bronchi), and *bronchiolitis* (inflammation of the bronchioles) commonly follow colds or *influenza. Pneumonia* (inflammation of the lung) is usually caused by infection by viruses or bacteria. Fungal infections of the lungs, such as *aspergillosis, actinomycosis, histoplasmosis,* and *candidiasis,* are relatively uncommon.



ALLERGIES
Bronchial *asthma,* in which the muscles of the bronchi contract and obstruct the free passage of air, often occurs in sensitized people exposed to pollens, house mites, fungal spores, animal dander, and many other agents. Allergic *alveolitis* (inflammation of the alveoli) may be caused by many organic dusts, such as moldy hay.

TUMORS
Lung cancer is one of the most common of all malignant tumors; in most cases it is associated with cigarette smoking. Secondary malignant tumors, which have spread from other parts of the body to the lungs, are common. However, benign tumors affecting the lung are uncommon.

INJURY
Lung injury usually results from penetration of the chest wall. *Pneumothorax* (air in the pleural cavity) and *hemothorax* (blood in the pleural cavity) are usually caused by a penetrating injury; either may cause collapse of the lung. Injury can also occur from the inhalation of poisonous dusts, gases, or toxic substances. *Silicosis* and *asbestosis* are caused by inhalation of silica and asbestos, respectively; they may lead to progressive *fibrosis* of the lung.

IMPAIRED BLOOD AND OXYGEN SUPPLY
The most serious disorder is *pulmonary embolism,* in which a blood clot formed in one of the major veins breaks free and is carried to the lungs. The clot may block the pulmonary arteries and cause death. Heart failure may cause pulmonary *edema,* in which the lungs become filled with fluid. *Respiratory distress syndrome,* which may affect newborn babies or adults, has many causes. In this condition, leakage of fluid into the alveoli seriously interferes with oxygen supply. *Emphysema,* in which the walls of the alveoli break down so that the area for oxygen exchange is reduced, is frequently seen in people suffering from chronic bronchitis and asthma.

INVESTIGATION
Lung disorders are investigated by *chest X ray, bronchoscopy, pulmonary function tests, sputum* analysis, *blood tests,* and physical examination. Sometimes a biopsy of lung tissue is taken for analysis.

Other rare benign tumors include *fibromas* (made up of fibrous tissue) and *lipomas* (made up of fatty tissue). No treatment is necessary unless the tumors are causing problems.

Lupus erythematosus

A chronic disease that causes inflammation of *connective tissue*. The more common type, discoid lupus erythematosus (DLE), affects exposed areas of the skin. The more serious and potentially fatal form, systemic lupus erythematosus (SLE), affects many systems of the body, including the joints and the kidneys.

Discoid lupus erythematosus on cheek
The disease causes circular, reddened areas of skin. The patch shown here is healing at its center to form white scar tissue.

CAUSES

Lupus erythematosus is an *autoimmune disorder* in which the body's *immune system*, for unknown reasons, attacks the connective tissue as though it were foreign, causing inflammation. It is probable that the disease can be inherited and that hormonal factors play a part. Sometimes the agent that triggers the immune response (e.g., a viral infection) can be inferred. Certain drugs can induce some of the symptoms of SLE, particularly in elderly people; drugs most frequently responsible are hydralazine, procainamide, and isoniazid.

INCIDENCE

Lupus erythematosus affects nine times as many women as men, usually those of childbearing age. It occurs worldwide, although its incidence is higher in certain ethnic groups, such as blacks in the US, West Indians, and Chinese in the Far East. In high-risk groups the incidence may be as high as one in 250 women.

SYMPTOMS

The symptoms of both varieties of lupus erythematosus periodically subside and recur with varying severity.

In DLE the rash starts as one or more red, circular, thickened areas of skin that later scar. They may occur on the face, behind the ears, and on the scalp, sometimes causing permanent hair loss in affected areas.

SLE causes a characteristic red, blotchy, almost butterfly-shaped rash over the cheeks and bridge of the nose. There is no scarring and the hair grows back between attacks. Most sufferers feel sick, with malaise, fatigue, fever, loss of appetite, nausea, joint pain, and weight loss. There may be iron-deficiency *anemia*, neurological or psychiatric problems, *renal failure*, *pleurisy* (inflammation of the lining of the lungs), *arthritis*, and *pericarditis* (inflammation of the membrane surrounding the heart).

DIAGNOSIS

Blood tests and sometimes a skin *biopsy* (removal of tissue for microscopic examination) are performed to look for specific *antibodies* that occur when the disease is active.

TREATMENT

Treatment aims to reduce inflammation and alleviate symptoms; there is no cure. *Nonsteroidal anti-inflammatory drugs* may be prescribed for joint pain, antimalarial drugs for the skin rash, and *corticosteroid drugs* for fever, pleurisy, and neurological symptoms. Sufferers whose symptoms are made worse by sunlight should avoid sun exposure and use *sunscreens*.

OUTLOOK

The future for patients with SLE has improved dramatically over the past 20 years, although the disease may be life-threatening if the kidneys are affected. Today, many people who have SLE survive for more than 10 years after diagnosis of the disease. This improvement may be due to earlier diagnosis, especially of mild cases, and to more effective treatment of kidney problems.

Lupus pernio

A variant of the disease *sarcoidosis* in which purple swellings appear on the nose, cheeks, or ears. It more commonly affects women than men.

Lupus vulgaris

A form of *tuberculosis* affecting the skin, especially of the head and neck. Painless, clear, red-brown nodules appear and ulcerate; they eventually heal, leaving deep scars.

Luteinizing hormone

A *gonadotropin hormone*, also known as LH, produced by the *pituitary gland*.

Luteinizing hormone-releasing hormone

A naturally occurring hormone released by the hypothalamus in the brain, also prepared synthetically as a drug. Natural luteinizing hormone-releasing hormone (LH-RH) stimulates the release of *gonadotropin hormones* from the *pituitary gland*. Gonadotropin hormones, in turn, control the production of *estrogen hormones* and *androgen hormones*.

WHY IT IS USED

Synthetic LH-RH is given to treat abnormally early onset of puberty. It is also currently under investigation as a male contraceptive and as a treatment for uterine *fibroids*, prostatic cancer (see *Prostate, cancer of*), and certain types of *breast cancer*.

HOW IT WORKS

Synthetic LH-RH reduces the amount of natural gonadotropins released from the pituitary gland and thus the amount of *estrogen hormones* and *androgen hormones* produced by the ovary and testes. This action reduces the level of cell activity in organs stimulated by these sex hormones, such as the uterus, breasts, testes, ovaries, and prostate gland.

POSSIBLE ADVERSE EFFECTS

LH-RH may cause headache, nausea, hot flashes, vaginal dryness, and irregular periods.

Luxated tooth

A tooth displaced in its socket as the result of an accident. The upper front teeth are the most vulnerable. The tooth may be depressed deep into the gum, tilted backward or forward, and loosened. A dentist can usually manipulate a luxated tooth back into position, after which it is usually immobilized with a splint (see *Splinting, dental*). If the tooth's blood vessels are torn and the pulp dies, the tooth requires *root-canal treatment*.

Lyme disease

A disease characterized by skin changes, flulike symptoms, and joint inflammation. It was first described in the community of Old Lyme, Connecticut, in 1975.

CAUSES AND INCIDENCE

Lyme disease is caused by the bacterium *BORRELIA BURGDORFERI*, which is transmitted by the bite of a tick that usually lives on deer but can infest dogs. Most cases have occurred in the northeastern US, but the disease has also been reported in other parts of the US and in other countries.

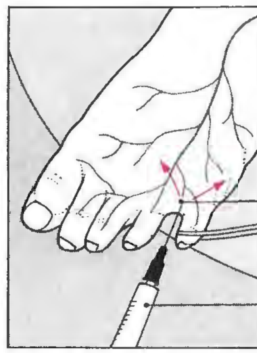
L

SYMPTOMS AND COMPLICATIONS

At the site of the tick bite, a red dot may appear and gradually expand into a reddened area several inches across (although in some cases the bite passes unnoticed). Symptoms such as fever, headache, lethargy, and muscle pains usually develop, followed by a characteristic joint inflammation, with redness and swelling typically affecting the knees and other large joints.

The symptoms may vary in severity and occur in cycles lasting a week or so. Unless the disease is diagnosed and treated, symptoms may continue for several years, gradually declining in severity. There is usually no permanent damage to joints.

Complications affecting the heart (such as *myocarditis* and *heart block*) or nervous system (such as *meningitis*) occur in some cases.



DIAGNOSIS AND TREATMENT

Anyone in whom the above symptoms develop, particularly after a tick bite, should consult a physician. The diagnosis of Lyme disease can be confirmed by blood tests.

If diagnosed before joint inflammation occurs, the disease can be quickly cleared up with antibiotics. If the disease is more advanced, *nonsteroidal anti-inflammatory drugs* and sometimes *corticosteroid drugs* are given and a cure may take longer.

PROCEDURE FOR LYMPHANGIOGRAPHY

To plan and monitor the progress of treatment for certain types of cancer, such as of the testis or cervix, X-ray pictures of the lymph vessels and nodes can be taken to reveal the spread of the cancer throughout the body. A contrast medium is injected into the foot, from where it travels throughout the lymphatic system. The procedure takes about two and a half hours.

1 A blue dye is injected through a needle into the web spaces between the toes of each foot, and into the outside of the little toes. The dye spreads rapidly into the tiny lymphatic vessels along the top of the foot, and makes them visible.

2 After the use of a local anesthetic, an incision is made over a stained lymphatic vessel in each foot. Contrast medium is injected through a needle into the vessels and passes up the legs, into the groin and abdomen. When the limit of diffusion is reached, the needles are removed and the incisions sewn.

3 The lymph vessels and nodes containing the dye show up clearly on the X-ray pictures. More lymphangiograms are taken after 24 hours.

Lymph

A milky body fluid that contains lymphocytes (a type of white blood cell), proteins, and fats. Lymph accumulates outside the blood vessels in the intercellular spaces of body tissues and is collected into the *lymphatic system* to flow back into the bloodstream. Lymph plays an important part in the *immune system* and in absorbing fats from the intestine.

Lymphadenitis

A little-used medical term for inflammation of the lymph nodes, a common cause of lymphadenopathy (swollen glands). See *Glands, swollen*.

Lymphadenopathy

The medical term for swollen lymph nodes (see *Glands, swollen*). A condition called persistent generalized lymphadenopathy, which causes generalized swelling of the lymph nodes, develops in some people infected with HIV (the *AIDS* virus).

Lymphangiography

A diagnostic procedure that enables lymph vessels and lymph nodes to be seen on X-ray film after a contrast medium (a substance opaque to X rays) has been injected into them.

WHY IT IS DONE

Until recently, lymphangiography was frequently used to determine the extent to which a cancer had spread throughout the body (because lymph nodes trap cancer cells). However, the more straightforward techniques of *CT scanning* and *MRI* also clearly reveal abnormal lymph nodes and have largely superseded lymphangiography. Even so, in certain types of cancer (such as cancer of the testis or cervix), the additional information provided by lymphangiography is useful in planning treatment and monitoring progress.

HOW IT IS DONE

A blue dye is injected into the web spaces between all the toes. This dye quickly finds its way into the tiny, usually invisible, lymphatic vessels, allowing the radiologist to see them and select suitable vessels for further examination (see box).

Lymphangiography is sometimes performed on the arms to reveal lymph nodes in the upper body.

Lymphangioma

A rare benign tumor of the skin or tongue consisting of a collection of abnormal lymph vessels. It is usually present from birth.

There are two types of lymphangioma. One consists of a group of clear blisters that may be inconspicuous at birth but are usually obvious by the age of about 2. If the blisters are damaged they fill with blood, giving a red and white appearance to the lymphangioma. The growth often disappears on its own, but some cases require removal.

The other type, known as a cystic hygroma, is a soft swelling that resembles a bunch of small white grapes. It grows just beneath the skin (commonly in the neck), and may become very large and unsightly. It is usually removed at about age 5.

Lymphangitis

Inflammation of the lymphatic vessels as a result of the spread of bacteria (commonly streptococci) from an infected wound. The inflammation is so severe that it causes tender red streaks to appear on the skin overlying

the lymphatic vessels. These streaks extend progressively from the site of infection toward the nearest lymph nodes (for example, from an infected finger up the arm toward the lymph nodes in the armpits). The affected nodes become swollen and tender. There is usually fever and a general feeling of illness.

Lymphangitis is a clear indication of a serious infection and requires urgent treatment with *antibiotic drugs*. Upon treatment, the condition usually clears up quickly without complications. (See also *Lymphadenitis*.)

Lymphatic system

A system of vessels (lymphatics) that drains *lymph* from all over the body back into the bloodstream. This system is part of the *immune system*, playing a major part in the body's defenses against infection and cancer.

STRUCTURE AND FUNCTION

All body tissues are bathed in a watery fluid derived from the bloodstream. Much of this fluid returns to the bloodstream through the walls of the capillaries, but the remainder (along with cells and small particles such as bacteria) is transported to the heart through the lymphatic system (see box, next page).

Throughout the course of the lymphatics lie *lymph nodes*, through which the lymph flows. These nodes are, in effect, filters that trap microorganisms and other foreign bodies in the lymph. The nodes contain many lymphocytes (a type of white blood cell), which can neutralize or destroy invading bacteria and viruses. If part of the body is inflamed or otherwise diseased, the nearby lymph nodes become swollen and tender as they limit the spread of the disease (see *Glands, swollen*). If an infection is particularly virulent, the lymphatics may also be inflamed, becoming visible as thin red lines running along a limb (see *Lymphangitis*).

The lymphatic system also plays a part in the absorption of fats from the intestine. While the products of carbohydrate and protein digestion pass directly into the bloodstream, fats pass into the intestinal lymphatics (lacteals); the lymph in them is so rich in fat that it appears milky.

DISORDERS

In some conditions, such as after radical breast surgery (which is rarely performed today), the lymphatics to a limb become obstructed and the limb becomes hard and swollen as a result, a condition known as *lymphedema*.

Cancer commonly spreads via the lymphatic system. A primary tumor invades the lymphatics and fragments (metastases) break off and travel to the local group of lymph nodes, where the metastases continue to grow and produce a secondary tumor. This is particularly evident in *breast cancer*, which tends to spread early to the lymph nodes in the armpit.

Lymphedema

An abnormal accumulation of *lymph* in the tissues, causing swelling of a limb. Lymphedema occurs if lymphatic vessels are blocked, damaged, or removed, resulting in disruption of the normal drainage of lymph (see *Lymphatic system*).

CAUSES

There are various causes. In the tropical disease *filariasis*, for example, the lymphatic vessels may be blocked by parasitic worms. Blockage may also occur if cancer spreads through the lymphatic system and deposits cancer cells in the lymph vessels.

Surgical removal of lymph nodes under the arm or in the groin or radiation therapy for a tumor destroys lymph nodes and vessels, sometimes resulting in lymphedema.

Lymphedema may also occur for no known cause. It may be present from birth or may develop later in life. Lymphedema of unknown cause affects twice as many women as men.

SYMPTOMS AND SIGNS

In about 10 percent of women who have had a radical mastectomy, lymphedema develops in the arm (but not usually in the hand) on the same side as the breast removed. In some such cases, the arm becomes disablingly heavy and cumbersome. The incidence of lymphedema is much lower with newer surgical techniques.

Other than following mastectomy, lymphedema usually causes swelling of one or both legs. Starting with only a slight, intermittent puffiness around one ankle, the swelling gradually extends up the leg. In about half of all cases, the other leg also becomes affected. The swelling is usually painless, but the leg feels heavy.

In some people the legs enlarge to an unsightly and incapacitating degree, but in others the swelling may be only minimal even 40 or more years after the onset of the condition.

TREATMENT

There is no known cure for lymphedema. Treatment consists of taking *diuretic drugs*, massaging the affected limb, wearing an elastic bandage or compression sleeve, and performing exercises with the leg or arm elevated. However, these measures usually produce only a slight improvement. If the leg or arm is so large that it causes disability, the swollen tissue and some of the overlying skin may be removed surgically.

Lymph gland

A popular name for a *lymph node*. (See also *Lymphatic system*.)

Lymph node

Popularly known as a lymph gland, a small organ lying along the course of a lymphatic vessel.

STRUCTURE AND FUNCTION

Lymph nodes vary considerably in size from microscopic to about 1 inch (2.5 cm) in diameter. Each node consists of a thin, fibrous outer capsule and an inner mass of lymphoid tissue. Penetrating the capsule are several small lymphatic vessels (which carry lymph into the gland) and a single, larger vessel (which carries it out).

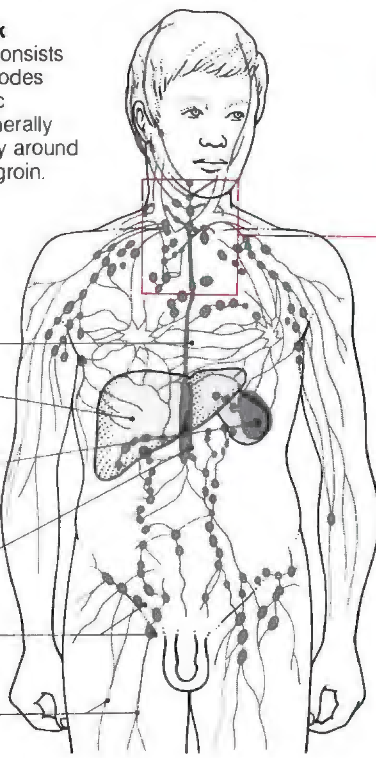
Lymphoid tissue forms *antibodies* and houses *lymphocytes*, both of which play a very important role in fighting infection. Lymph nodes also contain macrophages, large cells that engulf bacteria and other foreign particles. The nodes act as a barrier to the spread of infection, destroying or filtering out bacteria before they can pass into the bloodstream. (See also *Glands, swollen*; *Lymphatic system*.)

Lymphocyte

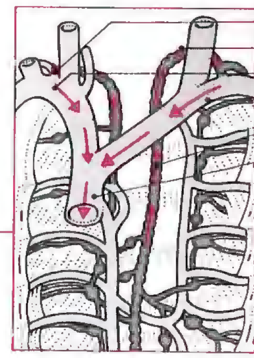
Any of a group of white *blood cells* of crucial importance to the adaptive part of the body's *immune system*. The adaptive portion of the immune system mounts a tailor-made defense when dangerous invading organisms penetrate the body's general defenses (such as those provided by other types of white blood cell).

Some lymphocytes retain a memory of invading microorganisms so that the invaders can be dealt with more rapidly when next encountered. It is this memory function that is stimulated by vaccines. Lymphocytes protect against the development of tumors and cause rejection of tissue in organ transplants.

TYPES

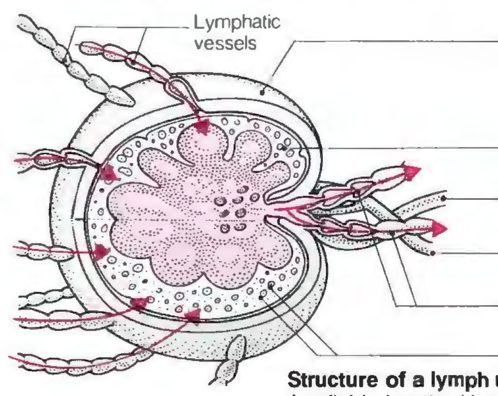


There are two principal types of lymphocytes. They are called B- and T-lymphocytes.



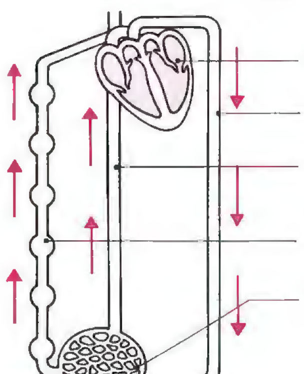
B-LYMPHOCYTES This type accounts for about 10 percent of circulating lymphocytes. When a particular *antigen* (foreign protein), such as a

STRUCTURE AND FUNCTION OF THE LYMPHATIC SYSTEM

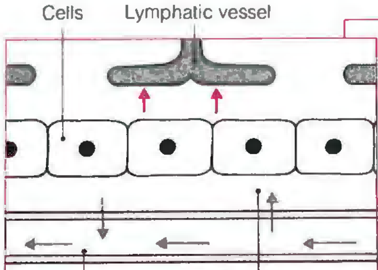


The lymphatic system is a collection of organs, ducts, and tissues that has the dual role of draining tissue fluid (lymph) back into the bloodstream and of fighting infection. Lymph is drained by a system of channels (the lymphatic vessels). White cells produced by the bone marrow, thymus, and spleen are present in lymph nodes or circulate through the lymphatic system, providing defenses against infection.

The lymphatic network
The lymphatic system consists of a network of lymph nodes connected by lymphatic vessels. The nodes generally occur in clusters, mainly around the neck, armpits, and groin.



Lymphatic drainage
Just below the neck, the thoracic duct and the right lymphatic duct drain into the two subclavian veins. These veins unite to form the inferior vena cava, which passes into the heart; in this way, the lymph fluids rejoin the circulation.



Structure of a lymph node
Any fluid absorbed into the lymphatic system passes across at least one lymph node before it returns to the circulation. The fluid filters through a mesh of tightly packed white blood cells—some of which are grouped into primary follicles consisting of similar cells—which attack and destroy harmful organisms. Every lymph node is supplied by its own tiny artery and vein.

MOVEMENTS OF BODY FLUIDS

Lymph is constantly moving around the body, but the lymphatic system has no central pump equivalent to the heart. Lymph is circulated by the movement of the body's muscles; a system of one-way valves in the lymphatic vessels ensures that it moves in the right direction. Exertion also pushes fluid from body tissues into the bloodstream.

Fluid exchange
During a 24-hour period, approximately 42 pints of serumlike fluid pass from the bloodstream to the body's tissues. This fluid bathes the cells and provides them with oxygen and nutrients. During the same period of time, approximately 36 pints of fluid pass back from the tissues to the bloodstream, carrying carbon dioxide and other waste products. The remaining 6 pints pass from the tissues to the lymphatic system and return eventually to the circulation from there.

Enlarged lymph nodes
This photograph shows a girl with marked enlargement of the lymph nodes in her neck. In this case, the appearance is due to Hodgkin's disease, a rare cancer that affects the lymph nodes. Enlargement of the lymph nodes may also be due to infection

substance on the surface of a bacterium, is encountered by the immune system, certain B-lymphocytes are stimulated to enlarge and undergo cell division, transforming into cells called plasma cells. The plasma cells secrete into the blood vast numbers of tailor-made *immunoglobulins* or *antibodies* that attach to the antigen on the surface of the microorganism. This starts a process that leads to the destruction of the microorganism. The protective effect of immunoglobulins is called humoral immunity.

T-LYMPHOCYTES This type accounts for more than 80 percent of circulating lymphocytes. T-lymphocytes are derived from white cells that have at some stage entered the thymus gland, where they were "educated" to fulfill a particular function.

There are two main groups of T-lymphocytes: killer (cytotoxic) and helper cells. The killer T-lymphocytes (like B-lymphocytes) are sensitized and stimulated to multiply by the presence of antigens, in this case by antigens present on abnormal body cells (e.g., cells that have been invaded by viruses, cells in transplanted tissue, and tumor cells). Unlike the B-lymphocytes, the killer cells do not produce antibodies; instead, they travel to and attach to the cells recognized as abnormal. The killer cells then release chemicals known as lymphokines, which help destroy the abnormal cells. This is called cell-mediated immunity.

Helper T cells enhance the activities of the cytotoxic cells and control other aspects of the immune response. In people infected with HIV (the *AIDS* virus) these helper T cells are reduced in number, thus impairing the body's ability to fight certain types of infections and tumors.

MEMORY FUNCTION

Some lymphocytes do not participate directly in immune responses; instead, they serve as a memory bank for the different antigens that have been encountered in the past. These cells may survive for many years.

Lymphogranuloma venereum

A sexually transmitted disease, common in tropical countries. It is caused by a *chlamydial infection* that is common in tropical countries.

The first sign of infection is a small genital blister that appears three to 21 days after infection; this blister heals in a few days without leaving a scar. There may also be fever, headache, muscle and joint pains, and a rash.

The lymph glands, particularly in the groin, become painfully enlarged and inflamed. Abscesses may form and ulcers may develop on the skin over the affected glands; the ulcers take several months to heal.

Treatment of lymphogranuloma venereum is with *antibiotic drugs*.

Lymphoma

Any of a group of cancers in which the cells of lymphoid tissue (found mainly in the lymph nodes and spleen) multiply unchecked.

Lymphomas fall into two categories. If characteristic abnormal cells (Reed-Sternberg cells) are present, the disease is called Hodgkin's lymphoma. All other types are called non-Hodgkin's. (See *Hodgkin's disease; Lymphoma, non-Hodgkin's.*)

Lymphoma, non-Hodgkin's

Any cancer of lymphoid tissue (found mainly in the lymph nodes and spleen) other than *Hodgkin's disease*.

Non-Hodgkin's lymphomas vary in their malignancy according to the nature and activity of the abnormal cells. Lymphomas are most malignant when the cells are primitive or are poorly differentiated (unspecialized). These cells tend to take over entire lymph nodes quickly. Low-grade lymphomas consist of cells that are better-differentiated.

CAUSES AND INCIDENCE

In most cases of non-Hodgkin's lymphoma, the cause is unknown. Occasionally, the disease is associated with suppression of the *immune system*, particularly after organ transplantation. One type of non-Hodgkin's lymphoma, called *Burkitt's lymphoma* (common only in the tropics), is thought to be caused by the Epstein-Barr virus. It is suspected that *HIV* (the *AIDS* virus) permits other viruses to cause lymphomas.

About eight new cases of non-Hodgkin's lymphoma are diagnosed annually per 100,000 people in the US. Most sufferers are over 50.

SYMPTOMS AND SIGNS

In most patients, there is painless swelling of one or more groups of lymph nodes in the neck or groin. The liver and spleen may enlarge and lymphoid tissue in the abdomen may be affected, in rare cases causing abdominal pain and bleeding from the intestines, which is revealed as tarry-looking feces or vomiting of blood. Many other organs may also become involved, leading to diverse symptoms ranging from headache to skin ulceration. Unless it is controlled, spread of the disease (often marked by fever) progressively impairs the immune system, leading to death from infections. The patient may also die of an uncontrolled spread of cancer.

DIAGNOSIS

Diagnosis is based on a *biopsy* (removal of a sample for analysis) of lymphoid tissue, usually from a lymph node. The extent of the disease is assessed by a process called staging. A *chest X ray*, *CT scanning*, *bone marrow biopsy*, and *lymphangiography* (X rays of the lymph glands) of the abdomen may be required.

TREATMENT AND OUTLOOK

If the lymphoma is confined to a single group of lymph nodes, treatment consists of *radiation therapy*. If the disease is more extensive, *anticancer drugs* are given. In some cases both forms of treatment are used. When all else fails, autologous *bone marrow transplantation* and high doses of chemotherapy and/or radiation may be used.

About three quarters of patients with a low-grade localized non-Hodgkin's lymphoma survive at least five years. In more severe types of lymphoma that have spread, 40 to 50 percent of patients survive for two years or more.

Lymphosarcoma

A now uncommonly used name for non-Hodgkin's lymphoma (see *Lymphoma, non-Hodgkin's*).

Lypressin

A synthetic preparation of *ADH* (antidiuretic hormone), a hormone that controls the volume of water excreted in the urine. Lypressin is used as a nasal spray to treat *diabetes insipidus* (a deficiency of ADH causing excessive urination and thirst).

Possible adverse effects are abdominal cramps, an urge to pass bowel movements, and nasal congestion that, if severe, may impair the efficiency of treatment.

Lysis

A medical term for the destruction of a cell by damage to its outer membrane. A common example is *hemolysis*, the breakdown of red blood cells. Lysis may be caused by chemical action, such as that of an *enzyme* (a protein that controls a chemical reaction), or by physical action, such as heat or cold. The term lysis is also occasionally used to refer to a sudden recovery from a fever.

M

Macro-

A prefix meaning large, as in macrophage (a large cell that plays an important part in the body's defense system by engulfing bacteria and other foreign particles) or macroglossia (enlargement of the tongue).

Macrobiotics

A diet based on the oriental belief that all foods are either yin or yang (possessed of negative or positive energy), and that a balance of yin and yang must be maintained for health. Foods are classified yin or yang according to many factors, including where they are grown, their color, texture, and taste. There are several levels of macrobiotic diet; the most advanced consists mainly of whole grains. Eating such a diet may lead to severe malnutrition, scurvy, or anemia due to the lack of protein, vitamins, and minerals.

Macroglossia

Abnormal enlargement of the tongue. Macroglossia is a feature of *Down's syndrome*, of *hypothyroidism*, and of *acromegaly*. Tumors of the tongue, such as a *hemangioma* or *lymphangioma*, also cause macroglossia; *amyloidosis* is another possible cause.

In addition to being unsightly, an abnormally large tongue can cause snoring and is sometimes responsible for *sleep apnea*. Treatment is limited and depends on the underlying cause.

Macular degeneration

A progressive disorder that affects the central part of the *retina*, causing gradual loss of vision. Macular degeneration is a painless condition that is common in the elderly. It usually affects both eyes, either simultaneously or one after the other.

The macula is the part of the retina that distinguishes fine detail at the center of the field of vision. Degeneration begins with partial breakdown of an insulating layer between the retina and the *choroid* (layer of blood vessels behind the retina). Fluid leakage occurs, and new blood vessels growing from the choroid destroy the retinal nerve tissue and replace it with scar tissue. The effect is a roughly circular area of blindness, increasing in size until it is large enough to obliterate two or three words at normal reading distance.

With early diagnosis, it is sometimes possible to seal off the leakage with a *laser*. In most cases, however, the disorder is untreatable.

Macule

A spot on the skin (level with the surface) discernible only by difference in color or texture.

Magnesium

A metallic element that plays several vital roles in the body. Magnesium is essential for the formation of bones and teeth, for muscle contraction, for the transmission of nerve impulses, and for the activation of many *enzymes* (substances that promote biochemical reactions in the body). There are about 1.25 ounces (35 g) of magnesium in an average-sized person, much of it in the bones and teeth.

The recommended daily intake of magnesium varies from 50 mg in the newborn to 400 mg in young men. Women require slightly less than men, except during pregnancy and breast-feeding. Dietary sources are green, leafy vegetables, nuts, whole grains, soybeans, milk, and seafood.

MAGNESIUM-CONTAINING DRUGS

Magnesium compounds are used in *antacid drugs* and *laxatives*. Magnesium carbonate and magnesium oxide are common ingredients of antacids; magnesium sulfate is used in laxatives. Magnesium is also a constituent of some mineral supplements.

DEFICIENCY AND EXCESS

A normal diet contains sufficient magnesium. Deficiency (which is rare) usually occurs as a result of an intestinal disorder that impairs absorption of both calcium and of magnesium, a severe kidney disease, alcoholism, or prolonged treatment with *diuretic drugs* or *digitalis drugs*. Symptoms of deficiency include anxiety, restlessness, tremors, palpitations, and depression. There is also thought to be an increased risk of kidney stones or coronary heart disease. Deficiency is treated with supplements.

Magnesium excess is usually caused by taking too much of a magnesium-containing antacid or laxative. Too much magnesium may cause nausea, vomiting, diarrhea, dizziness, and muscle weakness. Very large amounts may lead to heart damage or respiratory failure, especially in people with kidney disease. Mild magnesium excess does not usually require treatment. However, anyone who has taken a substantial overdose may require hospitalization so that breathing and heart activity can be monitored (and supported, if necessary) and drugs can be given to help the body excrete the excess.

Magnetic resonance imaging

See *MRI*.

Malabsorption

Impaired absorption of nutrients, vitamins, or minerals from the diet by the lining of the small intestine.

CAUSES

Malabsorption is caused by many conditions. In *lactose intolerance*, deficiency of the enzyme lactase in the intestine prevents the breakdown and absorption of lactose (sugar found in milk). In *cystic fibrosis* and chronic *pancreatitis*, damage to the pancreas prevents the production of enzymes required for the digestion and absorption of fats and other nutrients.

In *celiac sprue*, many nutrients cannot be absorbed because of damage to the small intestine by sensitivity to the protein gluten. Uncommon diseases in which the intestinal lining is damaged include *Crohn's disease*, *amyloidosis*, *giardiasis*, *Whipple's disease*, and *lymphoma*.

Removal of portions of the small intestine can cause malabsorption, as can stomach operations that cause food to pass through the digestive tract more quickly than normal.

There are also some disorders that interfere with the passage of bile salts to the small intestine or that interfere with their uptake, thus preventing the breakdown and absorption of fats. These disorders include *bile duct obstruction*, primary *biliary cirrhosis*, and Crohn's disease.

SYMPTOMS AND DIAGNOSIS

Common effects are diarrhea and weight loss; in severe cases, there may also be malnutrition (see *Nutritional disorders*), *vitamin* deficiency, *mineral* deficiency, or *anemia*.

The diagnosis is confirmed by examining feces for unabsorbed fat and by blood tests to detect anemia and deficiencies of nutrients, vitamins, and minerals. To determine the cause of malabsorption, tests may be carried out, including *barium X-ray*

examination of the small intestine and *jejunal biopsy* (removal of tissue from the jejunum for examination).

TREATMENT AND OUTLOOK

Treatment depends on the underlying cause. In most cases, modifications or supplements to the diet restore the affected person to health. However, if there is severe, irreversible damage to the lining of the intestine, infusion of nutrients into a vein may be necessary (see *Feeding, artificial*).

Maladjustment

Failure to adapt to a change in one's environment, resulting in an inability to cope with work or social activities. Maladjustment is common and can occur at any age as a reaction to stressful situations (such as starting school, changing residence, divorce, physical illness, or retirement). It may be expressed by feelings of *depression* or *anxiety*, or by *behavioral problems in children* and adolescents.

Maladjustment is usually temporary, clearing up when the person is removed from the stressful situation or learns to adapt to it.

Malaise

A vague feeling of being sick or of physical discomfort. It is a general symptom of little value in diagnosis.

Malalignment

Positioning of teeth in the jaw so that they do not form a smooth arch shape when viewed from above or below (see *Malocclusion*). The term is also used to refer to a *fracture* in which the bone ends are not in a straight line. These fractures must be manipulated back into position so that the bone is not deformed when it heals.

Malar flush

A high color over the cheekbones, with a bluish tinge caused by reduced oxygen concentration in the blood. Malar flush is considered to be a sign of *mitral stenosis* (narrowing of one of the heart valves), usually following *rheumatic fever*. However, malar flush is not always present in mitral stenosis, and many people with this coloring do not have heart disease.

Malaria

A serious parasitic disease, spread by the bites of *ANOPHELES* mosquitoes. The disease produces severe fever and, in some cases, complications affecting the kidneys, liver, brain, and blood that can be fatal.

Malaria is prevalent throughout the tropics, affecting up to 300 million people worldwide each year. It is the single most important disease hazard for travelers to warm climates.

CAUSES

The parasites responsible for malaria are single-celled (protozoal) organisms called plasmodia. Four different species can cause disease in humans: *PLASMODIUM FALCIPARUM*, *PLASMODIUM VIVAX*, *PLASMODIUM OVALE*, and *PLASMODIUM MALARIAE*. Each of these species spends part of its life cycle in humans and part in *ANOPHELES* mosquitoes (see diagram, overleaf).

Symptoms, including shaking, chills, and fever, appear only when red blood cells, infected with parasites, rupture to release more parasites into the bloodstream.

INCIDENCE

Malaria occurs in much of the tropics, where it is a major health problem (see map). Children in affected countries suffer repeated infections, and many die. Malaria kills about 1 million infants and children every year in Africa alone; those who survive gradually build up immunity. The World Health Organization has undertaken a massive program of malaria control, but little progress has been made in the past 20 years. Mosquitoes have developed resistance to insecticides and, in many areas, the parasites have developed resistance to drugs.

The number of cases diagnosed in the US has increased significantly over the last 15 years, from a few hundred cases annually in the early 1970s to about 1,000 cases in both 1984 and 1985. Part of this rise is attributable to increased travel; about 40 percent of cases occur in people recently returned from the tropics. The risk of contracting the disease in Africa seems particularly high. The remaining 60 percent of cases affect foreign immigrants to the US.

The chance of contracting malaria within the US is very small. Cases have occurred among drug users who have shared needles with an infected person, and in people who have received infected blood transfusions.

SYMPTOMS

The period between the mosquito bite and the appearance of symptoms is usually a week or two, but can be as long as a year if the person has been taking antimalarial drugs (which suppress rather than cure malaria).

The prime symptom of infection is the classic malarial ague (fever). Except for most *P. FALCIPARUM* infections, this fever has three stages: a cold stage of uncontrollable shivering (rigors), a hot stage in which the temperature may reach 105°F, and finally a sweating stage that drenches the bedding and brings down the temperature. A severe headache, general malaise, and vomiting may accompany the attack. At the end of an attack, the patient is left weak and tired, and sleeps. In many cases, the parasitized red blood cells rupture at the same time in each cycle and the fever develops cyclically, occurring every other day (with *P. VIVAX* and *P. OVALE* infections) or every third day (with *P. MALARIAE*).

P. FALCIPARUM infects all ages of red blood cells, whereas the other varieties attack only young or old cells. Falciparum malaria thus affects a greater proportion of the blood cells and is therefore more severe. It can be fatal within a few hours of the first symptoms. The fever is prolonged and irregular. So many blood cells may be destroyed that they block blood vessels in vital organs, especially the kidneys. The spleen becomes enlarged and the brain may be affected, leading to coma and convulsions. Destruction of blood cells leads to hemolytic *anemia*. Kidney and liver failure are common complications of falciparum malaria.

DIAGNOSIS

Malaria is diagnosed from studying *blood smears* in the laboratory at six- to 12-hour intervals; the parasites are clearly visible under the microscope.

TREATMENT

Malaria, especially falciparum malaria, is a medical emergency that is treated in the hospital.

The antimalarial drug chloroquine, which eradicates the parasites from the blood, is the usual treatment for all types of malaria. However, chloroquine-resistant falciparum malaria is now widespread in many tropical areas. If a chloroquine-resistant form is suspected, or if the number of parasites does not diminish over 24 hours, other drugs, such as quinine or the combination of pyrimethamine and sulfadoxine, may be given.

In serious illness, exchange blood transfusions have been investigated as a lifesaving effort.

For any type other than falciparum malaria, another drug, primaquine, must be taken for another two weeks to eradicate parasites in the liver. Primaquine may cause hemolytic anemia in people who have a disorder called *G6PD deficiency*.

PREVENTION

In countries where malaria is common, most people have acquired some immunity to the disease. However, this does not apply to visitors to the tropics, who should take preventive antimalarial drugs. These drugs should be taken a day or two before entering a malarious area and use should be continued for at least four weeks after leaving it.

The physician will want to know what countries are to be visited before prescribing a drug. For areas where there is no resistance to chloroquine, this drug is recommended; proguanil is recommended for longer term use because it has fewer side effects. For chloroquine-resistant areas there are various possibilities, such as a combination of chloroquine and proguanil, or the combination of pyrimethamine with either sulfadoxine or dapsone. These drugs may then be followed by a course of primaquine, which provides a radical cure of the forms of malaria found in the liver.

Antimalarial drugs should be taken even by pregnant women in highly malarious areas (proguanil or chloroquine are the recommended drugs in this case). Although the drugs present a slight risk to the fetus, it is less than the risk to the fetus if the mother contracts malaria.

In addition, visitors to the tropics should avoid mosquito bites by wearing protective clothing over the arms and legs in the evening; other preventive measures include screens over windows, insecticide sprays, and, if necessary, mosquito nets. People should also avoid entering jungle areas at night.

Even people who take antimalarial drugs and precautions against bites may contract malaria. Anyone in whom a fever and headache develops after returning from the tropics should see a physician as soon as possible and mention the trip abroad so that appropriate blood smears can be arranged to diagnose malaria.

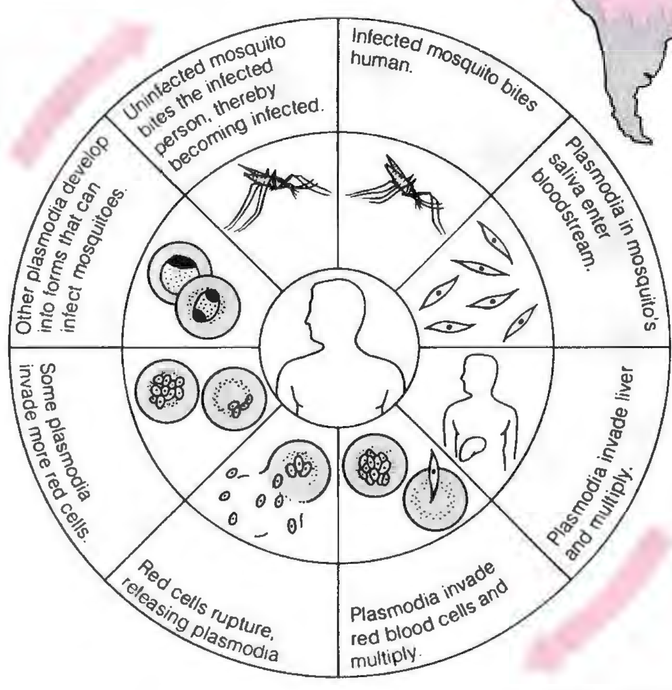
Malformation

A deformity, particularly one resulting from faulty development.

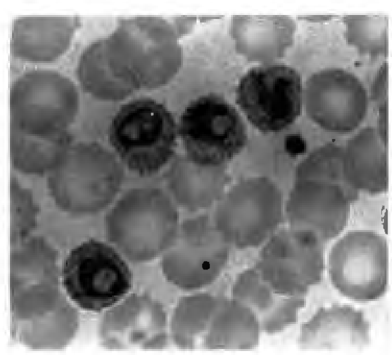
Malignant

A term used to describe a condition that tends to become progressively worse and to result in death. By contrast, a *benign* disorder remains relatively mild and is not usually fatal. The term malignant is primarily used to refer to a *tumor* that spreads from its original location to affect other parts of the body, with potentially life-threatening results.

Malignant melanoma



See *Melanoma, malignant.*



THE SPREAD OF MALARIA

Malaria parasites (plasmodia) are transmitted by the bites of infected *ANOPHELES* mosquitoes. The plasmodia invade the liver, and then the red blood cells, where they multiply. When the red cells rupture, some of the released parasites invade more red cells; other plasmodia develop into forms that can infect mosquitoes.

Prevalence of malaria
Malaria, rare in the US, is a major health problem in the tropics. It affects some 200 to 300 million people worldwide, and kills more than 1 million people a year in Africa alone.

Malarial infection of blood cells
Four red blood cells contain the typical "signet ring" forms of one type of malarial parasite.

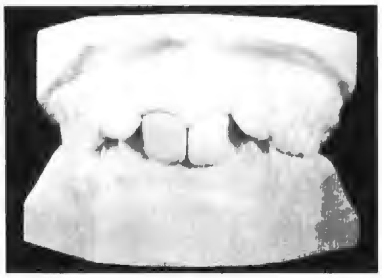
Malingering
Deliberate simulation of physical or psychological symptoms for a particular purpose, such as obtaining time off work, avoiding military service, or obtaining compensation. Malingering differs from *factitious disorders*, in which the person feigns illness for no reason other than a wish to gain the attention associated with illness and being a patient. Malingering is also distinguished from a *somatization disorder* (such as *hypochondriasis*), in which symptoms are not under the voluntary control of the person.

Mallet finger
See *Baseball finger*.

Mallet toe
A deformity of one or more toes (excluding the big toe) in one or both feet. The end of the affected toe bends downward so that the toe curls under itself. The cause is unknown. A painful corn may develop on the tip of the toe or over the top of the bent joint. Protective pads can sometimes relieve excessive pressure from footwear; if not, surgical treatment of the toe may be needed. (See also *Clawfoot*.)

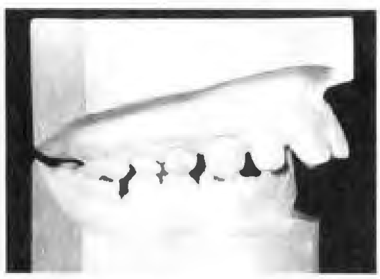
Mallory-Weiss syndrome
A condition in which a tear at the lower end of the esophagus causes vomiting of blood. Mallory-Weiss syndrome is particularly common in alcoholics after a bout of excessive drinking accompanied by retching and vomiting. Occasionally, the tear may be produced by violent coughing, a severe asthma attack, or epileptic convulsions. The damage is thought usually to result from violent contractions of the diaphragm during prolonged retching and vomiting.

DIAGNOSIS AND TREATMENT



Diagnosis is made by passing an *endoscope* (a tubelike instrument with a light source and lens attachment) down the esophagus. The tear usually heals within 10 days and no special treatment is required unless the person has lost a considerable amount of blood, in which case blood transfusions may be necessary.

Malnutrition
See *Nutritional disorders*.



Malocclusion
An abnormal relationship between the upper and lower sets of teeth when they are closed. In ideal occlusion the upper incisors and canines (front teeth) slightly overlap the lower ones, the outer ridges of the lower premolars and molars (back teeth) fit into the hollows in the corresponding upper teeth, and, except for the four frontmost incisors, the other upper and lower teeth alternate. This arrangement enables food to be bitten and chewed efficiently.

TYPES OF MALOCCLUSION

Unsatisfactory contact between the upper and lower teeth (malocclusion) is of three main types, shown below.

Type 1 malocclusion
In this (the most common) type, the jaw relationship is normal, but, because the teeth are poorly spaced, tilted, or rotated, the upper and lower set do not meet properly.

Type 2 malocclusion
In this type—called retrognathism—the lower jaw is too far back; the normal small overbite of the upper incisors is greatly increased, and the molar bite is displaced backward.

Type 3 malocclusion
In this (the least common) type (called prognathism), the lower jaw is too far forward; the lower incisors meet, or lie in front of, the upper ones, and the molar bite is displaced forward.

Ideal occlusion is uncommon; most people have some teeth slightly out of position. Only severe malocclusion usually requires treatment.

CAUSES

Malocclusion usually develops in childhood, when the teeth and jaws are growing. Most malocclusion is the result of *heredity*. Other cases may result from *thumb-sucking* beyond a certain age or from a mismatch between the teeth and the jaws (for example, large teeth in a small mouth, leading to *overcrowding*).

TREATMENT

Malocclusion may require treatment to improve appearance, to prevent strain from the abnormal bite (which causes pain, stiffness, and sometimes *arthritis* in the jaw joints), or to facilitate teeth cleaning and thus help prevent *periodontal disease* and decay (see *Caries, dental*).

The dentist may be able to correct uneven contacts between teeth by recontouring opposing tooth surfaces or by fitting an onlay restoration (see *Onlay, dental*) to alter the shape of a tooth. However, most serious abnormalities require orthodontic treatment, which consists mainly of using *orthodontic appliances* (braces) to train teeth to grow into the proper position. In cases of tooth crowding, some teeth may need to be extracted. *Orthognathic surgery* is used to treat recession or protrusion of the lower jaw.

Treatment is best carried out in childhood or adolescence, when the teeth and bones of the jaw are still developing. Problems left until adulthood can be treated successfully, but may take longer to correct than when treated earlier.

Malpractice
See *Liability insurance, professional*.

Malpresentation
A condition in which a baby is not in the usual face downward, head first position during *childbirth*. Only 5 percent of babies enter labor malpresented. Most malpresentations are bottom first (breech position) or head first but face upward (occipital posterior position); some lie transversely across the uterus.

A baby lying bottom first may be delivered by *breech delivery* or *cesarean section*. A baby lying transversely usually is delivered by cesarean section. A baby in the occipital posterior position usually rotates into a normal position during labor; sometimes a cesarean is necessary.

M

Mammary gland

See *Breast.*

Mammography

An X-ray procedure for detecting *breast cancer* at an early stage.

WHY IT IS DONE

Successful treatment of breast cancer depends on early diagnosis (detection of tumors less than about one half inch across). Growths this small may not be discernible on physical examination (see *Breast self-examination*) and can be effectively detected only by mammography. Screening tests using mammography have reduced death rates from breast cancer in women over the age of 50 by 30 percent.

Mammography is also used to aid diagnosis of established breast disease and to help plan treatment.

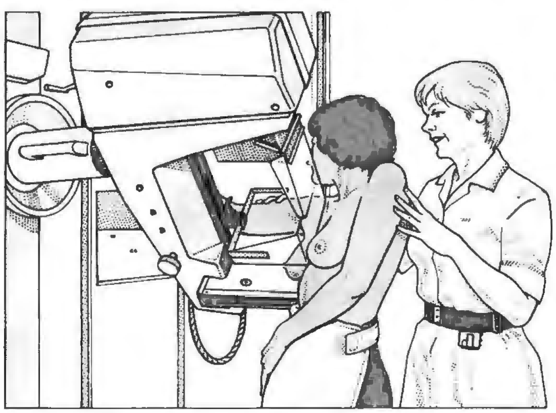
Mammoplasty

A cosmetic operation to reduce the size of extremely large or pendulous breasts, to enlarge small breasts, or to reconstruct a breast after it has been removed to treat cancer.

BREAST REDUCTION

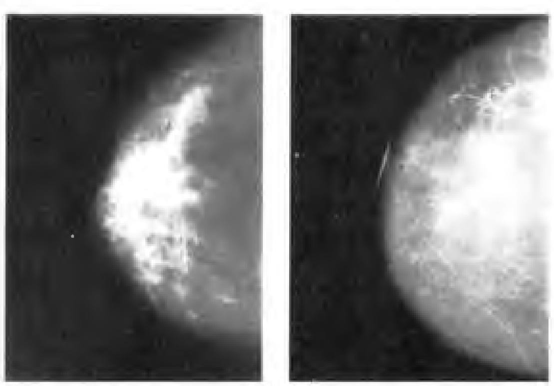
This operation is performed using a general anesthetic. Incisions are inconspicuous and positioned so that unwanted tissue is easily removed. This procedure reduces the size of the breast and raises its position to correct any drooping.

Most patients are pleased with the results. The nipple scar and the scar beneath the breast are usually well hidden, but the vertical scar is usually evident and may need to be made less obvious at a second, minor operation.



BREAST ENLARGEMENT

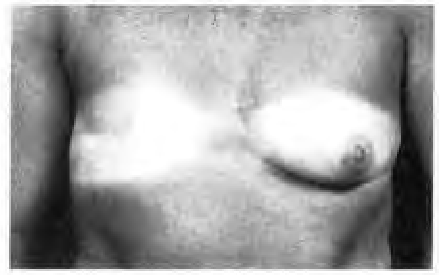
This procedure is usually performed using a short-acting general anesthetic. A small opening at the side or below the breast allows a pocket to be made to accommodate the implant.



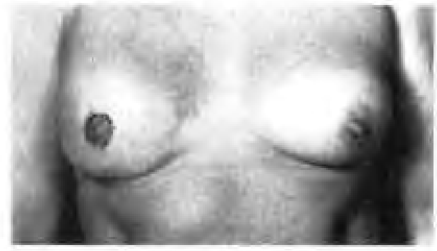
The immediate results are usually excellent, but internal scar tissue often eventually forms around the implant, altering its shape and making the breast harder. External pressure on the implant to restore its shape or sometimes another minor operation may be necessary.

PROCEDURE FOR MAMMOGRAPHY

Mammography is simple, safe, and causes minimal discomfort. Only low-dose X rays are used. The breast may be X-rayed from above, the side, or both; sometimes an oblique (angled) view is taken.



How mammography is done
In the method shown here, the breast is placed on the machine and gently compressed between the X-ray plate below and a plastic cover above. This flattens the breast so that as much tissue as possible can be imaged. Several views may be taken. In another method, the breast hangs freely and is X-rayed from the side.



Mammograms
The normal mammogram (far left) shows a side view of a healthy breast, with the milk ducts appearing as denser areas. In the abnormal mammogram (left), an irregular, dense mass in the upper part of the breast indicates a tumor. A biopsy (removal of a tissue sample for analysis) is necessary to determine whether a tumor is cancerous.

BREAST RECONSTRUCTION

This operation is carried out either at the same time as a *mastectomy* (breast removal) or at a later date, again using a general anesthetic. Depending on the type of mastectomy, reconstruction takes one of two forms.

Before

After

Reconstruction of a breast
A breast removed at an earlier mastectomy operation can be reconstructed later using a silicone rubber implant.

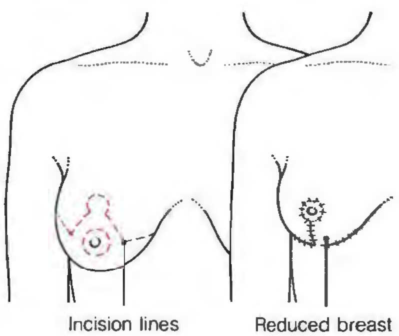
If the entire breast is removed, a portion of skin and underlying fat and muscle is transplanted from a site near the breast; a silicone rubber implant is incorporated at the same time. In this case, scarring is extensive.

Increasingly often, surgeons remove only the tumor and surrounding tissue, leaving the overlying skin in place; the implant can then be inserted with minimal scarring.

In both operations the size of the other breast may be reduced to make the breasts look balanced.

Mandible

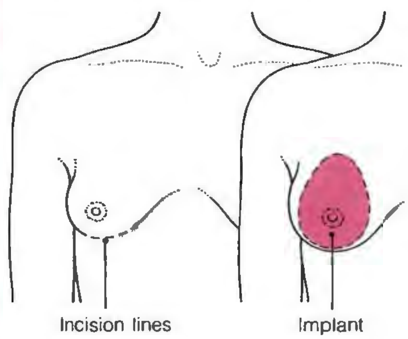
The lower *jaw.*



Mandibular orthopedic repositioning appliance

A device used by some dentists to treat conditions claimed to result from misalignment of the jaw, such as headaches, temporomandibular disorders, scoliosis (curvature of the spine), and loss of balance. A mandibular orthopedic repositioning appliance (MORA) is often mistaken for a mouth protector, but does not perform the same function.

PROCEDURE FOR MAMMOPLASTY



One of the most common cosmetic operations, mammoplasty is done to improve the appearance of the breasts by removal of excess fat and skin or by using an implant to increase their size.

BREAST REDUCTION

Incisions are made around the edge of the nipple and in the crease below the breast. These are joined by a third vertical cut. Excess tissue and skin are removed, and the incisions are closed with stitches.

BREAST ENLARGEMENT

An incision is made in the armpit or along the crease under the breast, and a pocket is created behind the breast to receive the implant. After the implant has been inserted, the incision is stitched.

Much controversy exists over whether a MORA can improve athletic performance by building strength and endurance. Such claims have not been scientifically proved. In fact, there is evidence that continued use of a MORA may result in severe malocclusion that requires extensive orthodontic or reconstructive treatment.

Mania

A mental disorder characterized by episodes of overactivity, elation, or irritability. Mania usually occurs as part of a *manic-depressive illness*.

SYMPTOMS

The primary symptom of mania is an abnormal increase in activity (for example, the sufferer may make elaborate plans for a constant round of social activity). Other symptoms may include extravagant spending, repeatedly starting new tasks, less need to sleep, increased appetite for food, alcohol, sex, and energetic exercise, outbursts of inappropriate anger, laughter, or sudden socializing, and a grandiose sense of knowing better than others. This may extend to delusions of grandeur (for example, believing oneself to be God). When symptoms are relatively mild, the condition is called hypomania.

Manic attacks usually first appear before the age of 30, and may last for a few days or several months. If attacks begin after age 40, they are frequently more prolonged.

TREATMENT

Severe mania often leads to marked social disruption or even violence; hospital admission is usually required. Treatment is generally by means of *antipsychotic drugs* and relapses are prevented by giving *lithium*. Carbamazepine is sometimes used to augment the effect of lithium.

Manic-depressive illness

A mental disorder in which a disturbance of mood is the major symptom. This disturbance may consist of *depression* or of *mania* (unipolar) or of a swing between the two states (bipolar).

CAUSES

A number of physical illnesses (especially brain disorders), certain drugs, and a clear inherited tendency are all established factors. Research has located at least one of the defective genes responsible on chromosome 11.

Overactivity seems due largely to extra amounts of the neurochemical dopamine in parts of the brain; this may simply represent a manic reaction to an underlying depression caused by loss or grief.

PREVALENCE

Depression is very common, affecting about one in 10 men and one in five women at some time in their lives. About a third of these illnesses are severe. By contrast, mania (unipolar or bipolar) is rare, affecting only about eight per 1,000 people, men and women equally.

TREATMENT

Admission to the hospital is often required for severe manic-depressive illness. *Antidepressant drugs* and/or *ECT* (electroconvulsive therapy) are effective in treating depression. *Antipsychotic drugs* (e.g., chlorpromazine and haloperidol) are used to control manic symptoms. *Lithium* alone or, when inadequate, with carbamazepine may be used during remission to prevent relapse.

Group, family, and individual therapy are useful in treating neurotic disorders and in aiding recovery after a severe episode. *Cognitive-behavioral therapy* may also be helpful.

OUTLOOK

Though often crippling in the acute phase, manic-depressive illnesses have a good prognosis. Abilities are not affected, and more than 80 percent of patients recover.

Repeated, severe illnesses, however, or persistent depression, can seriously disrupt life. A significant number of depressed people commit, or attempt, *suicide*. Others suffer from social isolation, poverty, and problems caused by alcohol dependence. Nevertheless, the widescale use of maintenance treatment with lithium has restored many people who have manic-depressive illness to near normal health.

Manipulation

As a therapy, the skillful use of the hands to move a part of the body or a specific joint or muscle to treat certain disorders. Manipulation at times is carried out by a physician, sometimes using a general anesthetic. The technique of manipulation is widely practiced by physical therapists, osteopaths, and chiropractors.

Manipulation is used to correct deformity by aligning the bones of a displaced *fracture*, putting a joint back into position following *dislocation*, or stretching a *contracture* (shortened muscle or tendon). It may also be used to increase the range of movement of a stiff joint, usually following injury. Occasionally, it is helpful in treating *frozen shoulder*, but does not usually relieve stiffness caused by *arthritis* (inflammation of a joint).

Mannitol

An osmotic *diuretic drug*. Mannitol is used as a short-term treatment for *glaucoma* (raised pressure in the eyeball) before corrective surgery. It is also given to reduce *edema* (fluid retention) in the brain before and after

surgical treatment of a *brain tumor* or an intracerebral *hematoma* (blood clot on the brain).

Mannitol is occasionally used to prevent *renal failure* following severe shock. In some cases of drug overdose, mannitol is given to increase urine production and thus the amount of the drug excreted from the body.

Possible adverse effects include headache, nausea, vomiting, dizziness, and confusion.

Manometry

The measuring of pressure (of either liquid or gas) by means of a manometer. The simplest type of manometer is a glass U-shaped tube containing mercury, oil, or water. One limb of the tube is connected by flexible tubing to the pressure source; the other limb is either open to the atmosphere or closed. Increased pressure forces the liquid down in one limb and up in the other; the change in height represents a measure of the pressure. This form of manometer is used to measure blood pressure (see *Sphygmomanometer*) and cerebrospinal fluid pressure.

There are also more sophisticated manometers that measure pressure by a coiled spring, a diaphragm, or an electrical transducer.

Mantoux test

A type of skin test for tuberculosis (see *Tuberculin tests*).

Maprotiline

An *antidepressant drug*. Because maprotiline has a sedative effect, it is useful in the treatment of *depression* accompanied by anxiety or difficulty sleeping. Maprotiline usually takes about six weeks to become fully effective. Possible adverse effects include dizziness, drowsiness, palpitations, and rash.

Marasmus

A severe form of protein and calorie malnutrition (see *Nutritional disorders*) that occurs principally in famine or semistarvation conditions. In developing countries, marasmus is widespread in children under 3 years of age, usually because they have been weaned too early onto an inadequate diet or kept too long on unsupplemented breast milk.

Children with marasmus are stunted and emaciated; they have loose folds of skin on the limbs and buttocks due to loss of muscle and fat. Other signs include sparse, brittle hair, diarrhea, and dehydration.

DIAGNOSIS AND TREATMENT

Marasmus is diagnosed from a physical examination and the child's dietary history. Treatment consists of keeping the child warm and giving a high-calorie, protein-rich diet. Persistent marasmus can cause permanent mental retardation and impairment of growth. (See also *Kwashiorkor*.)

Marble bone disease

See *Osteopetrosis*.

March fracture

A break in one of the *metatarsal bones* (long bones in the foot) caused by repeated jarring. Usually affecting the second or third metatarsal, march fracture is caused by running or walking long distances on a hard surface. The name is derived from the high incidence of this fracture in soldiers after long marches.

Pain, tenderness, and swelling occur around the site of the fracture. However, X rays may not show the fracture until healing has begun, when callus (new bone) appears as a white shadow. Treatment is rest and, occasionally, immobilization in a plaster cast. (See also *Stress fracture*.)

Marfan's syndrome

A rare, inherited disorder of connective tissue that results in abnormalities of the skeleton, heart, and eyes. The incidence of Marfan's syndrome is about two cases per 100,000 people. The precise cause is unknown.

SYMPTOMS AND SIGNS

The features of Marfan's syndrome usually appear after age 10. Affected people grow very tall and thin, the fingers are long and spidery, the chest and spine are often deformed, and the tendons, ligaments, and joint capsules are weak, leaving the sufferer "double-jointed" and prone to joint dislocation. In 90 percent of cases, the heart or aorta (major blood vessel leading from the heart) is abnormal; in over 60 percent of sufferers, the lens of the eye is dislocated.

Features of Marfan's syndrome
One of the characteristic features of Marfan's syndrome is long, thin, "spider" fingers (arachnodactyly)

DIAGNOSIS

There are no specific diagnostic tests for the syndrome; *echocardiography* may be used to examine the valve deformities in the heart. An eye examination may also be performed.

TREATMENT AND OUTLOOK

Orthopedic braces or surgery may be required to correct spinal deformity. Beta-blockers (such as propranolol) may help control heart problems, but heart surgery is sometimes necessary.

Affected people should receive genetic counseling; there is a 50 percent chance that their offspring will inherit the disease. Women with Marfan's syndrome risk heart complications if they become pregnant.

Sufferers usually do not live beyond 50, with death often caused by heart failure or rupture of the aorta.

Marijuana

The dried leaves and flowering tops of the Indian hemp plant CANNABIS SATIVA. Marijuana contains the active ingredient *THC* (tetrahydrocannabinol), which is also found in cannabis resin (hashish). The chopped leaves are usually smoked alone as a joint, or "reefer," but can be taken as tea or in food.

EFFECTS

When marijuana is smoked, effects occur within minutes and last for an hour or more. When eaten, one half to one hour usually elapses before effects are felt, and they may last for three to five hours.

Physical effects include a dry mouth, mild reddening of the eyes, slight clumsiness, and increased appetite. The main subjective feelings are usually of well-being and calmness, although depression occasionally occurs. Users become dreamy and relaxed, laughing readily and experiencing time as passing very slowly. Sights and sounds become more vivid, imagination increases, and random connections between things seem more relevant.

Large doses may result in panicky states, fear of death, and illusions. Rarely, true psychosis (loss of contact with reality) occurs, producing paranoid delusions, confusion, and other symptoms. These symptoms usually disappear within several days if triggered by the drug, which may

merely be acting on an underlying illness. A more permanent state of apathy and loss of concern—the amotivational syndrome—has been attributed to prolonged, regular use.

There is evidence that regular users of marijuana can become physically dependent on its effects. Whether the drug causes brain or other physical damage is much debated. Possession and use of marijuana is subject to legal controls, which vary from state to state.

Marital counseling

Professional therapy for married couples or established partners that is aimed at resolving problems in relationships. Usually the partners attend sessions together on a regular basis. The counselor promotes communication and sorts out differences between the partners.

HOW IT IS DONE

Marital therapy today is largely based on the ideas and methods of *behavior therapy*. It assumes that behavior in a relationship is learned; it also is based on the idea that both people are responsible for problems because they have either failed to reinforce desirable behavior in the partner or have failed to respond themselves with appropriate behavior.

Therapy starts by analyzing the good and bad aspects of the relationship, and then by detailing clearly how each partner would like the other to behave. A contract may be drawn up in which each person agrees to do something that the other wants. Alternatively, each person may be given a supply of tokens, which are used to reward the partner for pleasing or helpful behavior.

EFFECTIVENESS

Although behavioral marital therapy may seem superficial and ineffective, it has radically altered behavior and marital happiness. Research evidence shows that it may be more effective than lengthy personal analysis.

Marrow, bone

See *Bone marrow*.

Marsupialization

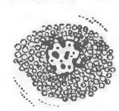
A surgical procedure used to drain an abscess of a *Bartholin's gland* (glands on either side of the entrance to the vagina) and to prevent further abscesses from developing. Marsupialization involves cutting out part of the abscess wall and a small piece of vaginal tissue, then stitching the opened abscess wall to the vaginal wall, forming a pouch. This maneuver is also used to drain certain pancreatic cysts into the bowel.

Masculinization

See *Virilization*.

Masochism

A desire to be physically, mentally, or emotionally abused. The term is derived from the name of the 19th century Austrian novelist Leopold von Sacher-Masoch.



Masochism is often used specifically to refer to the achievement of sexual excitement exclusively or preferably by means of one's own suffering. Activities include bondage, flagellation, and verbal abuse. The condition is usually chronic, and may be life-threatening when people increase the severity of their masochistic acts.

Masochists rarely seek professional treatment; when they do, it is usually at the instigation of a spouse who threatens to leave. (See also *Sadism*; *Sadomasochism*.)

Massage

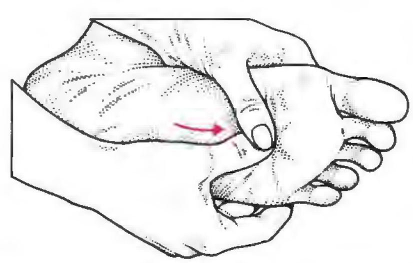
Rubbing and kneading areas of the body, usually using the hands. Massage is used to relieve painful muscle spasm, treat muscle injury, reduce edema (fluid retention in tissue), and, in the treatment of scars, to prevent tethering of skin and underlying tissue. Massage increases blood flow, reduces pain by counter-irritation (alleviation of deep-seated pain by irritation of nerve endings in the skin), relaxes muscles, and increases the suppleness of the skin.

Mast cell

A type of cell that plays an important part in the body's allergic response (see *Allergy*). Mast cells are present in most body tissues, but are particularly numerous in connective tissue, such as the dermis (innermost layer) of the skin.

In an allergic response, an allergen stimulates the release of antibodies, which attach themselves to mast cells.

SELF-MASSAGE



Although massage is most effective when carried out by another person, self-massage can still be useful; for example, it may help to alleviate pain caused by muscular tension.

Finger kneading of the neck and foot
For neck massage, the elbows are rested on a firm surface, such as a table, and the head is supported with one hand while the fingertips of the other hand knead the back and side of the neck. After one side of the neck has been massaged, switch hands and massage the other side. The foot contains few muscles, but many nerve endings, so foot massage is often very soothing.

Kneading the lower back
For self-massage of the lower back, the hands should be placed with the thumbs pointing forward, and the fingertips close together at the back. Firm finger pressure is required to massage this area.

As a result, the mast cells release substances such as *histamine* (a chemical responsible for allergic symptoms) into the tissue.

Mastectomy

Surgical removal of all or part of the breast. Mastectomy is usually performed to treat *breast cancer* and is often followed by a course of *radiation therapy* or *anticancer drugs*.

The amount of breast and surrounding tissue that is removed depends on the size and location of the tumor, how much the cancer has spread, and the age and health of the patient. The final choice of treatment should be a matter for discussion between the woman and her physician.

TYPES

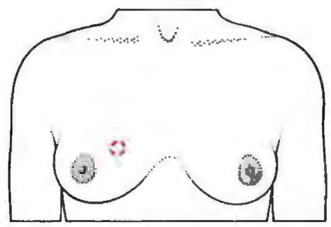
Until the late 1960s, the standard operation was the radical mastectomy, which involves removal of the affected breast, the chest muscles, all chest and underarm lymph nodes, and additional fat and skin from the chest. When certain chest muscles are left intact, the operation is known as a modified radical mastectomy.

Today, surgeons more often recommend lumpectomy (in which only cancerous tissue is removed) or a quadrantectomy (in which one quadrant of the breast is removed). Another alternative is simple mastectomy, which consists of removing the affected breast and sometimes a portion of the underarm lymph nodes. If possible, surgeons leave the overlying skin intact, or leave plenty of surrounding skin, to allow the breast to be reconstructed.

HOW IT IS DONE

Each of the operations is performed using general anesthesia. For lumpectomy and quadrantectomy, an incision is made over the breast lump, which is cut free and removed (with or without surrounding tissue).

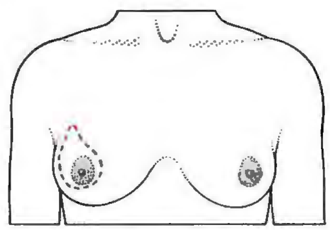
For simple mastectomy, leaving the skin intact, an incision is made along the perimeter of the breast closest to the tumor. For more extensive operations, the incision extends from the armpit to encompass the entire breast. Underlying tissue is then cut free and removed, and a drainage tube is inserted. In all cases, the skin is closed with stitches or clips, which are usually removed after a week. A skin graft is sometimes needed.



RECOVERY PERIOD

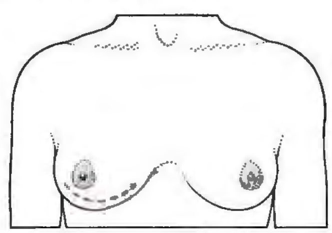
Patients can usually go home one to two days after lumpectomy and quadrantectomy, and can resume most activities within two weeks.

TYPES OF MASTECTOMY



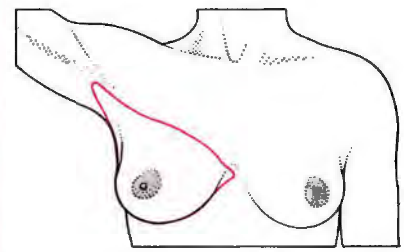
The type of operation depends on many factors, including the location of the tumor and the woman's health. A small tumor may be treated by lumpectomy; other cases may require more extensive surgery.

LUMPECTOMY



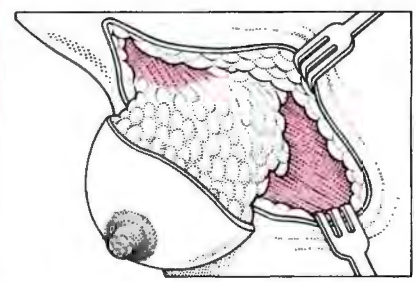
Only the area of cancerous tissue is removed. Lumpectomy is the least invasive procedure and leaves the breast looking normal.

QUADRANTECTOMY

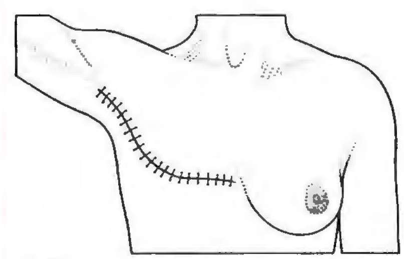


The cancerous tissue plus a wedge of surrounding tissue is removed. The lymph nodes in the armpit may also be removed. The breast is slightly smaller after the operation.

SIMPLE MASTECTOMY



An incision is made under the breast and internal breast tissue is removed, leaving most of the skin intact. The nipple is not involved, but the milk ducts leading to it are cut. In some cases, the appearance of the breast is restored by immediate insertion of a silicone rubber implant. More often, however, this is done later.



TOTAL MASTECTOMY

1 A large elliptical incision, encompassing the nipple and sometimes the entire breast, is made. The incision extends into the armpit.

2 All the breast tissue, including the skin and some of the fat, is dissected (cut out) down to the chest muscles. The dissection is continued under the skin into the armpit, to free the upper and outer "tail" of breast tissue with its lymph nodes. All bleeding vessels are tied off before inserting a drainage tube and closing the skin with stitches or clips.

3 The scar after the operation. The woman may wear a prosthesis or may have a silicone implant inserted later.

After other operations, the hospital stay is usually several days, with the drainage tube being removed on the second or third day. Analgesics (painkillers) may be necessary for the first week.

OUTLOOK

Healing is usually very good after lumpectomy and quadrantectomy, with no noticeable scarring. Wound infection is uncommon. Skin scars after more radical procedures may be extensive, but usually fade within a year. Possible long-term complications, particularly of radical mastectomy, include *lymphedema* (accumulation of fluid under the skin) and stiffness of the arm and shoulder.

If the entire breast has been removed, the woman may decide to be fitted with a prosthesis (artificial breast). A temporary prosthesis may be worn until the chest scars have healed, when a more permanent prosthesis can be fitted. Alternatively, a plastic silicone implant can be inserted either at the end of the mastectomy operation or at a later operation (see *Mammoplasty*).

Mastication

The process of chewing food. Mastication consists of two stages. In the first, the canines and incisors (front teeth) shear the food. In the second, the tongue pushes the food between the upper and lower premolars and molars (back teeth) to be ground by side-to-side and circular movements of the lower jaws. At the same time, saliva is mixed with the food to help break it down for swallowing.

Any food that spills over between the gums and cheeks is scooped up by rhythmic contractions of the cheeks and lips. The muscles of mastication, which attach the lower jaw to the rest of the skull, are controlled by signals from sensory nerves in the mouth to prevent undue stress on tooth-supporting tissues.

Only gross irregularities in the positional relationship of upper to lower teeth (see *Malocclusion*) prevent normal mastication.

Mastitis

Inflammation of breast tissue often caused by bacterial infection.

CAUSES

Mastitis usually occurs during breast-feeding when bacteria enter the breast through the nipple (especially if it is cracked). Infection with the *mumps* virus is another cause of mastitis.

Changes in levels of sex hormones can cause mastitis in the newborn (due to high levels of hormones from the mother's circulation) and at the start of puberty. Hormonal variations may also be the cause of chronic mastitis in women who are prone to lumpy breasts. This common disorder is known as fibrocystic disease of the breast, fibroadenosis, cystic mastitis, benign mammary dysplasia, or benign breast disease.

SYMPTOMS

Pain, tenderness, and swelling occur in all types of mastitis and may be present in one or both breasts.

In mastitis caused by bacterial infection during breast-feeding, the breasts become red and engorged. The problem tends to occur during the first month of breast-feeding and may result in a breast abscess.

Symptoms of acute mastitis in babies and at puberty usually last for only a few weeks and clear up without specific treatment.

In chronic mastitis, there may be diffuse lumpiness of the breasts or a single breast lump caused by an overgrowth of glandular and fibrous tissue and sometimes resulting in cysts. There may also be a feeling of heaviness in the breast and, occasionally, a discharge from the nipple. The symptoms are worse during the second half of the menstrual cycle and usually affect the upper, outer part of the breast.

DIAGNOSIS AND TREATMENT

If the cause of mastitis is unknown, *mammography* may be performed or a *biopsy* (removal of a small piece of tissue for examination) of a breast lump carried out to exclude the possibility of cancer.

Acute mastitis caused by infection is treated with *antibiotic drugs*, *analgesics* (painkillers), and *expressing milk* to relieve engorgement. Breast-feeding should be continued unless pus begins to drain from the nipple. If a breast abscess develops, it requires surgical drainage.

Breast tenderness caused by chronic mastitis generally requires no specific treatment, although *diuretic drugs* may relieve symptoms. If symptoms are severe, progesterone, danazol, or bromocriptine may be prescribed. Any cysts in the breast may be aspirated (drained by a needle and syringe).

Mastocytosis

An unusual condition, also called urticaria pigmentosa, characterized by numerous itchy, irregular, yellow or orange-brown swellings on the skin. Mastocytosis may affect any part of the body but is most commonly found on the trunk; it is worse after bathing or scratching.

Mastocytosis usually begins in the first year of life and disappears by adolescence. Treatment is difficult, although *antihistamine drugs* sometimes help.

Mastoid bone

The prominent bone behind the ear. Projecting from the temporal bone of the skull, it is honeycombed with air cells, which are connected to a cavity in the upper part of the bone called the mastoid antrum. This bone, in turn, is connected to the middle ear. As a result, infections of the middle ear (see *Otitis media*) occasionally spread through the mastoid bone to cause acute *mastoiditis*.

Mastoiditis

Inflammation of the *mastoid bone*, the prominent bone behind the ear.

CAUSE AND INCIDENCE

The disease is caused by the spread of infection from the middle ear (see *Otitis media*) to the antrum (a cavity in the mastoid bone), and from there to a honeycomb of air cells in the bone.

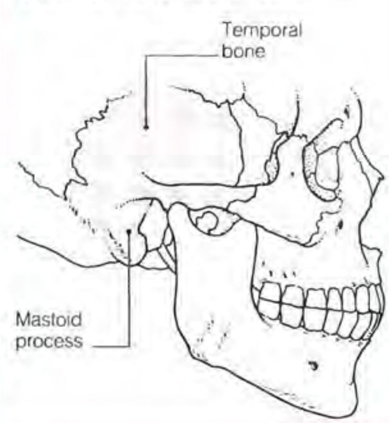
Mastoiditis has been uncommon since the advent of antibiotic drugs, which control middle-ear infection.

SYMPTOMS AND SIGNS

Mastoiditis causes severe pain, swelling, and tenderness behind the ear, as well as pain within the ear. These symptoms are usually accompanied by fever, a creamy discharge from the ear, progressive hearing loss, and some displacement of the outer ear.

COMPLICATIONS

There is always a risk that the infection may spread to inside the skull, causing *meningitis*, *brain abscess*, or blood clotting in veins within the brain. The infection may also spread outward to damage the facial nerve and cause *facial palsy*.



DIAGNOSIS AND TREATMENT

Prompt diagnosis, based on a physical examination, is essential because of the possible complications.

Treatment is with antibiotics, which usually clear up the infection. If the infection persists, an operation known as a mastoidectomy may be necessary. This procedure involves

LOCATION OF MASTOID BONE

Forming the prominence behind the ear, the mastoid process (bone) is not a separate bone but is part of the temporal bone.

making an incision behind the ear, opening up the mastoid bone, and removing the infected air cells. The wound is stitched up around a drainage tube, which is removed a day or two later.

Masturbation

Sexual self-stimulation, usually to orgasm. It is now accepted as a normal behavior, particularly among teenagers and young adults. Over 90 percent of men and about 65 percent of women masturbate at some time during their lives. Massaging the penis or clitoris with the hand is the usual method.

There is no evidence that masturbation causes any physical or psychological harm, despite the 19th-century belief that it caused insanity, blindness, or other disorders. This notion may have been based on the observation that people who are severely retarded or suffering from *schizophrenia* sometimes masturbate publicly. Such behavior is a sign, not a cause, of mental illness that also occurs in *dementia* and other forms of brain damage.

Maternal mortality

The death of a woman during pregnancy or within 42 days of *childbirth*, *miscarriage*, or elective *abortion* from any cause related to, or made worse by, pregnancy. Maternal mortality is the number of such deaths per year per 100,000 (or sometimes per 1,000 or 10,000) pregnancies.

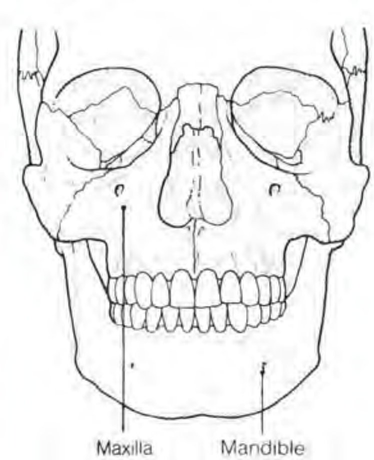
CAUSES

Maternal deaths may occur as a direct result of complications of pregnancy, or as an indirect result of a medical condition that has been aggravated by pregnancy. The principal direct causes include *pulmonary embolism* (blood clots in the lungs), *hypertension* (high blood pressure), *antepartum hemorrhage* or *postpartum hemorrhage*, *ectopic pregnancy* (development of the fetus outside the uterus), *eclampsia* (a condition characterized by seizures during late pregnancy), abortion, miscarriage, or *cesarean section*, and *puerperal sepsis* (infection of the uterus after childbirth). Important indirect causes are heart disease, *anemia*, *hyperthyroidism* (overactivity of the thyroid gland) or *hypothyroidism* (underactivity of the thyroid gland), *diabetes mellitus*, and some cancers.

RELATED FACTORS

Maternal mortality is highest for the first pregnancy, and for the fifth and subsequent pregnancies. It is also greater in women who are younger than 20 or older than 30. Statistically, it is safest for a woman to have her first baby when she is between 20 and 25 years old; it becomes increasingly less safe after age 30.

Social factors also play a part. Maternal mortality is higher among poor, less well-educated women, and is greater in blacks than in whites. Maternal mortality generally is greater among women who do not receive adequate prenatal care.



TRENDS

Maternal mortality has decreased considerably since about the 1940s. In the US, the death rate has fallen from 74 per 100,000 pregnancies in 1950, to eight per 100,000 in 1983. This dramatic decline is due largely to social improvements, better obstetric care, the development of antibiotics and other drugs to combat infection, and the availability of blood transfusions. In addition, because of the ready availability of contraception, fewer women than formerly have a large number of pregnancies.

Maxilla

One of a pair of bones that forms the upper jaw. At their base the maxillas carry the upper teeth and form the roof of the mouth; at the top they form the floor of the orbits (the sockets that contain the eyes). Each bone contains a large air-filled cavity (called the maxillary sinus) that is connected to the nasal cavity.

LOCATION OF THE MAXILLA
The maxilla is one of a pair of bones that together form the center of the face, the upper jaw, and the roof of the mouth.

DISORDERS

The most common disorder affecting the maxilla is *sinusitis* (inflammation of the mucous membrane that lines the maxillary sinuses), usually caused by infection spreading from the nose. Severe sinusitis occasionally leads to *osteomyelitis* (bone infection).

The maxilla is often fractured in motor vehicle accidents, causing a variety of facial deformities, such as backward displacement of the teeth or caving in of the center of the face. Immediate surgery to reposition and secure the bones is necessary to prevent permanent disfigurement.

Various kinds of tumors may develop in the maxillary sinus; 80 percent of them are malignant, and they may eventually alter the shape of the jaw, loosen the teeth, block one of the nasolacrimal ducts (causing the eye to water), push the eyeball upward or outward, or block the nose and cause a bloody, offensive-smelling discharge. Treatment is by *radiation therapy*, followed by surgical removal of the maxilla. About one third of sufferers survive for five years.

McArdle's disease

A rare genetic disorder characterized by muscular stiffness and painful cramps that increase during and after exertion. McArdle's disease is caused by a deficiency of the enzyme in muscle cells that stimulates the breakdown of *glycogen* (a complex carbohydrate) to glucose (a type of sugar). This deficiency results in a build up of glycogen within the muscle tissue and prevents the release of glucose as an essential source of energy during exercise.

Symptoms usually start between the ages of 20 and 30. Myoglobinuria (muscle cell pigment in the urine) occurs because of the damage to muscle cells; rarely, it is severe enough to cause *renal failure*. Affected people are usually healthy apart from the need to restrict their exercise.

There is no treatment, although symptoms may be helped by eating glucose or fructose before exercise.

Measles

A distressing viral illness that causes a characteristic rash and a fever. Measles mainly affects children but can occur at any age. One attack usually confers lifelong immunity.

CAUSES AND INCIDENCE

The measles virus is highly infective and is spread primarily by airborne droplets of nasal secretions. There is

an incubation period of nine to 11 days before symptoms appear. Infected children can transmit the virus from shortly after the start of this period up to one week following the development of symptoms. Infants under 8 months old are rarely affected because they have acquired some immunity from their mothers.

Measles was once very common throughout the world, occurring in epidemics. It is now less common in developed countries due to immunization. In the US, where proof of immunization is required before a child can attend school, there are several thousand cases reported annually. Prevention of the illness is important because it can have rare but serious complications. It may also be serious, or fatal, in children with impaired immunity (e.g., those being treated for leukemia).

In developing countries, measles is still common, accounting for more than 1 million deaths a year, especially in malnourished children whose defenses against infection are seriously impaired.

SYMPTOMS AND SIGNS

The illness starts with a fever, runny nose, sore eyes, and cough, and the sufferer is sick. After three to four days a red rash appears, usually starting on the head and neck and spreading downward to cover the whole body. The spots sometimes join to produce large red blotchy areas, and the lymph glands may be enlarged. After three days the rash starts to fade and symptoms subside.

The most common complications are ear and chest infections, which usually occur with a return of fever two to three days after appearance of the rash. Diarrhea, vomiting, and abdominal pain also occur. A more serious complication, occurring in about one in 1,000 cases, is *encephalitis* (inflammation of the brain). It causes headache, drowsiness, and vomiting, starting seven to 10 days after the rash appears. Seizures and coma may follow, sometimes leading to mental retardation or death (however, seizures are common with measles and do not necessarily indicate encephalitis).

Very rarely (in about one in a million cases) a progressive brain disorder (subacute sclerosing panencephalitis) develops years after the acute illness.

Measles during pregnancy results in death of the fetus in about one fifth of cases. There is no evidence that measles causes birth defects.

TREATMENT

Plenty of fluids should be given and acetaminophen taken to treat the fever. Antibiotics are not routinely required but may be needed to treat secondary infections.

IMMUNIZATION

In the US, children are routinely immunized early in the second year of life. The vaccine is given by injection (usually combined with mumps and rubella vaccine), producing immunity in 97 percent of people. Side effects of the vaccine are generally mild. There may be a low fever, slight cold, and rash about one week after vaccination.

The vaccine should not be given to children under age 1 or to those with any of the usual risk factors for vaccination (see *Immunization*). The vaccine may induce a seizure in children who have had one before and if there is a history of epilepsy in the family. In these cases simultaneous injection of measles-specific immunoglobulin (which contains antibodies against the virus) should be given.

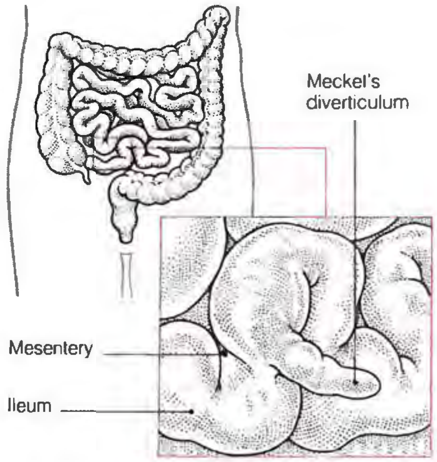
A pregnant woman who has never had measles or been immunized against the disease should avoid people with measles. If she does come into contact with an infected person, she should be passively immunized against measles with *immunoglobulin* within five days.

Meatus

A canal or passageway through part of the body. The term usually refers to the external auditory meatus, the canal in the outer *ear* that leads from the outside to the eardrum.

Mebendazole

An *antihelmintic drug* used to treat *worm infestations* of the intestine. Mebendazole is under investigation as a treatment for worms that infest other areas, such as the lungs and liver (as in *hydatid disease*).



Possible adverse effects include abdominal pain and diarrhea.

Meckel's diverticulum

A common congenital anomaly of the digestive tract in which a small, hollow, wide-mouthed sac protrudes from the *ileum* (the final section of the small intestine). Meckel's diverticulum occurs in 2 percent of people.

There are usually no symptoms unless the diverticulum is affected by infection, obstruction, or ulceration. The most common symptom is painless bleeding, which may be sudden and severe, making immediate blood transfusion necessary. Sometimes, inflammation causes symptoms so similar to those of acute *appendicitis* that the disorder is diagnosed only when abdominal surgery is carried out. A Meckel's diverticulum occasionally causes *intussusception* (telescoping) or *volvulus* (twisting) of the small intestine.

Disorders are treated by removal of the diverticulum.

Anatomy of Meckel's diverticulum
In this birth defect, an appendixlike sac protrudes from the ileum (the last part of the small intestine).

Meclizine

An *antihistamine drug* used as an *antiemetic drug*. Meclizine is given to treat nausea, vomiting, and *vertigo* in *motion sickness* and *Meniere's disease* and when these symptoms are due to *anticancer drugs* or *radiation therapy*. Meclizine may cause drowsiness, dry mouth, and blurred vision.

Meclofenamate

A *nonsteroidal anti-inflammatory drug* (NSAID) used to relieve joint pain and stiffness in types of arthritis, such as *osteoarthritis* and *rheumatoid arthritis*. Meclofenamate produces adverse effects, such as diarrhea and nausea, and is normally prescribed only when similar drugs have proved ineffective.

Meconium

The thick, sticky, greenish-black feces passed by infants during the first day or two after birth. Meconium consists of bile, mucus, and sloughed intestinal cells. After the baby starts feeding, the feces gradually change in color and consistency.

Occasionally, the fetus passes meconium into the amniotic fluid in the uterus. This is more common in

babies who experience *fetal distress* during labor or who are postmature (that is, over 40 weeks' gestation). Meconium in the amniotic fluid may be inhaled when the baby starts to breathe, sometimes blocking the airways and damaging the lungs.

In some babies with *cystic fibrosis*, the meconium is so thick and sticky that it blocks the intestine and causes intestinal obstruction.

Medial

A medical term meaning situated toward the midline of the body. Less commonly, the word is used to refer to the middle layer of a body structure, particularly of a blood vessel wall.

Median nerve

A branch of the *brachial plexus* (one of the main nerves of the arm) that runs down the arm's full length into the hand. The median nerve controls the muscles of the forearm and hand, which carry out bending movements of the wrist, fingers, and thumb, and which rotate the forearm palm-inward. This nerve also conveys sensations from the thumb, index finger, middle finger, part of the ring finger, and the region of the palm at the base of these digits.

DISORDERS

The nerve may be damaged where it originates from the brachial plexus as a result of injury to the shoulder, just above the wrist by a *Colles' fracture*, or by pressure on the nerve where it passes through the wrist (see *Carpal tunnel syndrome*). The principal symptoms of any damage are numbness and muscle weakness in the areas controlled by the nerve.

Mediastinoscopy

Investigation of the right side of the *mediastinum* (the central compartment of the chest containing the heart, esophagus, and trachea) by means of an *endoscope* (a viewing tube with a light and lens) inserted into the cavity through an incision in the neck. Because more of the heart occupies the left side of the mediastinal cavity, endoscopic investigation of this area is difficult and dangerous; *imaging techniques* are preferred.

Mediastinoscopy is used mainly to perform a *biopsy* (removal of a small sample of tissue for analysis) of a lymph gland to look for disease. Using a general anesthetic, an incision is made in the base of the neck and an endoscope is passed through it into the mediastinum. A tissue sample is removed by minute blades at the end of the endoscope. After the instrument has been withdrawn, the incision is closed with stitches.

Mediastinum

The space between the lungs and the structures within that space. The mediastinum extends from the sternum (breastbone) in front to the spine behind, and from the inlet of the thoracic duct (one of the main lymphatic vessels) at the top to the diaphragm at the bottom.

It contains the *heart*, *trachea* (windpipe), *esophagus*, *thymus* gland, the major blood vessels entering and leaving the heart, *lymph nodes* and lymphatic vessels, and nerves (including the *vagus nerve* and *phrenic nerve*).

Medicaid

A term applied (in some states) to a federal program that provides funds to support state programs of medical assistance to people receiving or eligible for welfare. Programs vary widely from state to state. (See also *Medicare*.)

Medical examiner

A public official and physician (often a pathologist) who is responsible for determining causes of death not obviously due to natural causes. The medical examiner (a county office in most cases) has largely replaced the office of *coroner*.

Medicare

A federal program that finances medical care for certain dependents. Part A of the program covers many hospital services. Part B helps with physician charges, assuming a retired person elects to pay a monthly insurance premium. (See also *Medicaid*.)

Medication

A term used to describe any substance prescribed to treat illness. (See also *Drug*; *Medicine*.)

Medicine

The study of human diseases, including their causes, frequency, treatment, and prevention. The term is also applied to any substance prescribed to treat illness.

EARLY HISTORY

In many early cultures, medicine was closely associated with religion because disease was regarded as a punishment from the gods. As a result, the victim would turn for help to a priest, who took on the additional function of a medicine man. Medicine probably became separated from religion with the emergence of people skilled in treating injuries such as broken bones and dislocated joints. These healers attracted patients and, in time, apprentices who wanted to learn the same skills.

By the fifth century BC, the Greek physician Hippocrates had established medicine as a profession with a body of learning and a code of ethics to be passed on to each new generation of physicians (the Hippocratic oath is still used as an ethical guide for the medical profession). The dominant figure after Hippocrates was the second-century, Greek-born Roman physician Galen, who made valuable contributions but whose many false theories about anatomy and physiology were uncritically accepted for more than 13 centuries; these theories effectively held back advances in medical knowledge.

RENAISSANCE DISCOVERIES

With the Renaissance, medicine began to emerge from its long period of stagnation. In 1543 the Flemish anatomist and physician Andreas Vesalius (1514-1564) produced the first truly accurate anatomical text; in 1628 the English physician William Harvey (1578-1657) first demonstrated how blood circulates through the body. Also in the 17th century, the Dutch microscopist Antonj van Leeuwenhoek (1632-1723) became the first to observe and describe microorganisms and the detailed structure of blood, muscles, and sperm.

MODERN MEDICINE

Despite the medical achievements of the Renaissance—and some notable later achievements, such as the English physician Edward Jenner's (1749-1823) discovery of the principle of vaccination in the late 18th century—it was not until the 19th century that the foundations of modern scientific medicine were laid. This was the result of a growing realization that medicine needed to become a true science, systematic in its approach and based on scrupulous observation and experimentation. Significant advances in other disciplines also played an important role. For example, the first practical high-powered microscope was developed during the 19th century; the ophthalmoscope (an instrument for examining the retina of the eye) was invented in 1851; the first practical thermometer was introduced in the 1860s; and X rays were discovered in 1896, an occurrence that revolu-

tionized medical diagnosis. These developments, along with the French scientist Louis Pasteur's (1822-1895) work on the germ theory of disease, brought about an enormous advance in the understanding of a large number of diseases.

Curing and controlling disease was not a reality until the 20th century, however, when vaccines were developed against many serious diseases (including typhoid, cholera, and diphtheria); insecticides and improved sanitation helped control diseases such as malaria, yellow fever, and sleeping sickness.

The early 20th century was also marked by the development of safe anesthesia, effective surgery, and a steady growth in the number of new drugs. In the late 1930s, the first effective antibacterial drugs (the sulfonamides) were produced, followed in the 1940s by penicillin, streptomycin, and the tetracyclines; these drugs saved millions of lives.

Among the important recent developments are the introduction of sophisticated diagnostic techniques, such as MRI, CT scanning, and ultrasound scanning; more effective drugs and other treatments (such as radiation therapy) to treat a wider range of diseases and disorders; and developments in surgical techniques that have made it possible to transplant organs and rejoin severed nerves.

Today, the boundaries between medicine and other sciences are becoming progressively less distinct; medical research is being increasingly undertaken by scientists who have little or no formal medical training. (See also entries for individual medical, surgical, and scientific specialties.)

Medicolegal

Relating to aspects of medicine and law that overlap, particularly to medical matters that come before the courts. Among the matters on which medicolegal experts advise are the laws concerning damages for injuries due to medical negligence or malpractice, medical evidence concerning the extent of injury in a civil action, the use of tests in determining paternity, the mental competence of people who have drawn up wills, and restrictions on the liberty of the mentally ill.

In recent years, new areas of medicolegal study have emerged, notably an individual's right to die (see *Brain death*; *Euthanasia*; *Will, living*); the necessity for informed consent to any surgical procedure; the legal aspects of *artificial insemination*, *in vitro fertilization*, *sterilization*, and *surrogacy*; and a person's right to confidentiality concerning his or her illness, particularly in the context of AIDS. (For medical aspects of criminal law, see *Forensic medicine*.)

Meditation

Concentration on an object, a word, or an idea with the intention of inducing an altered state of consciousness. Meditation of different kinds has traditionally been a feature of many religions, particularly Eastern ones.

At its deepest level, meditation can resemble a trance or be an all-engrossing spiritual experience. More commonly, it is a physically calming therapy for body and mind. Some clinical trials have shown that meditation can be a valuable therapy for reducing stress levels and in helping treat stress-related disorders. The most common form of meditation practiced in the west is transcendental meditation (TM), introduced by the Maharishi Mahesh Yogi in the 1960s.

Medroxyprogesterone

A *progesterone drug* used in the treatment of *endometriosis* and certain types of *breast cancer* and uterine cancer (see *Uterus, cancer of*). Medroxyprogesterone is occasionally given to treat menstrual disorders such as mid-cycle bleeding and *amenorrhea* (absence of menstruation). It is also given with an estrogen drug in *hormone replacement therapy* to reduce the risk of cancer of the uterus.

Injections of medroxyprogesterone are widely used as a contraceptive (see *Contraception, hormonal methods*) in developing countries; this use is not permitted in the US.

Possible adverse effects include weight gain, swollen ankles, and breast tenderness.

Medulla

The innermost part of an organ or body structure; the adrenal medulla is the central region of an adrenal gland, and the medulla of bone is the bone marrow. The term medulla is also sometimes used to refer to the medulla oblongata (part of the *brain stem* joining the spinal cord).

Medulla oblongata

Also known as the medulla, the medulla oblongata is the lowest part of the *brain stem*; it is situated in the skull between the pons (above) and the spinal cord (below).

Medulloblastoma

A type of malignant *brain tumor* that occurs mainly in children (in whom it is the most common type of brain tumor). The tumor usually arises from the cerebellum (the organ at the back of the brain concerned with posture and balance). It grows rapidly and may spread to other parts of the brain and spinal cord.

Several hundred cases of medulloblastoma are diagnosed each year in the US. Typically, a morning headache, repeated vomiting, and a clumsy gait develop, with frequent falls caused by disturbance of the function of the cerebellum. The tumor is diagnosed by *CT scanning* or *MRI* and often responds to *radiation therapy*. This, combined with surgery and the use of *anticancer drugs*, often allows survival for five years or more.

Mefenamic acid

A *nonsteroidal anti-inflammatory drug* (NSAID) used to relieve pain after a minor operation, injury to soft tissues (such as muscles and ligaments), or joint pain and stiffness caused by types of arthritis (including *osteoarthritis* and *rheumatoid arthritis*). It is also used to relieve the pain that can occur with menstruation.

Possible adverse effects include abdominal pain, nausea, vomiting, and, after prolonged use, a *peptic ulcer*.

Mega-

A prefix meaning very large, as in *megacolon*, a condition in which the colon (part of the large intestine) is greatly enlarged. The prefix megalo- is synonymous with mega-.

Megacolon

A grossly distended colon usually accompanied by severe, chronic constipation. Megacolon may be present at birth or may develop later in life; it occurs in all age groups.

CAUSES

In children, the main causes are *Hirschsprung's disease* (congenital absence of nerve cells in part of the colon), *anal fissures*, and psychological factors that may have developed at the time of toilet-training.

In the elderly, megacolon may be caused by long-term use of powerful laxatives, particularly those containing senna, rhubarb, or cascara.

People suffering from chronic depression or schizophrenia, particularly if they live in an institution, often suffer from megacolon. Other rarer causes include *Chagas' disease*,

hypothyroidism, neurological disorders (for example, spinal cord injury), and certain drugs (notably the narcotics morphine and codeine).

SYMPTOMS

The symptoms are severe constipation and abdominal bloating; some sufferers lose their appetite, which may result in weight loss. Occasionally there is diarrhea, caused by a leakage of semiliquid feces around the obstructing hard stools.

DIAGNOSIS

The condition is diagnosed by proctoscopic examination of the rectum (see *Proctoscopy*), *barium X-ray examination*, tests of bowel muscle function, and, if Hirschsprung's disease is suspected, *biopsy* (removal of a small sample of tissue for examination) of the large intestine.

TREATMENT

In severe cases, impacted feces are removed manually. Often, however, the large intestine can be emptied by saline enemas.

Megalomania

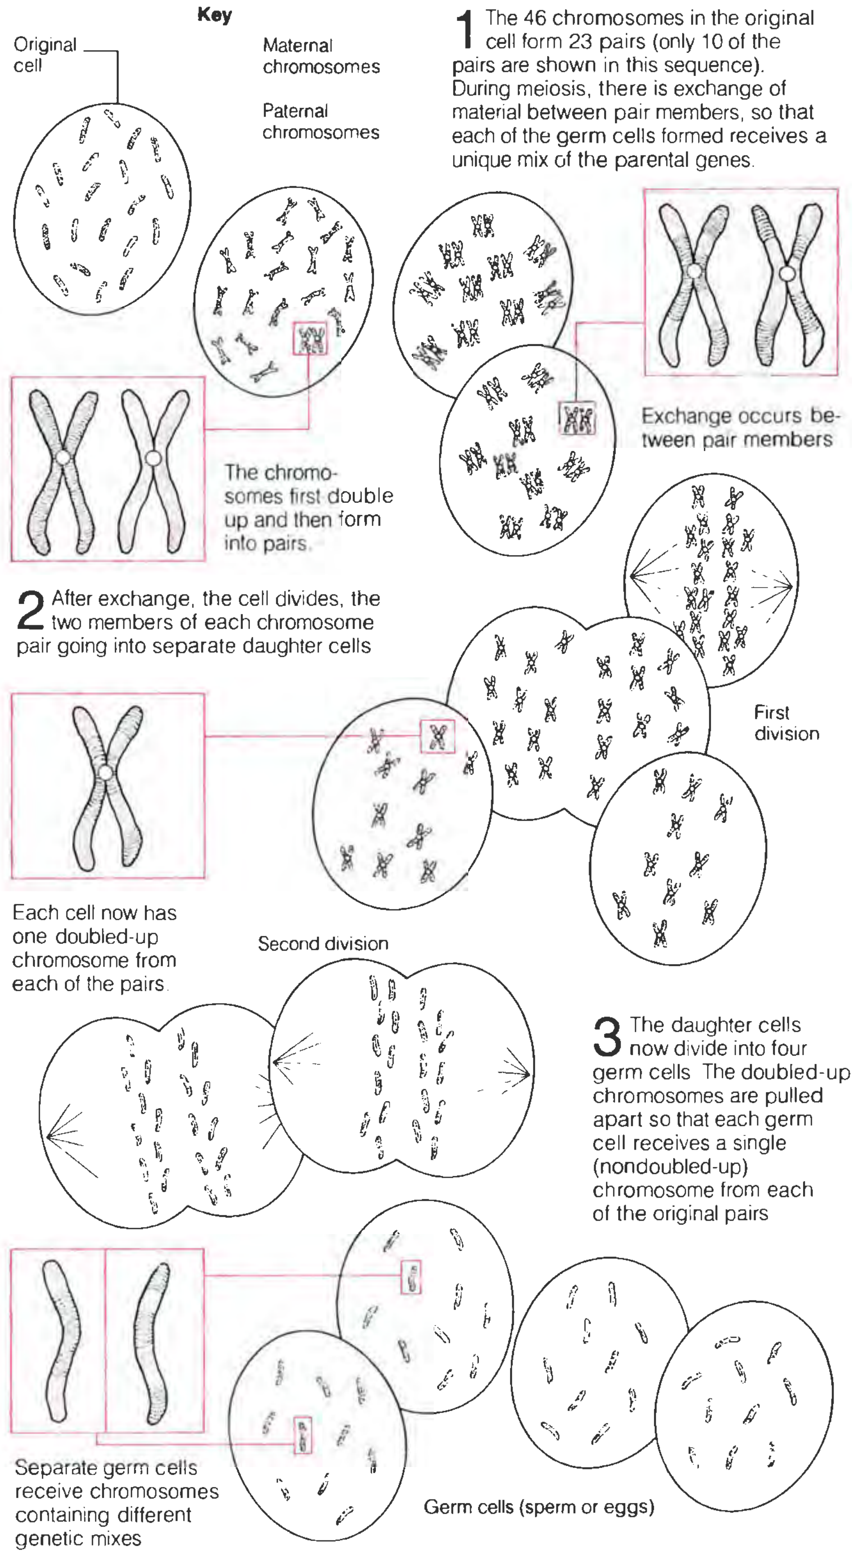
An exaggerated sense of one's own importance or ability. It may take the form of a *delusion* of grandeur (such as believing oneself to be Napoleon) or of a desire to organize activities that are expensive, large in scale, and involving many people (for example, leasing an ocean liner for a party). Megalomania is not a formal category of psychiatric illness, although such bizarre ideas and behavior often occur in *mania*.

-megaly

A suffix meaning enlargement, as in *acromegaly*, a condition in which there is enlargement of the skull, jaw, hands, and feet during adulthood as a result of excessive production of growth hormone in the fore part of the pituitary gland.

Megestrol

A *progesterone drug* used to treat certain types of *breast cancer* and uterine cancer (see *Uterus, cancer of*). Megestrol is usually prescribed when a tumor cannot be removed by surgery, if a tumor has recurred after surgery, or when other *anticancer drugs* or *radiation therapy* is ineffective.



Possible adverse effects include swollen ankles, loss of appetite, headache, dizziness, rash, and elevation of the blood's calcium level.

Meibomian cyst

See *Chalazion*.

MECHANISM OF MEIOSIS

In meiosis, a cell in the testis or ovary containing 46 chromosomes divides to form four germ cells (sperm or eggs), each with 23 chromosomes. Germ cells have only half the usual chromosome content because a child can receive only half the genes of each parent.

Meibomianitis
An inflammation of the glands on the eyelid, which causes the normal, oily secretion to thicken. Meibomianitis usually affects middle-aged people, often those with *blepharitis* (inflammation of the eyelid), and frequently leads to recurrent meibomian cysts (see *Chalazion*).

Meigs' syndrome
A rare condition in which *ascites* (fluid in the abdominal cavity) or a *pleural effusion* (fluid around one of the lungs) accompanies a tumor of the ovary. The fluid usually disappears with removal of the tumor.

Meiosis
A special type of cell division that occurs only within the ovaries and testes. The cells that undergo meiotic division are the forerunners of egg and sperm cells.

In meiosis, the *chromosomes* (inherited genetic material) within the nucleus of a cell are first duplicated. In the course of two successive cell divisions, the chromosomal material is then divided into four parts, each part going into one of four daughter cells. The four daughter cells each acquire only half of the original cell's chromosomal material, and each daughter cell acquires a different "selection" of this material. Consequently, every egg and sperm formed in the ovary or testis is different in its chromosomal content. As a result of meiosis, parents contribute exactly half of their chromosomal material (genes) to each child, and the selection that each child receives is unique.

Meiosis differs fundamentally from *mitosis*, the more common and simpler method of cell division, in which a cell's chromosomes are exactly duplicated in one division into two daughter cells.

Melancholia
An old term for *depression* derived from the Greek word for black bile, an excess of which was believed to be the cause of low spirits. Melancholia is used today to refer to certain symptoms that occur in severe depression. These include loss of pleasure in most activities, lack of reaction to pleasurable stimuli, and inappropriate guilt feelings.

Melanin
The yellow, brown, or black pigment that gives skin, hair, and the iris of the eyes their coloring. The amount of melanin present in a person depends on race and on exposure to sunlight. The pigment is produced by cells called melanocytes, whose activity is controlled by a hormone secreted by the pituitary gland in the brain.

Exposure to sunlight increases the production of melanin, protecting the skin against the harmful effects of ultraviolet rays and darkening skin color in the process.

Localized overproduction of melanin in the skin can result in a pigmented spot called a *nevus*, of which moles and freckles are the most common examples.

Melanoma, juvenile
A raised, reddish-brown skin blemish that sometimes appears on the face or legs in early childhood. A juvenile melanoma is a form of *nevus* that grows rapidly up to almost 1 inch (about 2 cm) across. Most juvenile melanomas are harmless. However, if the growth is unsightly, or if the physician suspects skin cancer, the melanoma can be removed surgically.

Melanoma, malignant
The most serious of the three types of skin cancer (the other two being *basal cell carcinoma* and *squamous cell carcinoma*). Malignant melanoma occurs in the melanocytes, the cells that produce *melanin* (the pigment that colors the skin, hair, and the iris of the eyes).

Development of malignant melanoma
Only one mole in a million becomes malignant, but change of shape, darkening, tenderness, pain, itching, or ulceration are warning signs.

CAUSES AND INCIDENCE
Malignant melanomas account for 2 percent of all cancers that occur and are most common in middle-aged and elderly people with pale skin who have been exposed to strong sunlight for many years.

In the US, the incidence varies with latitude from 22,500 cases per year in the northern states to 65,000 cases in the south. This incidence appears to be rising, probably due to increased recreational exposure to sunlight.

SYMPTOMS AND SIGNS
The growth usually develops on exposed areas of skin, but may occur anywhere on the body, including under the nails and in the eye (see *Eye tumors*). The melanoma usually grows from an existing mole, which may enlarge, become lumpy, bleed, change color, develop a spreading black edge, turn into a scab, or begin to itch. Occasionally, a tumor may develop on normal skin.

DIAGNOSIS AND TREATMENT
Because the tumor is highly malignant and often spreads to other parts of the body, early diagnosis is essential. The diagnosis is made by a skin *biopsy* (removal of a small sample of tissue for microscopic analysis).

Treatment consists of excising (cutting out) the melanoma. To avoid an unsightly scar on exposed areas, a *skin graft* may be carried out at the same time. *Radiation therapy* or *anticancer drugs* may also be necessary.

Melanosis coli
Black or brown discoloration of the lining of the colon, associated with chronic constipation and the use of certain laxatives (e.g., senna, rhubarb, and cascara) in chronic constipation.

Melanosis coli is most common in the elderly and usually produces no symptoms. The discoloration disappears after laxatives are stopped. Rarely, the condition is associated with cancer of the colon.

Melasma
See *Chloasma*.

Melena
Black, tarry feces caused by bleeding, usually in the upper gastrointestinal tract (esophagus, stomach, or duodenum). The blood is blackened by the action of secretions during digestion. Melena is a sign that should never be ignored. It is usually caused by a *peptic ulcer*, but may be an indication of cancer (or other disorders) of the stomach or of the cecum. (An intake of iron, bismuth, or licorice may also color the feces black.)

Melioidosis
An infectious disease, similar to *glanders*, caused by a bacterium that lives in soil and lakes. Melioidosis does not occur in the US and Europe but has been reported in Asia, Africa, and Australia. It may cause a high fever

and symptoms of pneumonia. Given early, antibiotics can cure the illness, but in some cases it is rapidly fatal.

Melphalan

An *anticancer drug* used mainly in the treatment of *multiple myeloma* (a cancer of the bone marrow). Melphalan is also prescribed to treat certain types of *breast cancer* and ovarian cancer (see *Ovary, cancer of*).

Possible adverse effects include nausea, vomiting, sore throat, and loss of appetite. Melphalan may also cause aplastic anemia, abnormal bleeding, and increased susceptibility to infection.

Membrane

A layer of tissue, often very thin, that covers a body surface (such as the *meninges*, which cover the surface of the brain); lines a cavity (such as the *peritoneum*, which lines the abdominal cavity); divides a space or organ (such as the tympanic membrane, or eardrum, which separates the *ear* canal from the middle ear); or forms the boundaries of individual *cells*.

Memory

The ability to remember what has happened in the past. It is a complex process, usually thought of as having three stages—registration, long-term memory, and recall (see box).

Many factors determine how well something is remembered, including its familiarity and how much attention has been paid to it. Techniques advertised for improving memory are generally based on teaching people methods of improving their coding systems by consciously associating new material with what is already known. For example, a person might be taught to visualize a well-known street and then think of each building as representing a new fact.

MECHANISM OF MEMORY

It is not known where in the brain the memory process takes place. There seems to be no set memory area; stimulating the brain with electrodes can evoke different memories from the same site. However, disturbances of the temporal lobe and limbic lobe typically cause memory disorders. Stimulation of a particular part of the temporal lobe in patients with temporal lobe *epilepsy* may consistently evoke the same memory.

The mechanisms for storing memory also are unknown. Memory may be held within the chemical structure of some substance within brain cells—possibly spare *DNA* that is not being utilized to hold the genetic code. Others stress the role of the brain's electrical circuits in memory storage.

A good memory is usually part of a high *IQ*, although some people have extraordinary "photographic" memories that are unrelated to their other intellectual abilities. Even some severely retarded people have phenomenal memories for specific types of information (the so-called "idiot savant"—learned idiot).

DISORDERS

Disturbances of memory can result from a problem at any of the three stages. Most disturbances involve an inability to recall past events due to failure at the retention or recall stage (see *Amnesia*). In some cases, the problem occurs at the registration stage (for example, in *mania* because the person's attention is continually distracted, or in *depression* as a result of preoccupation with personal thoughts and feelings). Some people with temporal lobe epilepsy have uncontrollable flashbacks of distant past events.

Memory, loss of

See *Amnesia*.

THE STAGES OF MEMORY

Stage 1
In the first stage, known as registration, information is perceived and understood. It is then retained in a short-term memory system that seems to be very limited in the amount of material it can store at one time. Unless refreshed by constant repetition, the contents of short-term memory are lost within minutes, to be replaced by other material.

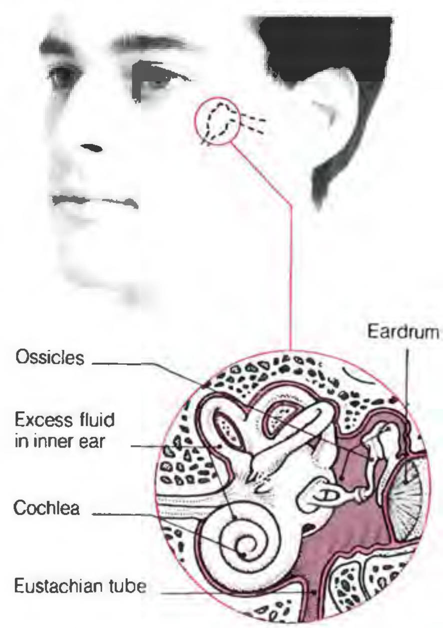
Stage 2
If information is important enough, it may be transferred into the long-term memory, where the process of storage involves associations with words or meanings, with the visual imagery evoked by it, or with other experiences, such as smell or sound.

Stage 3
The final stage is recall (or retrieval), in which information stored at an unconscious level is brought, at will, into the conscious mind. The reliability of recall depends on how well the material was coded at stage 2.

Menarche

The onset of *menstruation*. Menarche usually occurs around age 13, two or three years after the first physical signs of *puberty* start to appear.

Meniere's disease



A disorder of the inner ear characterized by recurrent *vertigo*, *deafness*, and *tinnitus* (ringing or buzzing in the ear). In 80 to 85 percent of cases, only one ear is affected.

CAUSES AND INCIDENCE

The disease is caused by an increase in the amount of fluid in the membranous labyrinth (the canals in the inner ear that control balance). This increase damages the labyrinth and sometimes the adjacent cochlea (a spiral organ that receives sound and transmits it to the brain). The cause of the fluid increase is not known in most cases. Meniere's disease is uncommon before age 50.

SYMPTOMS AND SIGNS

The main symptom is a sudden attack of vertigo, which may be so severe that the person falls to the ground. Vertigo is usually accompanied by nausea, vomiting, nystagmus (jerky eye movement), and, in the affected ear, deafness, tinnitus, and a feeling of pressure or pain. Attacks, which vary considerably in frequency, may last from a few minutes to several hours. However, the deafness and tinnitus tend to persist between the attacks of vertigo.

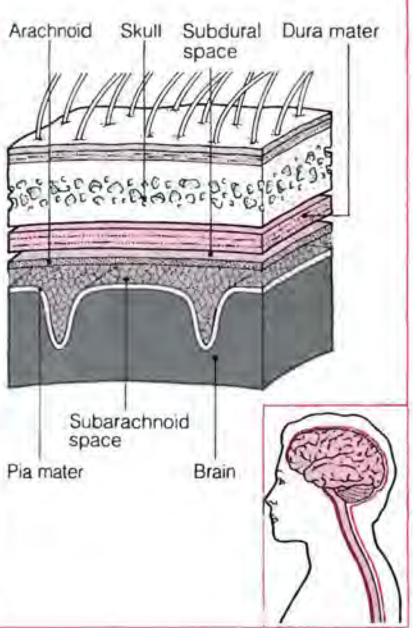
The cause of Meniere's disease
This condition is caused by excessive fluid in the middle ear, which may become damaged as a result.

DIAGNOSIS AND TREATMENT

Meniere's disease is usually diagnosed from the results of audiometry (see *Hearing tests*), a *caloric test*, and sometimes other tests.

During an attack, the person should rest in bed. An *antiemetic drug* (such as dimenhydrinate or cyclizine) may be given to relieve nausea and tinnitus.

Hearing tends to deteriorate progressively. If deafness becomes total, the other symptoms of the disease usually disappear.



Meninges

The three membranes that cover and protect the brain and the spinal cord. The outermost layer, the dura mater, is tough and fibrous; it lines the inside of the skull and forms a loose sheath around the spinal cord. The middle layer, the arachnoid mater, is elastic and weblike. It is separated from the innermost membrane, the pia mater, by the subarachnoid space, which contains *cerebrospinal fluid*. The pia mater is a thin layer that lies directly next to the brain and follows the folds and furrows of its surface.

Inflammation of the meninges, usually from infection, is called *meningitis*. Tumors of the meninges are called *meningiomas*.

ANATOMY OF THE MENINGES

The pia mater lies on the brain, separated from the arachnoid mater by the subarachnoid space. The dura mater lines the inside of the skull.

Meningioma

A benign *brain tumor* that develops from the meninges (protective coverings of the brain). The tumor arises from cells in the arachnoid (middle layer of the meninges) and usually becomes attached to the dura mater (outer layer).

Meningiomas are rare, with about one new case diagnosed annually per 100,000 population in the US. They may occur at any age. The tumor expands slowly, sometimes becoming large before it causes symptoms.

SYMPTOMS

Symptoms can include headache, vomiting, and impaired mental function from raised pressure within the skull; more specific symptoms include speech loss or visual disturbance due to pressure from the meningioma on underlying brain tissue. The tumor may invade the overlying bone, causing thickening and bulging of a region of the skull.

DIAGNOSIS AND TREATMENT

Meningiomas can be detected by skull *X ray*, *CT scanning*, and *MRI*. Because they are usually well demarcated from underlying brain tissue, meningiomas can often be completely removed by surgery. Tumors that cannot be removed surgically are treated by *radiation therapy*.

Meningitis

Inflammation of the *meninges* (the membranes that cover the brain and spinal cord) that usually results from infection by a variety of microorganisms. Viral meningitis is relatively mild; bacterial meningitis is life-threatening and needs prompt treatment.

CAUSES

The organisms that cause meningitis usually reach the meninges through the bloodstream from an infection elsewhere in the body. Less common means of transmission are through cavities in the skull from an infected ear or sinus, or from the air following a fractured skull.

INCIDENCE

Viral meningitis is far more common than bacterial meningitis, tending to occur in epidemics in the winter months. It affects between 9,000 and 12,000 people, mostly under the age of 30, in the US each year.

Meningococcal meningitis, the most common form of bacterial meningitis, sometimes occurs in small epidemics; more frequently, it occurs in isolated cases. It probably affects between 2,000 and 5,000 young people—70 percent under the age of 5—in the US each year. Tuberculous meningitis, which is a less common type of bacterial meningitis, occurs particularly in young children in parts of the world where there is a high incidence of tuberculosis.

SYMPTOMS

The main symptoms are fever, severe headache, nausea and vomiting, dislike of light, and a stiff neck. In viral meningitis the symptoms are mild and may resemble influenza.

In meningococcal meningitis the main symptoms develop more rapidly, sometimes over a few hours, and are followed by drowsiness and sometimes loss of consciousness. In about half the cases there is also a red, blotchy skin rash.

In tuberculous meningitis, the sufferer may be sick for several weeks before the typical symptoms of meningitis develop.

DIAGNOSIS AND TREATMENT

Meningitis is diagnosed by *lumbar puncture* and the removal of a small sample of cerebrospinal fluid from the spinal cord for examination.

Viral meningitis requires no treatment. Bacterial meningitis is a medical emergency treated with large doses of intravenous antibiotics.

OUTLOOK

Viral meningitis is usually not serious, clears up within a week or two, and leaves no aftereffects. Patients with bacterial meningitis who receive prompt treatment usually recover; in some cases, however, some brain damage results.

PREVENTION

Vaccination may occasionally be valuable in controlling an epidemic caused by certain strains of bacteria. However, giving antibiotics to people who have come into contact with sufferers is generally more effective than vaccination.

Vaccination against meningitis has achieved only limited success because vaccines exist against only some of the organisms responsible and the protection is of limited duration.

Meningocele

A protrusion of the meninges (protective coverings) of the spinal cord under the skin due to a congenital defect in the spine (see *Spina bifida*). Meningocele is less serious than myelocele, which is protrusion of the spinal cord and of the meninges.

Meningomyelocele

See *Myelocele*.

Meniscectomy

A surgical procedure in which the whole or part of a *meniscus* (cartilage disk) is removed from a joint. Meniscectomy is almost always performed on the knee.

WHY IT IS DONE

Meniscectomy is carried out when a meniscus has been badly damaged, usually as a result of injury, causing the knee to lock or give way repeatedly. Removing the damaged part of the meniscus cures these symptoms but may increase the likelihood of premature *osteoarthritis* in the joint. Today, the operation is avoided whenever possible.

HOW IT IS DONE

Arthroscopy (in which a viewing tube is inserted into the joint through a small incision) is performed to confirm that a torn meniscus is the cause of the symptoms and to locate the tear. The torn portion of the meniscus is then removed by means of instruments inserted through the arthroscope. The incision is closed with one stitch, a bandage is applied, and the patient goes home.

Alternatively, the surgeon may need to open up the knee joint through an incision at the side of the patella (kneecap). After the operation, the wound is stitched and an elastic bandage and a plaster splint are applied over the knee.

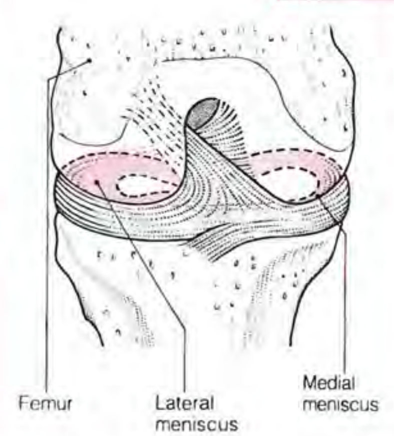
RECOVERY PERIOD

Patients can usually go home the day of arthroscopic surgery and are able to walk normally within several days. After an open operation, the patient stays in the hospital for a few days. He or she is allowed to put weight on the affected leg after two or three days; the splint is removed after about a week, but normal activities cannot be resumed for four to six weeks.

After either procedure, patients should do exercises to strengthen the thigh muscles, which help to stabilize the knee.

OUTLOOK

The procedures are about equally effective in relieving symptoms and restoring the knee to normal function, although the scar after an open operation is larger. In either case, there may be an increased risk of osteoarthritis in later life, although the risk is less than if the damaged meniscus had been left in place.



Meniscus

A crescent-shaped disk of cartilaginous tissue found in several joints in the body. The *knee* joint has two menisci; the *wrist* joint and *temporomandibular joints* (jaw joints) have one each. The main function of the meniscus, which is held in position by ligaments, is to reduce friction during joint movement.

MENISCI

The diagram (right) shows the sites of the menisci. The menisci of the knee are shown in detail below.

Menopause

The cessation of *menstruation*; the term is commonly used to describe the time in a woman's life when physical and psychological changes occur as a result of reduced production of *estrogen hormones* by the ovaries.

Menopause usually occurs between the ages of 45 and 55. The follicles in the ovaries stop producing ova (eggs) and less estrogen is produced. It is this reduction in estrogen that causes the problems associated with the menopause. Other hormonal changes include increased amounts of *gonadotropin hormones* (produced by the pituitary gland) and higher amounts of androgens (male hormones) present in the blood.

SYMPTOMS AND SIGNS

Hot flashes and night sweats occur in about 70 percent of all menopausal women. These symptoms occur with varying frequency and severity. The flashes are usually present for between two and five years, but may continue longer; in 25 percent of women they are so severe that the woman seeks medical help.

Vaginal dryness is the major symptom of 20 percent of menopausal women. Dryness occurs because the vaginal skin thins and its secretions diminish with the fall in estrogen levels. The vagina itself shrinks, loses elasticity, and becomes prone to minor infections; sexual intercourse is often more difficult and painful due to the dryness (see *Vaginitis*). The neck of the bladder and the urethra undergo similar changes, often resulting in the "urethral syndrome," in which the woman feels the need to empty her bladder frequently.

The skin becomes thinner during the menopause and the sebaceous secretions (the skin's natural oils) diminish, resulting in skin dryness. Body and scalp hair becomes dry and brittle and falls out more easily.

Psychological symptoms are often attributed to the menopause, but it is not clear whether these symptoms are caused by the lack of estrogen or are a reaction to the physical symptoms and the sleep disturbance caused by the night sweats. The most common symptoms are poor memory, poor concentration, tearfulness, anxiety, and loss of interest in sex.

Changes in *metabolism* (internal body chemistry) also occur during the menopause, but may not cause symptoms until later. The bones lose calcium more rapidly, especially in the first two to five years of the menopause; over a period of 10 to 15 years, *osteoporosis* (brittle bones) may develop. Other metabolic effects include a rise in blood pressure and an increase in fats in the blood. These changes result in an increase in *atherosclerosis* (fatty deposits in the arteries) and an increased incidence of *coronary heart disease* and *stroke*.

TREATMENT

If symptoms are severe, *hormone replacement therapy* is recommended to treat the physical and psychological symptoms and also to prevent menopause-related osteoporosis and heart disease. *Beta-blocker drugs* are sometimes given to women for whom hormone replacement therapy is unsuitable (e.g., women who have been treated for breast cancer).

Menorrhagia

Excessive loss of blood during *menstruation*. The average amount of blood lost during a normal menstrual period is about 2 fluid ounces (60 milliliters). A woman with menorrhagia may lose 3 fluid ounces (90 milliliters) or more. Some women regularly have menorrhagia, while others rarely or never do.

Menorrhagia is usually caused by an imbalance of estrogen and progesterone, the hormones that control menstruation. This imbalance causes an excessive buildup of endometrium (lining of the uterus).

Any disorder that affects the uterus can cause menorrhagia, including *fibroids*, polyps of the uterus, the presence of an *IUD*, or a pelvic infection. In some women with menorrhagia no physical cause can be found.

TREATMENT

Treatment depends on the severity of the bleeding, the age of the woman, whether or not she wants children in the future, and on any underlying disorder. A *D and C* (dilatation and curettage) may be performed to investigate the cause of menorrhagia. Hormones may be prescribed to reduce the amount of bleeding, especially if the woman is very young. If the condition is severe, a *hysterectomy* (removal of the uterus) may be considered.

Menotropins

A *gonadotropin hormone* given as a drug to stimulate cell activity in the ovaries and testes. Menotropins is prepared from human menopausal gonadotropin, which is obtained from urine samples of women who have passed the menopause.

WHY IT IS USED

Menotropins is used together with human chorionic gonadotropin (see *Gonadotropin, human chorionic*) in the treatment of certain types of female and male *infertility*. Menotropins prepares the ovary for ovulation and helps stimulate sperm production.

POSSIBLE ADVERSE EFFECTS

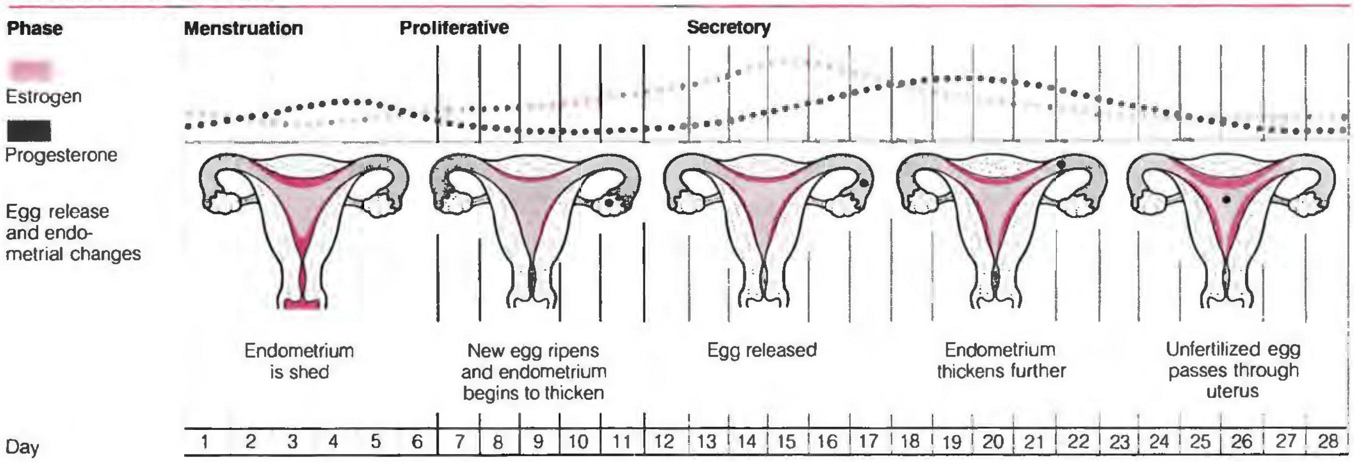
In women, menotropins may cause multiple pregnancy, abdominal pain, bloating, and weight gain. In men, breast enlargement may occur.

Menstrual extraction

A procedure in which the endometrium (the lining of the uterus), which is ordinarily sloughed off during *menstruation*, is removed all at one time. The procedure is also known as menstrual regulation. Menstrual extraction is usually performed to terminate a pregnancy.

Menstrual extraction is carried out in the first two weeks after a missed period. The procedure can be performed in a physician's office with or without local anesthetic. A narrow plastic tube is inserted into the uterus and the contents, including any embryo if the woman is pregnant, are suctioned out.

Menstruation



The periodic cyclical shedding of endometrium (lining of the uterus), accompanied by bleeding, that occurs in a woman who has not become pregnant. Menstruation identifies the fertile years of a woman's life. Menstrual periods usually begin at *puberty* and continue until the *menopause*.

MECHANISM

Menstruation is the end result of a complicated series of hormonal interactions. At the beginning of the menstrual cycle, *estrogen hormones* cause the endometrium to thicken to prepare the uterus for the possibility of *fertilization*; this is known as the proliferative or follicular phase of the menstrual cycle. *Ovulation* (egg release) usually occurs around midcycle and is accompanied by the increased production of *progesterone hormone*. This hormone induces marked changes in the endometrium, and the cells become swollen and thick with retained fluid. These changes, which occur during the secretory (or luteal) phase of the menstrual cycle, enable a fertilized egg to implant in the endometrium. If pregnancy fails to occur, the production of estrogens and progesterone from the ovaries diminishes. The blood-filled lining of the uterus is not required and both the unfertilized egg and the lining are shed about 14 days after the start of ovulation. Uterine contractions force the menstrual discharge to be expelled through the cervix and into the vagina.

Blood loss varies from cycle to cycle and from woman to woman, averaging about 2 fluid ounces (60 milliliters). The menstrual cycle, which is counted from the first day of bleeding to the last day before the next menstrual period, lasts between 24 and 35 days in 95 percent of women, the average being 28 days. The length of bleeding also varies—usually lasting from one to eight days, with the average length being five days. (See also *Menstruation, disorders of; Menstruation, irregular*.)

THE MENSTRUAL CYCLE

During menstruation, estrogen and progesterone levels are low, and the unfertilized egg and endometrium are shed. Following menstruation, a pituitary hormone stimulates the ovaries to produce egg follicles. The follicles secrete estrogen, and one eventually releases an egg. The empty follicle also produces progesterone, which, with estrogen, prepares the endometrium to receive the egg. If the egg is unfertilized, follicle hormone levels fall and a new menstrual cycle begins.

Menstruation, disorders of

An abnormality in the monthly cycle of menstrual bleeding. Regular *menstruation* depends on development of a healthy endometrium (lining of the uterus) and regular cyclical production of *estrogen hormones* and *progesterone hormone*. This delicate balance is easily upset, making abnormal menstruation one of the most common disorders of women. Any change in a woman's periods can indicate a problem in the pelvic area, such as *fibroids*, *endometriosis*, or *pelvic inflammatory disease*.

Dysmenorrhea (painful periods) is the most common disorder. In most women the cause is unknown.

Amenorrhea (absence of menstruation) is most frequently caused by pregnancy; it may also be caused by a hormonal imbalance, stress, starvation, and *anorexia nervosa*. Polymenorrhea (too frequent menstruation) occurs when the length of the menstrual cycle is reduced to less than 22 days. It is usually due to a hormone imbalance. If the periods occur infrequently or the blood loss is scanty, it is termed oligomenorrhea.

Menorrhagia (excessive bleeding) may be caused by a hormone imbalance, the presence of an IUD, fibroids, or *polyps*.

In metrorrhagia, there are extreme variations in the interval between periods, the duration of bleeding, and the amount of blood lost each month (see *Menstruation, irregular*).

Menstruation, irregular

A variation from the normal pattern of *menstruation*. Menstruation is considered irregular if there are wide variations in the interval between periods, the duration of bleeding, or the amount of blood lost.

CAUSES

Disturbance of a woman's menstrual pattern can be caused by stress, travel, or changing the method of contraception. Because menstruation depends on a balance of estrogen and progesterone hormones, the cause of irregular menstruation is often a hormone disturbance. For the first few years after menstruation starts, and for the few years before the *menopause*, cycles are often irregular and ovulation does not occur.

A common cause of irregularity is unsuspected pregnancy or early miscarriage. Disorders of the uterus, ovaries, or pelvic cavity (e.g., *endometriosis*) can also lead to irregularity. (See also *Vaginal bleeding*.)

Mental hospital

A hospital specializing in the treatment of psychiatric illness. Formerly called asylums (or lunatic asylums), many were built in the 19th and early 20th century and were of enormous size. They became infamous as institutionalized backwaters filled with chronic patients who were commonly neglected and abused. Recently, many mental hospitals have been closed as the trend toward care in the community has increased. Still, the debate continues over how much this has contributed to the number of homeless people and how best to protect and treat old, long-stay patients (many of whom are homeless) and new, long-stay patients (such as those suffering from *schizophrenia* or advanced *dementia*).

Today, most admissions to mental hospitals are for acute psychiatric illness. People are admitted to remove them from a stressful or harmful home environment, to provide treatment possible only in the hospital, or to protect them or others from harm. The majority of these admissions are voluntary, but in some cases legal *commitment* is necessary.

Mental illness

A general term that describes any form of psychiatric disorder. It is common to divide these illnesses into two broad categories, the more severe *psychoses* and the less disturbing *neuroses*. While the former are probably caused by complex biochemical brain disease, the latter seem related to upbringing and personality.

The concept of mental illness is also important, for legal reasons, in determining whether a person can be held responsible for his or her actions. In this respect, there is much uncertainty as to whether *personality disorder*, which is often characterized by antisocial behavior, should be regarded as a form of mental illness.

Mental retardation

Impaired intellectual function that results in an inability to cope with the normal responsibilities of life.

CLASSIFICATION AND PREVALENCE

To be classified as mentally retarded, a person must have an IQ below 70 (see *Intelligence tests*) and impairment must be present before the age of 18. Within this group (which comprises about 1 percent of the population) there are various degrees of severity, resulting in different levels of handicap (see table for classification).

MENTAL RETARDATION

Severity	IQ
Mild	50 to 70
Moderate	35 to 49
Severe	20 to 34
Profound	Under 20

Mild retardation is the most common form, accounting for 80 percent of the retarded population. The other 20 percent have moderate, severe, or profound retardation.

CAUSES

The more severe grades of retardation (IQ below 50) usually have a specific physical cause; their incidence is the same in all social classes. About a quarter are due to *Down's syndrome*, another quarter to other inherited or congenital conditions (such as *phenylketonuria* or brain damage due to *hemolytic disease of the newborn*), and about one third result from trauma or infection around birth or early childhood. In about 15 percent of cases the cause is unknown, but the recently discovered *fragile X syndrome* may account for some of them.

By contrast, mild mental retardation usually has no specific cause, is concentrated in the lowest social classes, and seems to run in families. Poverty and *malnutrition* probably contribute to it along with inheritance.

SYMPTOMS

The mildly retarded usually show no obvious psychological symptoms apart from slowness in carrying out mental tasks, such as arithmetic or problem-solving. Reading is variably impaired and emotions may be expressed in a more childlike manner. However, *hyperactivity*, repetitive involuntary movements, and *autism* are up to four times more common than in the general population.

In more severely retarded people, speech is limited or absent, and epileptic seizures and neurological impairments are common. Fecal and urinary incontinence and self-injury may also occur.

TREATMENT

There is no specific means of eliminating the intellectual deficit. Special training and behavior modification can enhance the skills and quality of life for retarded people, many of whom are cared for in the community rather than in institutions. Family support and counseling can be crucial in preserving a stable home for the retarded person.

MENSTRUATION, IRREGULAR

Any variation in the interval between menstrual periods, the duration of bleeding, or the amount of blood lost, or bleeding that occurs in between normal periods, during pregnancy, or after the menopause. An occasional irregular period is generally no cause for concern if it is normal in other respects.

Absent or reduced bleeding

Are you 16 or over and have you never had a period?

YES → The menarche starts late in certain families. If you feel you should have had your first period by now, consult your physician.

See • *Amenorrhea*

NO ↓

Have you had periods that have now stopped either suddenly or gradually?

YES → **Have you recently been exercising rigorously AND/OR have you recently lost more than 15 pounds?**

YES → Exercising or a dramatic weight loss can cause periods to stop.

NO ↓

Have you been ill or under stress or have you undergone an upheaval such as a divorce?

YES → Physical or emotional upsets often disturb the body's hormonal balance.

See • *Amenorrhea*
• *Stress*

NO ↓

NO ↓

Could you be pregnant?

YES → Pregnancy is the most common reason for lack of periods.

NO ↓

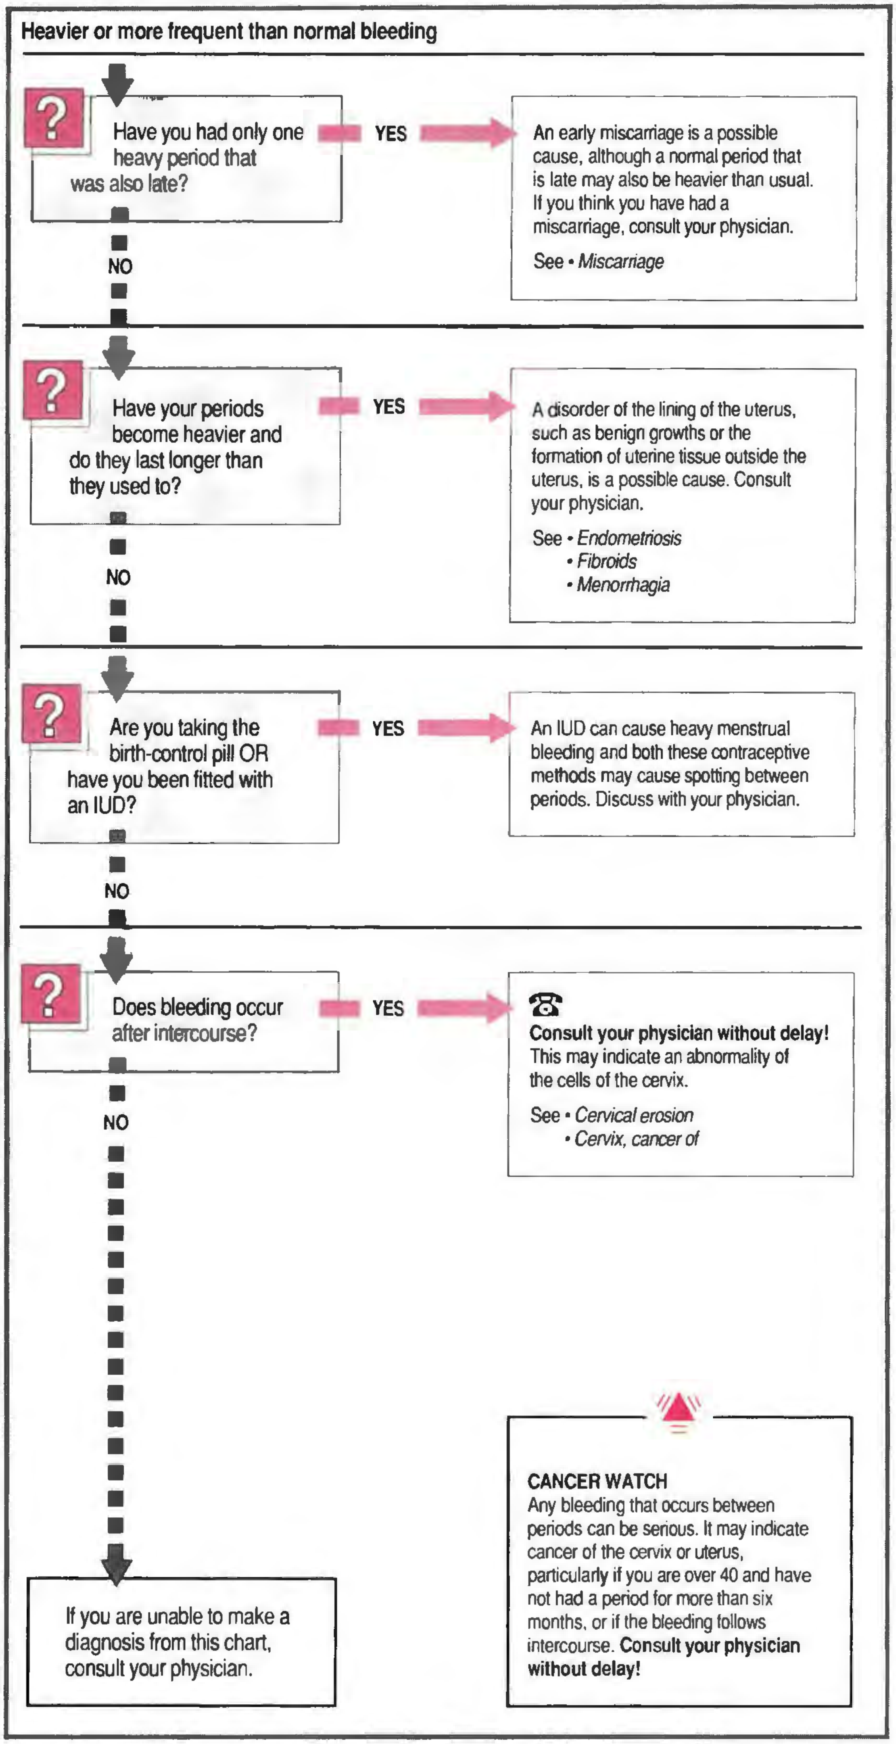
Have you recently had a baby?

YES → After childbirth you are unlikely to start having regular periods as long as you are breast-feeding.

See • *Childbirth*

NO ↓

Are you over 40?



YES → It is common for women between 40 and 50 to begin missing periods.

See • *Menopause*

NO ↓

Continued on next page

M

Anticonvulsant drugs may be needed in the treatment of epilepsy and *antipsychotics* in the treatment of other mental illness that may accompany mental retardation; these drugs help control symptoms and thus reduce impairment.

In the future, the incidence of retardation should be reduced by prevention. Preventive measures include *genetic counseling*, the elimination of infections such as *rubella*, reducing the alcohol and drug intake during pregnancy, and the early identification of fetal abnormalities.

OUTLOOK

While caring for a mentally retarded relative is often a demanding and time-consuming task, there is evidence that such people, even if severely impaired, can live rewarding and emotionally stable lives. Handicap is caused not by an absolute limit on achievement, but by delay in acquiring skills; as they grow older, the mentally retarded are able to improve in terms of personal and social function.

Meperidine

A synthetic narcotic *analgesic drug* (painkiller) similar to, but less powerful than, *morphine*. Meperidine, which is used almost exclusively in hospitals, is given as a *premedication* (a drug used to relax and sedate a person before an operation). It is also used to relieve severe pain after a major operation, during childbirth, and, occasionally, in terminal illness.

Since meperidine may cause nausea and vomiting, it is usually given with an *antiemetic drug* to control these symptoms. Used for long periods, meperidine may cause constipation.

ABUSE

Meperidine may cause euphoria and is abused for this effect. Taken regularly, it is likely to cause psychological and physical dependence (see *Drug dependence*).

Meprobamate

An *antianxiety drug* that is used to treat *anxiety* and *stress*. Meprobamate, which also has a muscle-relaxant effect, is combined with aspirin to relieve pain caused by rheumatic disorders (such as *osteoarthritis*) or injury to soft tissues (such as muscles and ligaments).

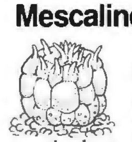
Since meprobamate has a sedative effect, it may cause drowsiness and dizziness. After long-term use, its discontinuation may be followed by severe withdrawal reactions.

Mercaptopurine
An *anticancer drug* used to treat certain types of *leukemia* (cancer of white blood cells). Mercaptopurine is also used as a treatment for *Crohn's disease* and for *lymphoma* (cancer of lymph nodes) in children.

Possible adverse effects include nausea, vomiting, mouth ulcers, and appetite loss. Rarely, mercaptopurine may cause liver damage, anemia, and abnormal bleeding.

Mercury
The only metallic element that is liquid at room temperature. Mercury is used in *thermometers*, *sphygmomanometers* (instruments for measuring blood pressure), and dental *amalgam*. Various compounds of mercury are used in some paints, pesticides, cosmetics, medicines, and in certain industrial processes.

Mercury poisoning
All forms of mercury are poisonous (except the amalgam in dental fillings), but some forms are absorbed into the body more readily than others and are therefore more dangerous. The liquid metal itself is absorbed very slightly through the intestines, so accidentally swallowing mercury from a broken thermometer is unlikely to lead to poisoning. However, liquid mercury is highly volatile and mercury vapor is readily absorbed into the body via the lungs. Inhalation of mercury vapor—usually as a result of industrial exposure—is the most common cause of poisoning. Mercury compounds (not highly volatile) cause poisoning by absorption through the skin or intestines.



SYMPTOMS AND SIGNS

The initial symptoms of mercury poisoning depend on the part of the body affected. Inhalation of mercury vapor may cause shortness of breath from lung damage; mercury compounds that come into contact with the skin may cause severe inflammation. A swallowed mercury compound can cause nausea, vomiting, diarrhea, and abdominal pain.

After mercury has entered the body, it passes into the bloodstream and later accumulates in various organs, principally the brain and kidneys. Mercury deposits in the brain cause a wide range of symptoms, including tiredness, incoordination, excitability, tremors, numbness in the limbs, and, in severe cases, impairment of vision and sometimes *dementia*. Deposits of mercury in the kidneys may lead to *renal failure*. Without treatment, severe mercury poisoning may be fatal.

TREATMENT

Mercury poisoning is treated by giving *chelating agents* (such as penicillamine) to detoxify the mercury and help the body excrete it at a faster rate. In some cases, purification of the blood by hemodialysis (see *Dialysis*) may also be performed, especially if the kidneys have been damaged. Inducing vomiting or pumping out the stomach is helpful only if mercury has been swallowed within the previous few hours.

Mescaline

A drug obtained from the Mexican peyote (or peyotl) cactus and classified as a psychedelic or *hallucinogenic drug*. The dried tops of the cactus, known as peyote buttons, have been used historically by Mexican and North American Indians in religious ceremonies. In modern times, psychologists have used mescaline to study the mechanism of *psychosis*, since the drug induces temporary psychotic symptoms.

The effects, which generally last for four to eight hours, are similar to those of *LSD* and *psilocybin*. Effects include illusions, changes in thought and mood, a sense of being in touch with the unknown, intense self-absorption, and an altered sense of time. Although the "trip" is most often pleasant and seemingly insightful, frightening ideas or experiences leading to panic and injury may occur. True psychosis, persisting after the drug has worn off, and addictive craving may occur.

Mesenteric lymphadenitis
An acute abdominal disorder in which lymph nodes in the mesentery (a membrane anchoring organs to the abdominal wall) become inflamed. Mesenteric lymphadenitis mainly affects children. Its cause is unknown but it may be related to some type of viral infection.

The main symptoms are pain and tenderness in the lower right abdomen, as in appendicitis. There may be mild fever, and sometimes the condition is preceded by a sore throat, chest infection, or swollen neck glands.

The disorder usually clears up rapidly. Analgesics (painkillers) may be given to reduce pain and fever. If the sufferer is no better after six hours or if the symptoms worsen dramatically, a *laparotomy* (surgical opening of the abdominal cavity) may be carried out to exclude appendicitis.

Mesentery
A membrane that attaches various organs to the abdominal wall. The term is used particularly to refer to the membranous fold that encloses the small intestine, attaching it to the back of the abdominal wall. The mesentery contains the arteries, veins, nerves, and lymphatic vessels that supply the large and small intestines.

Mesothelioma
A tumor of the pleura (lining of the lung and chest cavity). There are two types of mesothelioma—a solitary growth that remains localized in one area of the pleura and a diffuse malignant form. There is an increased incidence of mesothelioma in people exposed to asbestos dust (see *Asbestosis*), especially smokers.

Mesothelioma may cause no symptoms or it may cause cough, chest pain, and breathing difficulty, especially if a *pleural effusion* (collection of fluid around the lung) develops.

A chest X ray may show abnormal shadowing; the diagnosis can be confirmed by examination of a sample of fluid from any effusion or by pleural *biopsy* (removal of a sample of tissue for examination).

Surgical removal of a solitary tumor may result in complete cure. There is no effective treatment for the malignant form, although *radiation therapy* may help alleviate symptoms.

Mesothelium
A type of *epithelium* (surface cell layer) that lines the body cavities of the *peritoneum* and the *pleura* and makes up the *pericardium* (the saclike covering of the heart).

Mestranol
An *estrogen drug* used in various *oral contraceptive* preparations.

Metabolism
A collective term for all the chemical processes that take place in the body. Metabolism is divided into catabolism and anabolism. A catabolic process is a chemical reaction in which a complex substance is broken down into simpler ones, usually with the release of energy. An example is the "burning" of glucose (sugar) in body cells to produce energy and the by-products carbon dioxide and water. An anabolic process is a chemical reaction in which

a complex substance is built up from simpler ones, usually with the consumption of energy (which is provided by catabolism). The synthesis of complex *proteins* from *amino acids* is an anabolic process.

METABOLIC RATE

The basal metabolic rate (BMR) is the energy required to keep the body functioning at rest (that is, to maintain breathing, heart beat, body temperature, and other basic body functions). It is measured in Calories (or joules) per square meter of body surface per hour. The metabolic rate increases in response to factors such as exertion, stress, fear, and illness. It is controlled principally by various endocrine hormones (such as *epinephrine*, *norepinephrine*, *insulin*, *corticosteroid hormones*, and thyroid hormones—see *Thyroid gland*), which influence the rate at which chemical processes are carried out in body cells.

DISORDERS

The primary types of metabolic disorders include inherited abnormalities in which a specific enzyme (a substance that promotes a metabolic reaction) is lacking or malfunctions in some way (see *Metabolism, inborn errors of*). Other metabolic disorders are endocrine disorders in which there is underproduction or overproduction of a hormone that controls metabolic activity. Examples are *Cushing's syndrome*, *diabetes mellitus*, *insulinoma*, *hyperthyroidism* (overproduction by the thyroid gland), and *hypothyroidism* (underproduction by the thyroid).

Metabolism, inborn errors of

Inherited defects of body chemistry. These are *genetic disorders* in which the disturbance of body chemistry is caused by a single gene defect.

TYPES AND INCIDENCE

There are about 180 known inborn errors of metabolism. They vary in severity, from harmless abnormalities to serious diseases that may cause death in a newborn baby or result in severe physical or mental handicap. Examples include *Tay-Sachs disease*, *phenylketonuria*, *galactosemia*, the various *porphyrias*, *Hurler's syndrome* and various other types of *mucopolysaccharidosis*, hereditary fructose intolerance, Lesch-Nyhan syndrome, homocystinuria, glycogen storage diseases, mucolipidoses, and sphingolipidoses.

Individual disorders are rare. Most affect only one child in every 10,000 to 100,000, but the precise incidence is often unknown because sufferers may have only vague symptoms that are never investigated, or because they die before any characteristic features appear. Collectively, these disorders affect about one child in 1,000.

CAUSES

All inborn errors of metabolism are caused by abnormal functioning of a specific *enzyme* (protein that stimulates a chemical reaction) caused by a defect of a *gene*. Most defects show an autosomal recessive pattern of inheritance (see *Genetic disorders*).

Individual disorders vary in their effects. In some cases the abnormal enzyme is nonfunctional; in others there is some residual activity.

SYMPTOMS AND SIGNS

Symptoms are usually present at or soon after birth, although they may not appear until later in childhood. Symptoms may include unexplained illness or failure to thrive in a newborn, developmental delay, floppiness, drowsiness, persistent vomiting, or seizures. Signs may include enlarged body organs, bone deformities, anemia, cataracts, persistent jaundice, unusual body odor, the recurrent development of kidney stones, or a rash brought on by sunlight. The child may be intolerant to specific foods.

Miscarriages, stillbirths, or deaths in early infancy suggest the possibility of an inborn error of metabolism.

DIAGNOSIS

Investigations include tests to measure the levels of various substances in the affected child's blood, including *liver function tests* and *kidney function tests*. Chemical analysis of a *biopsy* specimen (small piece of tissue removed from the body) may be performed to check the level and function of a specific enzyme.

Early diagnosis can be important in preventing serious complications. Routine tests are done in the newborn for some of the more common disorders, such as phenylketonuria. Additional screening may be performed for disorders that are more common in certain countries or racial groups (for example, Tay-Sachs disease in European Jews).

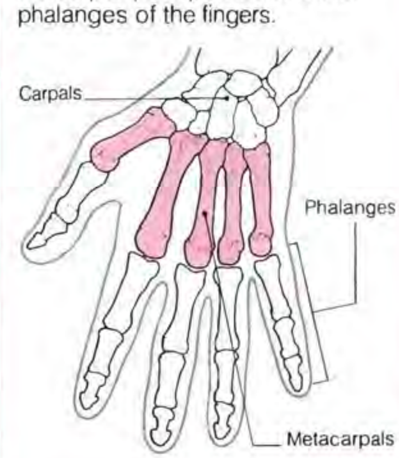
Certain disorders can now be diagnosed prenatally following *chorionic villus sampling* or *amniocentesis*, allowing for an elective abortion.

TREATMENT

Some inborn errors of metabolism do not require treatment. Some respond to avoidance of a specific environmental factor to which an affected person is abnormally sensitive. For example, avoiding exposure to sunlight may help certain types of porphyria, avoiding food containing phenylalanine helps in phenylketonuria.

In some cases, a vitamin supplement can help compensate for defective enzyme function. In others, injections of the defective enzyme are given. Transplanting enzyme-producing cells from a donor has been effective in some cases (such as to treat Hurler's syndrome). Treating inborn errors of metabolism at the gene level is still, however, only theoretical. (See also *Genetic counseling*.)

Metabolite



Any substance that takes part in a metabolic reaction (a biochemical reaction in the body). In the breakdown of glucose (sugar) to produce energy, the metabolites are glucose, carbon dioxide, and water. The term metabolite is sometimes used to refer only to the products of a metabolic reaction. (See also *Metabolism*.)

Metacarpal bone

One of five long, cylindrical bones within the body of the hand. The bones run from the base of each digit to the wrist. On the palm of the hand, they are covered by a thick layer of fascia (fibrous connective tissue); on the back of the hand, they can be seen and felt through the skin. The heads of the metacarpal bones form the knuckles, standing out prominently when the hand is clenched. Fracture of the metacarpal bones is fairly common, usually as the result of a fall on the hand or a blow to the knuckles.

LOCATION OF METACARPAL BONES

The five metacarpals lie between the carpal (wrist) bones and the phalanges of the fingers.

Metaplasia
A change in tissue resulting from the transformation of one type of cell into another. Usually harmless, but occasionally precancerous, metaplasia can affect the lining of various organs, such as the bronchi (airways) and bladder. Metaplasia of the cervix, which occurs in *cervical erosion*, can be detected by a *cervical smear test*.

Metaproterenol
A *bronchodilator drug* used in the treatment of *asthma*, chronic *bronchitis*, and *emphysema*. Possible adverse effects include anxiety, restlessness, tremor, and palpitations.

Metastasis
A secondary malignant tumor (one that has spread from a primary *cancer* to affect other parts of the body). A metastasis in the liver may arise as a result of the spread of a cancer in the colon. The term metastasis also applies to the process by which such spread occurs. The degree of malignancy of a tumor depends largely on its ability to invade surrounding normal tissue and on its ability to send metastases to other parts of the body.

Metastases can spread from one part of the body to another through the lymphatic system, in the bloodstream, or across a body cavity (such as that between the inner and outer layer of the peritoneal membrane in the abdomen).

Metatarsal bone
One of five long, cylindrical bones within the foot. The bones make up the central skeleton of the foot and are held in an arch by surrounding ligaments. Fracture of the metatarsal bones may be caused by a heavy object falling onto the foot, by a twisting injury in which the foot turns over on its outside edge, or by prolonged walking or running on a hard surface (see *March fracture*).

LOCATION OF METATARSAL BONES

The five metatarsals lie between the tarsal bones (which form the ankle and back of the foot) and the phalanges of the toes

Metatarsalgia
Pain in the foot. Causes include a fracture of one of the *metatarsal bones*, *flatfeet*, or a *neuroma* (benign tumor) of one of the nerves in the foot.

Metatarsophalangeal joint
The joint between each *metatarsal bone* and its adjoining toe bone (see *Phalanges*). The metatarsophalangeal joint at the base of the big toe is commonly affected by *gout* and osteoarthritis (see *Hallux rigidus*). Deformity may result in a bunion (see *Hallux valgus*).

Methadone
A synthetic narcotic *analgesic drug* (painkiller) that resembles *morphine*. Methadone causes only mild symptoms when it is withdrawn and is therefore used to relieve withdrawal symptoms in people undergoing a supervised heroin or morphine detoxification program.

Possible adverse effects include nausea, vomiting, constipation, dizziness, and dryness of the mouth.

Methane
A colorless, odorless, highly flammable gas that occurs naturally in the gas from oil wells and in coal mines, where it is an explosion hazard. Methane is also produced by the decomposition of organic matter; it is one of the gases present in intestinal gas (see *Flatus*).

Methanol
A poisonous type of *alcohol* used as a solvent or paint remover, and as an ingredient in some types of antifreeze. Also known as wood alcohol or methyl alcohol, methanol may cause blindness or death if ingested.

POISONING

Methanol is toxic; poisoning usually occurs as a result of drinking it as a substitute for ordinary alcohol (ethanol, or ethyl alcohol), although its inebriating effect is weaker.

Symptoms of poisoning, which develop 12 to 24 hours after drinking the methanol, include headache, dizziness, nausea, vomiting, and unconsciousness. The symptoms are caused by the breakdown in the liver of methanol into formaldehyde and formic acid. These substances may also damage the retina and optic nerve, causing blurred vision. If methanol is drunk repeatedly, or if a single large dose is taken, permanent blindness may result.

TREATMENT

If somebody has ingested methanol and is conscious, vomiting should be induced and medical help obtained. Treatment may include pumping the stomach (see *Lavage, gastric*) and inducing vomiting, although this is effective only within about two hours of having drunk the methanol (before it has been absorbed into the bloodstream). In addition, ethanol may be given by injection into the bloodstream because it slows the rate at which the liver breaks down the methanol. An intravenous infusion of sodium bicarbonate may be used to neutralize formic acid in the blood. Occasionally, purification of the blood (by *dialysis*) is also necessary.

Methimazole
A drug used in the treatment of *hyperthyroidism* (overactivity of the thyroid gland). Methimazole suppresses the production of thyroid hormones by the thyroid gland.

Possible adverse effects include nausea, rash, dizziness, headache, and aching in the joints. Rarely, methimazole may cause increased susceptibility to infection.

Methocarbamol
A *muscle-relaxant drug* used to relieve stiffness caused by muscle injury and back pain. Methocarbamol is sometimes given to treat symptoms of *tetanus* (lockjaw). During prolonged treatment, methocarbamol may cause drowsiness, dizziness, and, in rare cases, liver damage.

Methotrexate
An *anticancer drug* used in the treatment of *lymphoma* (cancer of the lymph nodes) and certain forms of *leukemia*. Methotrexate is also used to treat some cancers of the uterus, breast, ovary, lung, bladder, and testis. It is given to treat *rheumatoid arthritis* when other treatments have proved ineffective and is sometimes used to treat severe *psoriasis*.

Methotrexate may cause nausea, vomiting, diarrhea, and mouth ulcers. It may also cause anemia, increased susceptibility to infection, and abnormal bleeding.

Methoxsalen
A *psoralen drug* used in the treatment of *psoriasis* and *vitiligo* when other

treatments have been ineffective. Potential adverse effects are typical of other psoralen drugs.

Methyclothiazide
A commonly prescribed thiazide *diuretic drug*.

Methyl alcohol
Another name for *methanol*.

Methylcellulose
A bulk-forming *laxative drug* commonly used to treat *constipation*, *diverticular disease*, and *irritable bowel syndrome*. Methylcellulose is also used to increase the firmness of bowel movements in *diarrhea* and to regulate their consistency in people who have had a *colostomy* or *ileostomy*.

In eye-drop form, methylcellulose is given to relieve dryness caused by sun, wind, and other irritants.

POSSIBLE ADVERSE EFFECTS

Methylcellulose may cause bloating, flatulence, and abdominal pain, or even bowel obstruction if sufficient amounts of fluids are not taken.

Methyldopa
An *antihypertensive drug* used in the treatment of *hypertension* (high blood pressure), usually in conjunction with other drugs from this group. Unlike most antihypertensives, methyldopa is safe to use during pregnancy. Adverse effects include drowsiness, depression, and nasal congestion.

Methylprednisolone

CORTICOSTEROID

Tablet Injection Ointment Enema

Prescription needed

Available as generic

A *corticosteroid drug* used to replace hormones in *pituitary* or *adrenal gland* disorders that reduce the body's natural corticosteroid production. Methylprednisolone is also used in the treatment of severe *asthma*, skin inflammation, *inflammatory bowel disease*, and types of arthritis, including *rheumatoid arthritis*.

Possible adverse effects are typical of corticosteroid drugs.

Methysergide
A drug used to prevent *migraine* and cluster *headaches* (recurrent severe headaches). Methysergide is usually given only when other treatments have been ineffective.

Long-term drug treatment with methysergide may cause abnormal tissue growth in the lungs, around the ureters, or around blood vessels (resulting in chest pain, kidney failure, or leg cramps). Other possible adverse effects include dizziness, drowsiness, nausea, and diarrhea.

Metoclopramide
An *antiemetic drug* used to relieve nausea and vomiting caused by *anticancer drugs*, *radiation therapy*, or anesthetic drugs (see *Anesthesia, general*).

Metoclopramide is often given with a *premedication* (drug used to relax and sedate a person before an operation) to empty the stomach's contents and thereby reduce the risk of a person inhaling vomit. Metoclopramide is sometimes used to treat *heartburn*.

HOW IT WORKS

Metoclopramide reduces nerve activity in the part of the brain that stimulates vomiting. It also increases the speed with which fluid and food pass from the stomach.

POSSIBLE ADVERSE EFFECTS

Adverse effects may include rash, dryness of the mouth, agitation, and irritability. Large doses or prolonged use may cause sedation, diarrhea, or uncontrollable movements of the face, mouth, and tongue.

Metolazone
A *diuretic drug* used in the treatment of *hypertension* (high blood pressure). Metolazone is also given to reduce *edema* (fluid retention) in people with *heart failure* (reduced pumping efficiency of the heart), kidney disorders, *cirrhosis* of the liver, or *premenstrual syndrome*.

Metolazone is also a useful treatment for certain types of kidney stones (see *Calculus, urinary tract*) because it reduces the amount of calcium in the urine.

Possible adverse effects include weakness, lethargy, and dizziness caused by an increase in the amount of potassium excreted in the urine.

Metoprolol
A cardioselective *beta-blocker drug* used in the treatment of *angina pectoris* (chest pain due to impaired blood supply to heart muscle) and *hypertension* (high blood pressure). Metoprolol is also prescribed to relieve symptoms of *hyperthyroidism* (overactivity of the thyroid gland). It is occasionally given following a *myocardial infarction* (heart attack) to reduce the risk of further damage to the heart.

Possible adverse effects of metoprolol include lethargy, cold hands and feet, nightmares, and rash.

Metronidazole
An *antibiotic drug* that is particularly effective against infections caused by *anaerobic* bacteria (those that do not depend on oxygen), such as a tooth abscess and *peritonitis*. Metronidazole is also used to treat infections caused by *protozoa*, such as *trichomoniasis*, *amebiasis*, and *giardiasis*.

Adverse effects include nausea and vomiting, loss of appetite, abdominal pain, and dark-colored urine. Drinking alcohol during treatment often produces severe unpleasant effects such as nausea and vomiting, hot flashes, abdominal pain, palpitations, and headache.

Mexiletine
An *antiarrhythmic drug* used in the treatment of certain heart rhythm disorders, usually after a *myocardial infarction* (heart attack).

Adverse effects include nausea, vomiting, dizziness, and tremor.

Miconazole

ANTIFUNGAL

Injection Vaginal suppository Cream

Prescription needed

Available as generic

An *antifungal drug* used to treat *tinea* skin infections, such as ringworm and *athlete's foot*, vaginal *candidiasis* (thrush), and rare fungal infections that affect internal organs, such as the lung.

Miconazole in the form of a cream or vaginal suppository causes a burning sensation and rash in rare cases. Injections of miconazole may cause nausea, vomiting, and fever.

Micro-
A prefix meaning small, as in microorganisms, tiny living organisms (such as bacteria, viruses, and protozoa), most of which are too small to be seen by the naked eye.

Microangiopathy
Any disease or disorder of the small blood vessels. Microangiopathy may be a feature of various conditions, including some kidney diseases, such as *glomerulonephritis* (inflammation of the kidneys' filtering units) or *hemolytic-uremic syndrome* (premature

destruction of red blood cells accompanied by kidney damage); *eclampsia* (a disorder characterized by seizures in late pregnancy); *septicemia* (blood poisoning); and advanced cancer. When microangiopathy accompanies these conditions, the small blood vessels become distorted, resulting in red blood cells becoming damaged or destroyed. This, in turn, leads to a certain type of anemia called microangiopathic hemolytic anemia (see *Anemia, hemolytic*).

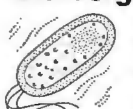
Another cause of microangiopathy is thrombotic thrombocytopenic purpura, a rare, often fatal disease that mainly affects young adults. In this condition, the small blood vessels in many organs throughout the body become blocked and the vessel walls are damaged; hemolytic anemia, fever, and a patchy, purplish rash known as *purpura* develop.

Microbe

A popular term for a *microorganism*, especially one that causes disease.

Microbiology

The study of *microorganisms*, particularly pathogenic (disease-causing) ones. Microbiology began in the 17th century with the discovery by the Dutch microscopist Antonj van Leeuwenhoek (1632-1723) of a wide variety of organisms too small to be seen by the naked eye. However, relatively little progress was made until the 19th century when, largely due to the work of scientists such as Louis Pasteur (1822-1895) and Robert Koch (1843-1910), it was recognized that microorganisms cause many infectious diseases and are also responsible for processes such as fermentation and decay. Microbiology continued to progress with the discovery of viruses, the development of vaccines and antibiotics against many diseases, and studies of the chemical processes fundamental to all living cells. Recently, microbiologists have played an important role in the study of genetics by pioneering techniques of *genetic engineering*.



In hospitals, microbiologists help identify the infectious organisms responsible for a patient's illness; they also advise clinicians on the sensitivity of these organisms to drugs.

Microcephaly

An abnormally small head, usually associated with mental retardation. Microcephaly may occur if the brain is damaged before birth by congenital *rubella* (German measles) or if the mother is exposed to X rays during early pregnancy. It may also be the result of brain damage during birth, or of injury or disease in early infancy. Microcephaly may also occur if the skull bones fuse too early (see *Craniosynostosis*). There is also a rare inherited form of microcephaly in which the forehead slopes backward and the top of the head is pointed.

There is no method of treatment for this condition.

Microorganism

Any tiny, single-celled living organism, usually too small to be seen by the naked eye. In medicine, the most important microorganisms are those that are pathogenic (disease-causing), although this group constitutes a relatively small minority of the vast number of microorganisms known to exist.

The principal pathogenic microorganisms are *bacteria*, which cause certain types of pneumonia, typhoid, diphtheria, and some types of food poisoning; *viruses* (usually classified as microorganisms although they are not true cells), which cause numerous infections, including AIDS, the common cold, influenza, and measles; *protozoa*, which are the causative agents of malaria, giardiasis, and amebic dysentery; *fungi*, which cause disorders such as ringworm and thrush; *rickettsiae*, which cause typhus, Rocky Mountain spotted fever, and Q fever; and chlamydiae, which cause various genital, eye, and respiratory infections (see *Chlamydial infections*).

Microscope

An instrument for producing enlarged images of small objects. There are many types of microscopes, ranging from simple, one-lens instruments (magnifying glasses), to compound microscopes and high-powered electron microscopes.

HISTORY

The single-lens microscope may date from as early as the 15th century, but the first truly powerful lenses were probably made by Antonj van Leeuwenhoek (1632-1723). His single-lens microscopes were capable of magnifying up to about 300 times. With them, he discovered microorganisms, thereby founding the science of *microbiology* and providing the basis for the development of the germ theory of disease. Probably the greatest of the early microscopists was the Italian Marcello Malpighi (1628-1694), who is generally regarded as the founder of *histology*.

The compound microscope, which has two lens systems, was developed toward the end of the 16th century. However, the single-lens microscope continued to be widely used until the 19th century, when improvements in optical design and glass technology made the compound microscope a practicable instrument.

Light microscopes continued to be refined with the development of the phase-contrast microscope. However, the next major advances were instruments that use electrons in place of light—the transmission electron microscope (TEM), invented in the early 1930s, and the scanning electron microscope (SEM), invented in the middle 1960s.

LIGHT MICROSCOPES

Compound microscopes are the most widely used instruments. They have two lens systems. The objective and eyepiece are mounted at opposite ends of a tube called the body tube. There is also a stage to hold the specimen, a light source, and an optical condenser (see box, overleaf).

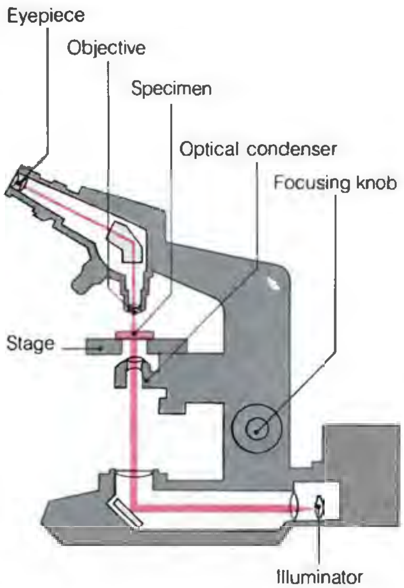
For ordinary light microscopes, the maximum magnification is about 1,500 times. By using a beam of electrons, much higher magnifications are possible.

ELECTRON MICROSCOPES

TEMs are similar to light microscopes, except that they use a beam of electrons instead of light, and electromagnetic "lenses" instead of glass ones. Furthermore, because electrons are invisible, the image must be formed on a fluorescent screen or photographic film. Modern TEMs can magnify up to about 5 million times, enabling tiny viruses and large molecules (such as DNA) to be seen.

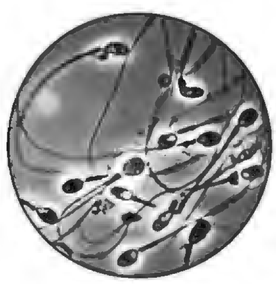
The SEM works in a different way from the TEM (see box). SEMs have a lower maximum magnification (about 100,000 times) than do TEMs. However, unlike TEMs, SEMs produce three-dimensional images. This makes SEMs particularly valuable for studying the surface structures of cells and tissues.

OTHER MICROSCOPES



Phase-contrast and interference microscopes are types of light microscopes with modified illumination and optical systems that make it possible for unstained transparent specimens to be seen clearly. These microscopes are particularly useful for examining living cells and tissues.

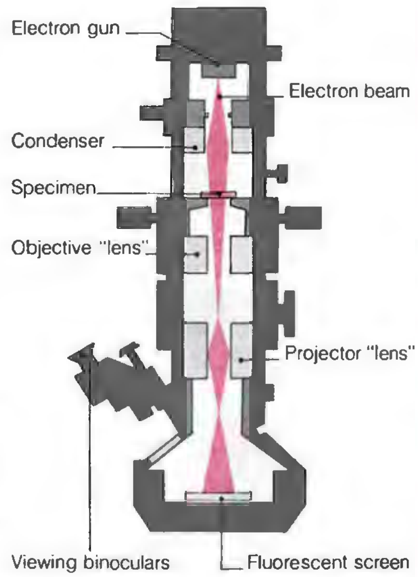
M



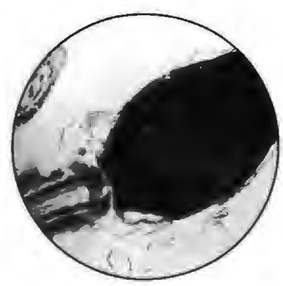
TYPES OF MICROSCOPES

Microscopes are indispensable in medicine. For many purposes, the light microscope, with a magnification of up to 1,500 times, is sufficient. Modern research increasingly requires the much higher magnifications (up to about 5 million times) of a transmission electron microscope or a scanning electron microscope.

LIGHT MICROSCOPE

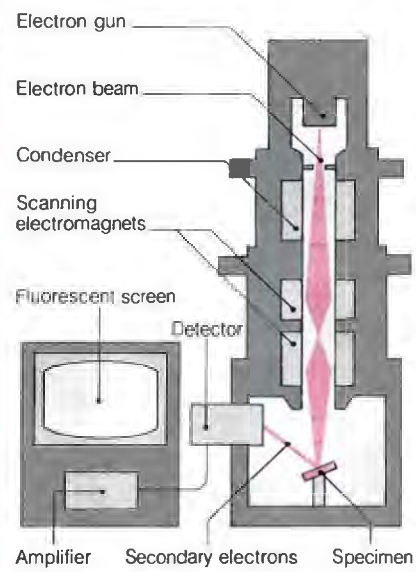


Shown is a collection of sperm cells.

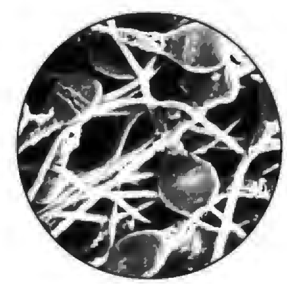


The compound light microscope
One lens (the objective) forms a magnified image of the specimen; this image is then magnified further by the eyepiece (viewing) lens. The specimen is held on a stage, beneath which is an optical condenser that concentrates light (usually from a built-in illuminator) onto the specimen. Focusing is carried out by altering the distance between the objective and specimen.

TRANSMISSION ELECTRON MICROSCOPE



Shown here is the sperm's internal structure.



The transmission electron microscope
An electron beam (generated by a "gun") is concentrated by an electromagnetic condenser, then passes through the specimen. An electromagnetic objective "lens" then produces a magnified "image" of the specimen; this image is further magnified by an electromagnetic projector "lens," which also focuses the image onto a fluorescent screen, where it can be viewed through special binoculars.

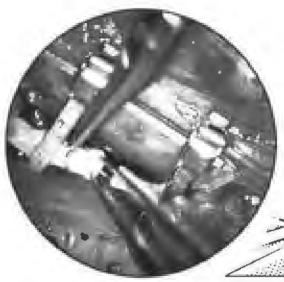
SCANNING ELECTRON MICROSCOPE

This shows the sperm cells in close detail.

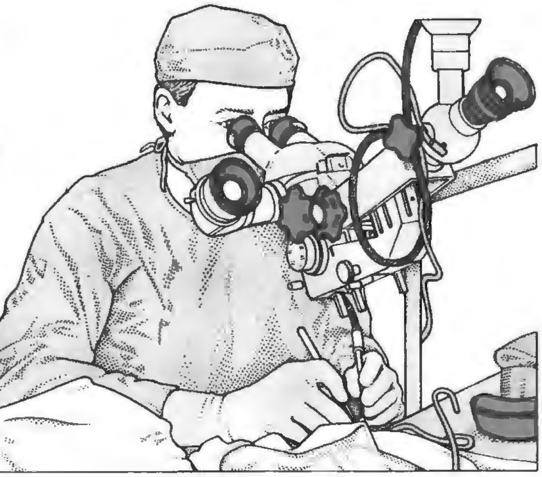
The scanning electron microscope
An electron beam (generated by a "gun") is scanned over the surface of the specimen, causing the emission of a beam of secondary electrons, the intensity of which varies according to the surface features of the specimen. A detector converts the secondary electrons into an electric current, which is then amplified and used to control an electron beam that forms an image on a fluorescent screen.

Another instrument, the fluorescence microscope, is used to study the chemical composition of cells. In fluorescence microscopy, a specimen that has been selectively stained with fluorescent dyes is illuminated with ultraviolet light, which makes the stained parts glow.

Operating microscopes are low-powered compound microscopes with several modifications. They do not have a stage, and the illumination system is arranged to shine light down onto the living tissues rather than up through the specimen.



USES

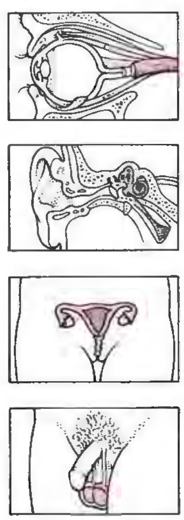


The microscope is probably the single most important instrument in biological and medical science. Its applications are vast, ranging from the study of molecular structures to *microsurgery*. Microscopes have enabled scientists to examine both the structure and chemical composition of cells (*cytology*) and tissues (histology). They are used to investigate diseased tissues (a specialty called *histopathology*), thereby playing a vital role in diagnosis. In the operating room, microscopes have enabled the development of microsurgery, one application of which is to rejoin individual nerve fibers.

TECHNIQUES OF MICROSURGERY

Microsurgery started with ophthalmic surgeons, whose demands for more delicate operating instruments led to the adoption of the operating microscope. The results were so favorable that surgeons working in other specialties began to use the technique for intricate operations.

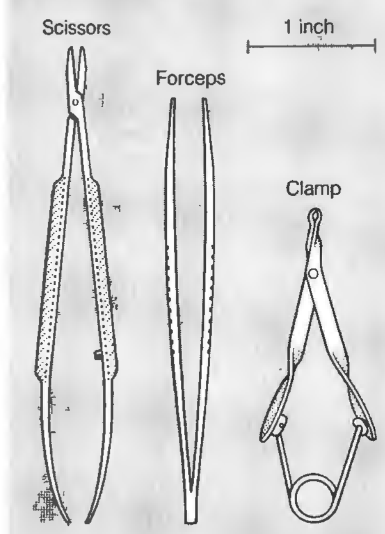
The operating microscope
This surgeon is performing microsurgery with the aid of an operating microscope. The photograph (below) shows small blood vessels as seen through the microscope.



Replantation microsurgery
A major application of microsurgery is the replantation of severed fingers, toes, hands, feet, or even entire limbs. This is successful only if the severed blood vessels and nerves are accurately rejoined so that regeneration occurs.

MAIN AREAS OF OPERATION
Microsurgery is most commonly employed in ophthalmic, vascular, neurological, gynecological, urological, and otological surgical procedures, in which delicate structures are involved.

Ophthalmology
By using microsurgery, even operations on the delicate retina of the eye are now possible.



Otology
Microsurgery is routinely used for operations on the tiny bones in the middle ear.

Gynecology
With microsurgery, blockages of the fallopian tubes can often be corrected, restoring fertility.

Urology
A vasectomy (male sterilization) can sometimes be reversed by using microsurgery to rejoin the cut ends of the vas deferens.

INSTRUMENTS

Microsurgery is possible only by using extremely delicate operating instruments, such as the fine scissors, forceps, and clamp shown above (their sizes can be judged from the scale bar).

Microsurgery

Delicate surgery in which the surgeon views the operation site through a special binocular *microscope* with pedal-operated magnification, focusing, and movements.

Microsurgery technique is used for surgery involving minute, delicate, or not easily accessible tissues. It has strikingly improved the success rate of some operations and made others possible that were previously impracticable. These operations include removing a diseased cataract from the eye and implanting a new lens (see *Cataract surgery*); transplanting a new cornea to the eye (see *Corneal graft*); replacing a diseased stirrup bone in the middle ear to treat deafness caused by otosclerosis (see *Stapedectomy*); restoring a severed limb by rejoining disconnected blood vessels and nerves; and unblocking and rejoining obstructed fallopian tubes to restore a woman's fertility.

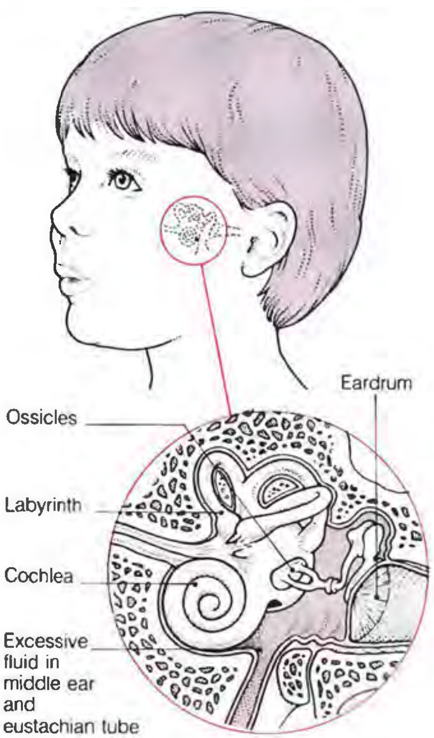
Micturition

A term for passing *urine*.

Midbrain

Also known as the mesencephalon, the midbrain is the topmost part of the *brain stem*, situated above the pons.

Middle ear



See *Ear*.

Middle-ear effusion, persistent

Fluid accumulation in the middle-ear cavity that causes impaired hearing. Persistent middle-ear effusion is most common in children, often accompanied by enlarged *adenoids*; it frequently occurs with viral upper respiratory tract infections, such as colds. Usually both ears are affected.

CAUSES

The mucus-secreting lining of the middle-ear cavity sometimes becomes overactive, producing large amounts of sticky fluid. If there is blockage of the eustachian tube, which links the middle ear to the back of the nose, the fluid cannot drain away. The fluid subsequently accumulates and interferes with the movement of the delicate bones in the middle ear.

Effects of middle-ear effusion

In this condition, sticky fluid in the middle ear prevents free movement of the eardrum and ossicles, causing deafness.

SIGNS

The first, and often the only, sign is some degree of deafness. The child may be unaware of it and, unless his or her unresponsiveness is noticed by parents or teachers, the condition may pass undetected.

DIAGNOSIS

Middle-ear effusion is sometimes first detected through *hearing tests*, which should be carried out routinely on all children. Once any hearing loss is detected or suspected in a child, a physician uses an *otoscope* (viewing instrument) to examine each eardrum for the characteristic changes in appearance and color that occur in middle-ear effusion.

TREATMENT

In mild cases the patient is given nose drops containing *decongestant drugs* to unblock the affected eustachian tube, so that the fluid can drain through it.

When the condition is severe, a *myringotomy* (a surgical opening in the eardrum) may be needed to drain the fluid. Removal of the adenoids may also be required (see *Adenoidectomy*).

Middle-ear infection

See *Otitis media*.

Mid-life crisis

A popular phrase that describes the feelings of distress that affect some people in early middle age (35 to 45 years) after realizing that they are no longer young. The term is used most often to describe men who strive to recapture their sense of lost youth by having extramarital affairs, suddenly changing jobs, or adopting youthful fashions. Sometimes anxiety or depression, brought on by fears of declining powers and death, can lead to psychiatric illness. Counseling and support are usually effective in helping people come to terms with the changes of age.

Midwifery

The profession concerned with the assistance of women in pregnancy and childbirth. A midwife provides care and information throughout pregnancy, supervises labor and delivery, and cares for both mother and baby during the period immediately following childbirth.

Certified midwives (called nurse-midwives) have met the graduate training standards of the American College of Nurse-Midwives and are licensed to practice in most states. Unqualified, or lay, midwifery is illegal in most states. The vast majority of qualified midwives practice in hospitals or birthing centers, usually with physician backup in case of complications and emergencies. Others work in private practice, and some midwives deliver in the woman's home.

Migraine

A severe headache, lasting for two hours to two days, accompanied by disturbances of vision and/or nausea and vomiting. A sufferer may experience only a single attack; more commonly, he or she has recurrent attacks at varying intervals.

CAUSES AND INCIDENCE

Migraine occurs in at least 10 percent of the population and is three times more common in women than in men. It may affect children as young as 3; 60 percent of migraine sufferers have their first attack before the age of 20. It is extremely rare for migraine to appear for the first time after age 50.

There is no single cause of migraine. It tends to run in families, although the exact mechanism of inheritance is not understood. A number of factors, singly or in combination, may bring on an attack in a susceptible person. These factors may be stress-related (such as anxiety, anger, worry, excitement, depression, shock, overexertion, changes of routine, and changes of climate), food-related (particularly chocolate, cheese and other dairy products, red wine, fried food, and citrus fruits), or sensory-related (such as bright light or glare, loud noises, and intense or penetrating smells). Menstruation and the birth-control pill may also trigger migraine.

TYPES

There are two types of migraine: common and classical. In common migraine, the pain of the headache develops slowly, sometimes mounting to a throbbing pain that is made worse by the slightest movement or noise. The pain is often, but not always, on one side of the head only and usually occurs with nausea and sometimes vomiting. Many sufferers, particularly children, recover after they have vomited.

Classical migraine is comparatively rare. The headache is preceded by a slowly expanding area of blindness surrounded by a sparkling edge that increases to involve up to one half of the field of vision of each eye. The blindness clears up after about 20 minutes and is often followed by a severe one-sided headache with nausea, vomiting, and sensitivity to light. Other temporary neurological symptoms, such as weakness in one half of the body, may occur.

DIAGNOSIS

Special tests are rarely necessary. The physician can usually make a diagnosis from the patient's history and a physical examination. However, if there are accompanying persistent symptoms (such as tingling or weakness of a limb) or if the type of

M

headache changes or becomes more severe, a full neurological examination may be carried out to exclude the unlikely possibility of a serious condition, such as a brain tumor.

TREATMENT

If migraine attacks occur less frequently than once a month, treatment of the acute attack is all that is required. If the attacks are more frequent, preventive treatment may be necessary. The simplest form of prevention is to avoid known trigger factors; keeping a careful diary can help the sufferer pinpoint them.

The best treatment for an acute migraine attack is with aspirin or acetaminophen plus an *antiemetic drug* (often provided in suppository form). If this combination is not effective, *ergotamine* may also be prescribed. Certain ergotamine preparations may help prevent an attack if taken in the early phases before the headache begins. Most people find that they recover more quickly if they can then sleep in a darkened room.

If migraine attacks occur more than once a month, prophylactic drugs (for example, *beta-blockers* and *calcium channel blockers*) may be prescribed.

Milia

Tiny, hard, white spots that most commonly occur in clusters on the upper cheeks and around the eyes of young adults. The cause is usually unknown although they may sometimes follow injury or blistering. They are painless and harmless.

Miliaria

Another name for *prickly heat*.

Milk

A *nutrient* fluid produced by the mammary gland of any mammal. Human milk differs considerably from cow's milk in the proportions of its ingredients. It contains about the same amount of fat, but twice as much lactose (sugar) and half as much protein.

Virtually all babies can digest milk, but early in childhood some lose the enzyme that breaks lactose down to simpler sugars (see *Lactase deficiency*). Milk allergy occurs in some infants, caused by a *food allergy* or intolerance to the proteins in cow's milk. (See also *Breast-feeding; Feeding, infant*.)

Milk-alkali syndrome

A rare type of *hypercalcemia* (abnormally high level of calcium in the blood) accompanied by *alkalosis* (reduced acidity of the blood) and *renal failure*. Milk-alkali syndrome is caused by excessive, long-term intake of calcium-containing *antacid drugs* and milk. It is most common in people with the symptoms of a *peptic ulcer* and associated kidney disorders.

The symptoms include weakness, muscle pains, irritability, and apathy. Treatment is to reduce the intake of milk and antacids.

Milk of magnesia

A magnesium preparation used as an *antacid drug* and a *laxative drug*.

Milk teeth

See *Primary teeth*.

Minamata disease

The name given to a severe form of *mercury* poisoning that occurred in the middle 1950s in people who had eaten fish from Minamata Bay, Japan. The fish contained large amounts of mercury as a result of water polluted with industrial mercury waste. By the time the cause of the condition was identified and brought under control, many people had suffered severe nerve damage and some had died.

Mineralization, dental

The deposition of calcium crystals and other mineral salts in developing teeth. (See *Calcification, dental*.)

Mineralocorticoid

The term used to describe a corticosteroid hormone (a hormone produced by the *adrenal gland*) that controls the amount of salts, including potassium and sodium, excreted in the urine. Some corticosteroid hormones (e.g., *aldosterone*) have only a mineralocorticoid action; others (such as *hydrocortisone*) also have a glucocorticoid effect (that is, they help regulate the body's use of carbohydrates).

Mineral oil

A lubricant *laxative drug* obtained from petroleum. Taken orally or given as an enema, mineral oil is used to treat *constipation*. Prolonged use may impair the absorption of vitamins from the intestine into the blood.

Minerals

Defined in *nutrition* as chemical elements that must be present in the diet for the maintenance of health. At least 13 minerals are essential to health. Important among them are potassium, sodium, calcium, magnesium, and phosphorus. Others, such as iron, zinc, and copper, are needed in only tiny amounts (see *Trace elements*). A balanced diet usually contains all the minerals the body requires. (See also chart, next page.)

Mineral supplements

A group of drug preparations containing one or more *minerals*. Mineral supplements, which are available over-the-counter in tablet or liquid form, should be used only when deficiency exists and on the advice of a physician. Most people obtain adequate amounts of minerals from the diet and additional amounts do not have any beneficial effects. Taken in excess, some mineral supplements may have harmful effects.

MEDICAL USES

The most commonly used mineral supplement is iron, which is used to treat iron-deficiency *anemia* and is sometimes needed by a woman who is pregnant or breast-feeding.

Other types of mineral deficiency are rare, with the exception of *magnesium* deficiency, which may occur as a result of alcohol abuse, a kidney disorder, or prolonged treatment with *diuretic drugs*.

Mineral supplements are sometimes needed by people suffering from an intestinal disorder that impairs the absorption of minerals from the diet. (See also individual mineral entries.)

Minilaparotomy

See *Sterilization, female*.

Minimal brain dysfunction

A postulated explanation for a variety of behavioral and other problems occurring in young children for which a physical cause might be expected but for which none is found.

Minimal brain dysfunction may be a cause of attentional difficulties, impulsiveness, *hyperactivity*, and some *learning disabilities*.

Minocycline

A tetracycline *antibiotic drug* used in low doses to treat *acne*. In rare cases, it is used to treat other disorders.

Minoxidil

A *vasodilator drug* used to treat severe *hypertension* (high blood pressure) when other drugs have been ineffective. Prolonged treatment often stimulates hair growth, especially on the face. Minoxidil in lotion form was approved by the FDA in 1988 as a treatment for male pattern *alopecia* (baldness).

MINERALS AND MAIN FOOD SOURCES

Mineral	Sources
Calcium	Milk, cheese, butter and margarine, green vegetables, legumes, nuts, soybean products, hard water
Chromium	Red meat, cheese, butter and margarine, whole-grain cereals and breads, green vegetables
Copper	Red meat, poultry, liver, fish, seafood, whole-grain cereals and breads, green vegetables, legumes, nuts, raisins, mushrooms
Fluorine	Fish, fluoridated water, tea
Iodine	Milk, cheese, butter and margarine, fish, whole-grain cereals and breads, iodized table salt
Iron	Red meat, poultry, liver, eggs, fish, whole-grain cereals and breads
Magnesium	Milk, fish, whole-grain cereals and breads, green vegetables, legumes, nuts, hard water
Phosphorus	Red meat, poultry, liver, milk, cheese, butter and margarine, eggs, fish, whole-grain cereals and breads, green vegetables, root vegetables, legumes, nuts, fruit
Potassium	Whole-grain cereals and breads, green vegetables, legumes, fruit
Selenium	Red meat, liver, milk, fish, seafood, whole-grain cereals and breads
Sodium	Red meat, poultry, liver, milk, cheese, butter and margarine, eggs, fish, whole-grain cereals and breads, green vegetables, root vegetables, legumes, nuts, fruit, table salt, processed foods
Zinc	Red meat, fish, seafood, eggs, milk, whole-grain cereals and breads, legumes

Miosis

Constriction (reduction in size) of the pupil of the eye. Miosis may be caused by certain drugs (such as pilocarpine or opium), by a disease affecting the *autonomic nervous system* (such as *Horner's syndrome*), or simply by bright light. A degree of miosis is normal in older people.

Miscarriage

Loss of the fetus before the 22nd week of pregnancy or before viability (the ability to survive outside the uterus without artificial support). The medical term for miscarriage is spontaneous abortion.

INCIDENCE

The incidence of miscarriage is difficult to determine, since not all women who miscarry seek medical attention or even realize they are miscarrying. It is estimated that from 10 to 30 percent of all pregnancies end in miscarriage, with the majority occurring in the first 10 weeks.

CAUSES

A wide range of problems can cause miscarriage. Many miscarriages occur because of abnormalities of the fetus itself, such as *chromosomal abnormalities* or major developmental defects. Severe maternal illness or exposure to toxins may also cause miscarriage. Less common causes of miscarriage include abnormalities such as inadequate progesterone secretion or an *autoimmune disorder* of the pregnant woman.

After the first three months, miscarriage is less common. Of the 3 to 5 percent of pregnancies that miscarry between 12 and 22 weeks, problems include genetic defects, *cervical incompetence* (inability of the cervix to hold the pregnancy), a defect such as a septate (subdivided) uterus, and large uterine fibroid tumors. Severe maternal infection or illness can also trigger a late miscarriage.

SYMPTOMS AND SIGNS

The symptoms of miscarriage are cramping and/or bleeding. Light bleeding during the early months of pregnancy occurs in up to half of all pregnancies and is often caused by low placental implantation or by *cervical erosion*. Many of these pregnancies continue uneventfully to term.

Heavy bleeding with cramping is generally more serious since it may signal impending miscarriage. Spotting and severe pain can be a symptom of either a threatened miscarriage or *ectopic pregnancy*. A gush of clear or pink fluid caused by rupture of the amniotic sac is an ominous sign.

DIAGNOSIS AND TREATMENT

In early pregnancy a woman in whom bleeding and cramping develop is often prescribed bed rest to minimize bleeding (although bed rest probably does not influence the outcome). Ultrasound scanning may be recommended to determine that the pregnancy is intrauterine (i.e., not ectopic) and that it appears to be progressing normally. A pelvic examination may be performed to find out if the size of the uterus feels appropriate and to see if the cervix is open or closed.

If a miscarriage is incomplete or inevitable and bleeding is heavy, a *D and C* (scraping out of the uterus) may be required. If the miscarriage seems complete (i.e., all fetal and placental material has been passed), no further treatment may be needed. Missed abortion may require *induction of labor*. Often, women are given antibiotics and other drugs to minimize bleeding. Rh-negative women are given Rh_o(D) immune globulin to prevent future Rh complications (see *Rh incompatibility*).

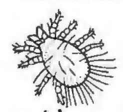
After the first trimester, any cramping or spotting merits immediate medical attention; at this stage a significant number of possible miscarriages are caused by treatable problems, such as an incompetent cervix, rather than by severe fetal defects.

If there is evidence of an incompetent cervix, the cervix may be stitched shut. Prolonged bed rest may be recommended and uterine relaxants may be administered to women with uterine or cervical abnormalities.

A woman who miscarries three or more times consecutively is called an habitual aborter. Habitual abortion may be caused by genetic or hormonal

M

TYPES OF MISCARRIAGE



Threatened abortion	The fetus remains alive and has not been expelled from the uterus, despite bleeding from the woman's vagina.
Inevitable abortion	The fetus has died and is being expelled from the uterus. An inevitable abortion may be complete (when all the uterine contents are expelled) or incomplete (when the fetus and/or placenta are not completely expelled).
Missed abortion	The fetus has died but is retained with the placenta in the uterus.

abnormalities, chronic infection, autoimmune disease, or uterine abnormalities. Evaluation includes genetic studies for hormonal and infectious problems as well as *hysterosalpingography* (X-ray imaging of the uterus and fallopian tubes).

OUTLOOK

The majority of women who miscarry can eventually carry a pregnancy to term. Current diagnostic and treatment measures have made the outlook better than ever before. (See also *Abortion; Abortion, elective.*)

Mites and disease

Mites are small, eight-legged animals, less than one twentieth of an inch (1.2 mm) long, similar to tiny spiders. Many have piercing and blood-sucking mouthparts and may parasitize animals and humans.

Mites can cause problems in a variety of ways. One species, the *scabies* mite, lives solely in human skin, where its burrowing activities cause an intense itch. Another, the house-dust mite, is common in bedding; inhaling dust containing dead mite parts can cause *asthma*.

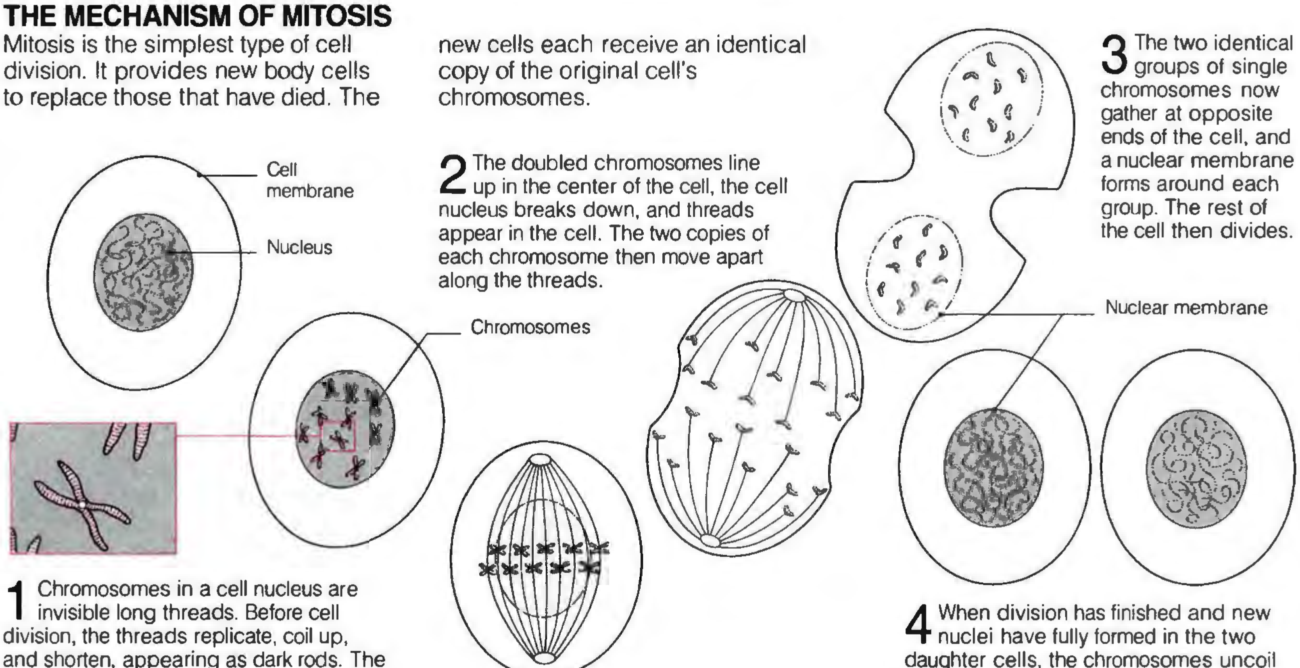
Other types of mites inhabit grassy areas or affect crops. Chiggers (harvest mites) can be picked up when walking through thick grass. Their bites can produce an itchy rash (see *Chigger bites*). Mites in grain or fruit may cause various types of skin irritation, commonly known as grocers' itch or bakers' itch.

In some parts of the world, certain mites transmit disease, particularly scrub *typhus* and rickettsialpox. Both these diseases are caused by *rickettsiae* (organisms intermediate between bacteria and viruses), which normally infect rodents, but which can be transmitted to humans by mites.

The use of insect repellents (such as dimethyl phthalate) is advisable when walking through mite-infested areas.

Mitosis

The way in which most cells divide, so that the *chromosomes* (inherited genetic material) within the nucleus of the original cell are exactly duplicated into two daughter cells.



Each person begins as a single cell (a fertilized egg) and, following successive mitotic divisions of this cell, is born as a multicellular being with trillions of cells, most of which contain exactly the same chromosomal material. Mitotic divisions occur in the body thousands of times every second as dead cells are replaced by new ones formed by the division and multiplication of other cells.

Mitosis can be observed in a cell culture under a microscope. The sequence of events as the original cell divides to form two daughter cells is shown below.

A minority of cells (in the ovaries and testes) undergoes a fundamentally different type of division that results in the daughter cells receiving only half of the original cell's chromosomal material. This process, called *meiosis*, occurs in the formation of egg and sperm cells.

THE MECHANISM OF MITOSIS

Mitosis is the simplest type of cell division. It provides new body cells to replace those that have died. The new cells each receive an identical copy of the original cell's chromosomes.

1 Chromosomes in a cell nucleus are invisible long threads. Before cell division, the threads replicate, coil up, and shorten, appearing as dark rods. The two copies of each chromosome are joined, so they appear X-shaped.

2 The doubled chromosomes line up in the center of the cell, the cell nucleus breaks down, and threads appear in the cell. The two copies of each chromosome then move apart along the threads.

3 The two identical groups of single chromosomes now gather at opposite ends of the cell, and a nuclear membrane forms around each group. The rest of the cell then divides.

4 When division has finished and new nuclei have fully formed in the two daughter cells, the chromosomes uncoil to resume their invisible, threadlike form. Mitosis is now complete.

Mitral insufficiency

Failure of the mitral valve of the heart to close properly, which allows blood to leak back into the left atrium (upper chamber) when pumped out of the left ventricle (lower chamber). Also known as mitral incompetence or mitral regurgitation, the disorder may occur in conjunction with *mitral stenosis* (narrowing of the valve).

In mitral insufficiency, the left side of the heart must work harder to clear the regurgitated blood. Eventually left-sided (and later, right-sided) *heart failure* may develop; generally, however, this is not a life-threatening condition. A buildup of blood from the left side of the heart can result in pulmonary *edema*.

CAUSES AND INCIDENCE

The most common cause (though much less common than it once was) is damage to the valve as a result of *rheumatic fever*. Other causes include *mitral valve prolapse* (floppy valve syndrome), damage following a *myocardial infarction* (heart attack), and stretching of the valve due to enlargement of the ventricle in left-sided heart failure. Rarely, the disorder may be present from birth or occurs as part of *Marfan's syndrome*.

SYMPTOMS AND SIGNS

The characteristic symptoms are increasing shortness of breath and fatigue, sometimes accompanied by *palpitations*. Later, as right-sided heart failure develops, the ankles swell.

An occasional complication is *endocarditis* (infection of the valve). Another risk is that a thrombus (blood clot) may form in the left atrium and travel to the brain, resulting in a *stroke*.

DIAGNOSIS

The physician makes a diagnosis from the patient's history, from a characteristic heart *murmur* heard through a stethoscope, and from the results of chest *X rays*, *ECG*, *echocardiography*, and cardiac *catheterization*.

TREATMENT AND OUTLOOK

If shortness of breath is troublesome, a *diuretic drug* may be prescribed to reduce fluid in the lungs and other tissues. *Digitalis drugs* may be given to increase the force of the heart's contraction and control rhythm disturbances. *Anticoagulant drugs* may be given to prevent the formation of blood clots. Before undergoing dental or other surgery, a person with mitral valve disease should take *antibiotic drugs* to prevent a blood infection that could cause endocarditis.

Heart valve surgery is considered only if severe heart failure develops or if drug treatment fails to prevent the patient's symptoms from becoming severe and disabling.

The outlook for mitral insufficiency is good whether treated by drugs or by valve surgery. Breathlessness and fatigue cannot be relieved by treatment once there has been permanent heart damage.

Mitral stenosis

Narrowing of the orifice of the mitral valve in the heart. This causes the atrial portion of the left side of the heart to work harder to force blood through the narrowed valve. The consequences are similar to those of *mitral insufficiency* (failure of the valve to close properly), which may accompany stenosis.

CAUSES AND INCIDENCE

Mitral stenosis is almost always due to scarring of the valve from an earlier attack of *rheumatic fever*, although in about half the cases there is no medical record of the illness. Mitral stenosis is four times more common in women than in men.

SYMPTOMS AND SIGNS

Symptoms do not usually develop until adulthood, many years after rheumatic fever. The primary symptom is shortness of breath, which at first occurs only on exertion; as the stenosis worsens, breathing difficulty is felt with less exertion and is eventually present when the person is at rest. Other symptoms and signs include *palpitations*, *atrial fibrillation* (rapid, uncoordinated, irregular heart beat), and deeply flushed cheeks. Congestion of the lungs can lead to recurrent chest infections, coughing up of blood, and fatigue.

Possible complications are as for mitral insufficiency.

DIAGNOSIS

Mitral stenosis is diagnosed from the patient's history, by a physician listening to heart sounds through a stethoscope, and by investigations that may include an *ECG*, chest *X rays*, *echocardiography*, and cardiac *catheterization*.

TREATMENT AND OUTLOOK

Drug treatment (with *diuretic drugs* and *digitalis drugs*) is broadly the same as for mitral insufficiency, as are the precautions to help prevent *endocarditis* (infection of the valve).

If symptoms persist despite drug treatment, *heart valve surgery* may be considered to repair or replace the defective valve. The outlook following surgery is good, although the operation may need to be repeated several years later.

Mitral valve prolapse

A common, slight deformity of the mitral valve, situated in the left side of the heart, that can produce a degree of *mitral insufficiency* (leakage of the valve). Also known as "floppy valve syndrome," the condition affects up to 5 percent of the population and is most common in young to middle-aged women. Mitral valve prolapse causes a characteristic heart *murmur* that may be heard by the physician through a stethoscope during a routine examination.

The cause is not known in most cases, although there is some evidence that the condition is inherited. Occasionally the prolapse results from *rheumatic fever*, *coronary heart disease*, or *cardiomyopathy*.

Usually, there are no symptoms and the condition is of no consequence; treatment is not required. Occasionally, however, it may produce chest pain, *arrhythmia* (disturbance of heart rhythm), or leakage of the valve sufficient to cause *heart failure*. These conditions may require treatment with heart drugs (such as *beta-blockers*, *diuretics*, or *digitalis drugs*) or, rarely, *heart valve surgery*.

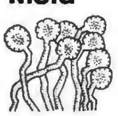
Mittelschmerz

Pain in the lower abdomen that occurs in some women at the time of *ovulation* midway through each menstrual cycle. The pain is usually one-sided and lasts only a few hours; slight spotting (vaginal blood loss) may accompany the pain. Mittelschmerz is usually not severe. However, if it is, *oral contraceptives* may be prescribed to suppress ovulation.

Mobilization

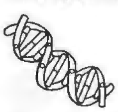
The process of making a part of the body capable of movement. Mobilization refers to treatment aimed at increasing mobility in a part of the body recovering from injury or affected by disease. Examples include exercises to treat *frozen shoulder* or joint stiffness caused by *arthritis*, and retraining in walking following a *stroke* or lower limb *fracture*.

Surgeons use the term mobilization to refer to the freeing, during an operation, of an organ or structure from surrounding connective tissue and fibrous adhesions. For example, in a *cholecystectomy*, the gallbladder has to be mobilized from the liver before it can be removed.



Molar

See *Teeth*.



M

Molar pregnancy
A pregnancy in which a tumor develops from placental tissue and the embryo fails to develop normally. A molar pregnancy may be benign (*hydatidiform mole*) or malignant, when it is called an invasive mole. *Choriocarcinoma* is an invasive mole that has spread outside the uterus.

A different type of molar pregnancy occurs after a missed abortion (a type of *miscarriage* in which the dead embryo and placenta are not expelled from the uterus). The dead tissue is called a carneous mole.

Mold

Any of a large group of *fungi* that exist as many-celled, filamentous colonies. Some molds are the source of antibiotics, such as penicillin. Some can cause disease, such as *aspergillosis*.

Mole
A type of pigmented *nevus*.

Molecule

The smallest complete unit of a substance that can exist independently and still retain the characteristic properties of that substance. Almost all molecules consist of two or more atoms that are linked. A molecule of carbon dioxide comprises one carbon atom linked to two oxygen atoms. Certain unusual molecules, called monatomic molecules, consist of only one atom (e.g., molecules of inert gases such as argon and neon).

Molecules vary enormously in size and complexity. At one extreme are the small, simple ones, such as oxygen, consisting of two linked oxygen atoms. At the other extreme are huge, complicated molecules, such as *DNA* (deoxyribonucleic acid), containing thousands of atoms of carbon, hydrogen, oxygen, nitrogen, and phosphorus that are linked to form a double-helix structure shaped like a spiral staircase.

Molluscum contagiosum
A harmless viral infection characterized by shiny, pearly white papules (tiny lumps) on the skin surface. Each papule is circular, has a tiny central depression, and produces a cheesy fluid if squeezed. A crust forms before healing occurs.

The papules appear in groups, or sometimes alone, on the genitals, the inside of the thighs, the face, or elsewhere. Children or, less commonly, adults may be affected. The infection is easily transmitted by direct skin contact or during intercourse.

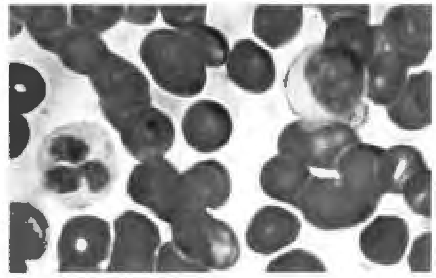
Molluscum contagiosum usually clears up in a few months, but may require treatment by a physician.

Mongolian spot
A blue-black pigmented spot found singly or in groups on the lower back and buttocks at birth. The spot may be mistaken for a bruise, although it is a type of *nevus*. Mongolian spots are common in black or Asian children and are caused by a concentration of melanocytes (pigment-producing cells) deep within the skin. They usually disappear by the age of 3 or 4.

Mongolism
The outdated name for the disorder now called *Down's syndrome*.

Moniliasis
See *Candidiasis*.

Monitor
To maintain a constant watch on a patient's condition so that any change can be detected early and appropriate treatment given. The term also refers to any device used to carry out monitoring, such as the cardiac monitor used in intensive-care units. A cardiac monitor displays the patient's *ECG* (a record of the electrical impulses generated by the heart) on a screen and signals the heart rate both visually and audibly.



Monoarthritis
Inflammation of a single joint, causing pain and stiffness. Common causes are *osteoarthritis*, *gout*, and infection.

Monoclonal antibody
See *Antibody, monoclonal*.

Mononucleosis, infectious
An acute viral infection characterized by a high temperature, sore throat, and swollen lymph glands, particularly in the neck (hence its common name, glandular fever).

CAUSES AND INCIDENCE
Infectious mononucleosis is caused either by the Epstein-Barr virus or cytomegalovirus, both members of the herpesvirus family. The disease develops only if the virus is encountered for the first time at an age when the response of the body's *immune system* is most vigorous (that is, during adolescence and early adult life). The peak incidence of the illness occurs around ages 15 to 17. Kissing is thought to be a common method of transmitting the virus.

Once in the body, the virus multiplies in the *lymphocytes* (white blood cells that form part of the immune system). Lymphocytes are also called mononuclear cells. When infected with the virus, the lymphocytes change their appearance and are referred to as "atypical."

Blood smear in mononucleosis
The large cell with one nucleus, surrounded by many red blood cells, is an atypical lymphocyte (it is bigger than normal).

SYMPTOMS AND SIGNS
The illness usually starts with a fever and headache, followed by swelling of the lymph glands in the neck, armpits, and groin and a severe sore throat due to tonsillitis. The enlarged, inflamed tonsils make swallowing difficult and, in rare cases, may obstruct breathing. Occasionally, mild liver damage may occur, leading to jaundice for a few days. A physician may feel an enlarged spleen in the upper left part of the abdomen.

DIAGNOSIS
The diagnosis is often obvious from the symptoms and from examination of a blood smear, which shows many atypical lymphocytes in the blood. A test for the infection—the heterophil antibodies test—may also be carried out. This test looks for antibodies (proteins produced by the immune system to counter the virus) that possess the unique ability to cause clumping of red cells taken from sheep's blood. More specific tests are also available when the diagnosis is in doubt.

TREATMENT AND OUTLOOK
Almost all patients recover after four to six weeks without drugs. If the antibiotic ampicillin is mistakenly given, it may produce a rash and worsening of symptoms. Rest is needed for a month or so to allow the body's immune system to destroy the virus. In rare cases, *corticosteroid drugs* are required to reduce severe inflammation, particularly if breathing is obstructed by swollen tonsils. For two to three

months after recovery, patients often feel depressed, lack energy, and feel sleepy during the day. However, the majority of people who have chronic fatigue that they attribute to chronic Epstein-Barr virus disease produce no laboratory results to substantiate this diagnosis.

Monorchism
The presence of only one testis in a male. Unless a testis has been removed surgically (see *Orchiectomy*), the most likely cause of monorchism is *congenital* absence. The term monorchism should not be used to describe an undescended testis (see *Testis, undescended*).

Monosodium glutamate
A *food additive* frequently used as a flavor enhancer and seasoning. Until recently, monosodium glutamate (MSG) was suspected to be the cause of *Chinese restaurant syndrome*, in which a sense of pressure in the face, pain in the chest, and a feeling of burning in the head and upper trunk comes on 20 minutes after a meal and lasts for about 45 minutes. Clinical trials have shown that MSG does not produce exactly this symptom pattern, although it may occasionally cause some of these symptoms in sensitive people.

Monteggia's fracture
Fracture of the ulna (the bone on the inner side of the forearm) just below the elbow, with dislocation of the radius (the bone on the outer side of the forearm) from the elbow joint. Monteggia's fracture can be caused by a fall onto the arm or by a blow to the back of the upper arm.

Treatment usually requires an operation through two incisions on either side of the forearm. First, the radius is replaced in the joint. The fractured bone ends of the ulna are then realigned and fixed with a plate and screws or a long nail. The incisions are sewn up and the limb is immobilized in a plaster cast until healing occurs, which usually takes about 12 weeks.

Montezuma's revenge
A name given to a type of *gastroenteritis* (especially the resulting diarrhea) that is often contracted by tourists visiting Mexico.

Moon face
The rounded facial appearance that is a feature of *Cushing's syndrome*.

MORA
The abbreviation for *mandibular orthopedic repositioning appliance*.

Morbid anatomy
Also known as pathological anatomy, the study of the structural changes that occur in body tissues as a consequence of disease.

The term morbid anatomy refers especially to those changes that are visible to the naked eye during a postmortem examination (in contrast to changes visible only through a microscope).

Morbidity
The state or condition of being diseased. The morbidity ratio is the proportion of diseased to healthy people in a community.

In the US, detailed statistics on morbidity are recorded at the *Centers for Disease Control* in Atlanta, Georgia.

Morbilli
Another name for *measles*.

Morning-after pill
See *Contraception, postcoital*.

Morning sickness
See *Vomiting in pregnancy*.

Moron
An outdated term, derived from the Greek word for dull, for a person with mild *mental retardation* (IQ 50 to 70).

Morphea
A condition in which one or more well-defined, hard, flat, round or oval patches develop on the skin. Morphea is a nonspreading type of *scleroderma* (a disease in which there is progressive hardening of tissues).

The skin patches of morphea are white or reddish, measuring up to several inches in diameter. They usually occur on the trunk, neck, hands, or feet. Loss of hair or ulceration at the affected site may also occur. The condition most often affects middle-aged women. Although harmless, morphea can be disfiguring. There is no treatment.

Morphine
The best known narcotic *analgesic* (painkiller), derived from the unripe seed pods of the opium poppy.

MAJOR CAUSES OF DEATH IN THE US IN A REPRESENTATIVE YEAR

Cause	Total deaths (per 100,000 population)	Male deaths (per 100,000 men)	Female deaths (per 100,000 women)
Circulatory system diseases	421.5	435.3	408.4
Acute myocardial infarction	122.4	145.7	100.3
Other ischemic heart disease	113.8	116.0	111.7
Hypertension	13.6	12.1	15.0
Other forms of heart disease	79.9	81.5	78.4
Stroke	66.5	55.3	77.1
Atherosclerosis	11.3	8.8	13.6
Cancer (all forms)	189.9	209.7	170.1
Colon	19.7	19.7	19.8
Lung, bronchus, trachea	49.2	70.7	28.8
Breast	—	—	31.6
Prostate	—	22.0	—
Accidents	39.5	56.2	23.8
Traffic accidents	18.6	27.1	10.2
Suicide	12.1	19.2	5.4
Homicide	8.5	13.4	3.9
Pneumonia	23.3	24.2	22.4
Bronchitis, emphysema, asthma	8.7	11.3	6.3
Other respiratory diseases	28.1	36.7	19.9
Diabetes mellitus	15.5	12.9	17.9
Other endocrine and metabolic diseases	4.3	4.1	4.4
Chronic liver disease and cirrhosis	11.7	15.4	8.1
Other digestive system disorders	14.3	13.8	14.7
Infections and parasitic diseases	9.3	9.9	8.8
Septicemia	5.7	5.6	5.8

M

WHY IT IS USED
Morphine is given to relieve severe pain caused by *myocardial infarction* (heart attack), major surgery, serious injury, and cancer. It is occasionally used as a *premedication* (a drug used to prepare a person for surgery).

HOW IT WORKS
Morphine blocks the transmission of pain signals at specific sites (called opiate receptors) in the brain and spinal cord, thereby preventing the perception of pain.

POSSIBLE ADVERSE EFFECTS
Morphine causes drowsiness, dizziness, constipation, nausea, vomiting, and confusion. Short-term use is unlikely to cause *drug dependence.*

ABUSE
The euphoric effects of morphine have led to its abuse. Long-term abuse leads to a craving for the drug and *tolerance* (the need for greater amounts to have the same effect). It also causes physical dependence, with flulike symptoms (such as sweating, shaking, and cramping) when the drug is suddenly withdrawn.

Mortality

The death rate, that is, the number of deaths per 100,000 (or, occasionally, per 1,000 or per 10,000) of the population per year. The total mortality is made up of the individual mortality from different causes (such as accidents, coronary heart disease, and cancer). The study of differences in these proportions between one country and another, or between different periods in the same country, can offer valuable information about the comparative state of health of a population or about disease trends.

Mortality is often calculated for specific groups of the population. For example, *infant mortality* quantifies deaths of live-born infants during the first year of life; perinatal mortality quantifies deaths (including all stillbirths) during the first week (or sometimes month) of life.

Standardized mortality compares the death rate in an occupational or socioeconomic group with the average for the entire population. It is a useful indicator of the relative safety of an occupation, or of whether a specific socioeconomic group is at particular risk. (See also table, left; *Life expectancy; Maternal mortality.*)

Mosaicism

The presence of two (or more) groups of cells containing different chromosomal material within one person.

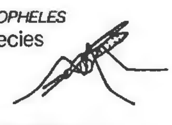
Usually, each of a person's body cells contains 46 chromosomes. They include the two sex chromosomes, termed XX in females and XY in males (see *Chromosomes*). In a mosaic person, some cells may contain 46 and others 45, 47, or other numbers of chromosomes. The probable cause in most cases is a fault in the process of cell division early in embryonic life. The diagnosis is made by *chromosome analysis* of skin or white blood cells.

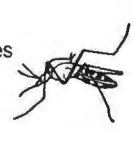
Mosaicism can give rise to syndromes associated with *chromosomal abnormalities* (such as *Down's syndrome* and *Turner's syndrome*). A girl with Turner's syndrome mosaicism has some cells with a normal chromosome complement and others missing an X sex chromosome. About 3 percent of children with Down's syndrome have mosaicism. These children carry a mixture of normal cells and others containing an extra number 21 chromosome.

Depending on the proportion of abnormal cells and type of abnormality, people with mosaicism range from looking physically normal to having features typical of a chromosomal abnormality syndrome. People with mosaicism are often less severely affected than those with the abnormality in all their cells.

Mosquito bites

Mosquitoes are flying insects found throughout the world. The females require blood from humans or animals to produce eggs; they obtain this blood through their bites. The mosquito eggs are laid and hatched in stagnating water, so mosquitoes are most prevalent close to marshes, ponds, reservoirs, and water tanks, especially after a rainy period. Male mosquitoes do not bite.





Mosquitoes are a nuisance simply because of their bites. However, the main problem with mosquitoes is disease transmission—particularly in the tropics. During a bite, a mosquito may acquire infectious organisms from the blood of an infected person; the organisms multiply within the insect and are transferred to another person during a subsequent bite.

The main disease-transmitting mosquitoes belong to three groups: ANOPHELES, AEDES, and CULEX. They have varying appearances and habits and transmit different diseases (see chart). The only illnesses acquired from mosquito bites in the US are certain types of viral *encephalitis* (inflammation of the brain), such as St. Louis encephalitis, eastern and western equine encephalitis, and California encephalitis. Several thousand cases of these infections occur in the US each year, with features similar to other types of encephalitis. A hundred years ago, malaria was commonly transmitted in parts of the South and middle West.

TREATMENT
Mosquito bites should be washed with soap and water, and a soothing cream applied. A physician should be consulted if mosquito bites cause a severe skin reaction.

PREVENTION
Protective measures against mosquitoes (to limit the chances of infection) should be taken in the tropics and subtropics and in any area where the insects are rampant. The most effective measures are the wearing of long sleeves and socks at dusk to reduce the amount of exposed skin,

DANGEROUS MOSQUITOES

Mosquito	Appearance	Habits	Diseases transmitted
ANOPHELES species 	Head and body in straight line and at an angle to surface	Mainly rural; bite at night	Malaria; filariasis
CULEX species 	Body parallel to surface; head bent down; whining flight; brown color	Urban or rural; bite in evening or at night	Viral encephalitis; filariasis
AEDES species 	Body shape as for CULEX, but tropical species are black and white	Urban or rural; bite during day	Dengue; yellow fever; viral encephalitis

placing mosquito screens over windows, and the use of insect-repellent sprays or slow-burning coils that release a smoke containing insecticide. A mosquito net that surrounds the bed is of value in preventing mosquitoes from biting during sleep.

Attempts to control mosquitoes in the tropics have included direct attack with insecticides, efforts to limit breeding areas, and even the release of vast numbers of sterilized male mosquitoes. However, these efforts have achieved only limited success. (See also *Insect bites; Insects and disease.*)

Motion sickness

A condition produced in some people by road, sea, or air travel. In its mildest form, motion sickness may be only a feeling of uneasiness and a headache; in severe cases, there may be distress, excessive sweating and salivation, pallor, nausea, and vomiting.

Motion sickness is caused by the effect of any constant pronounced movement on the organ of balance in the inner ear. Other factors also play a part, however. Anxiety based on previous attacks, a stuffy or fume-laden atmosphere, a full stomach, or the sight of food can make the condition worse. So, too, can focusing on nearby objects; sufferers should look at a point on the horizon.

PREVENTION

Various *antiemetic drugs* are available to prevent or help control motion sickness. Scopolamine or cyclizine (an *antihistamine drug*) should be taken about an hour before the start of a journey. The longer-acting antihistamines (promethazine or meclizine) need to be taken about a day before the journey.

Motor

A term used to describe anything that brings about movement, such as a muscle or nerve. The word is usually applied to nerves (including those in the part of the brain called the cerebral cortex) that stimulate muscles to contract and thereby produce movement.

Motor neuron disease

A group of rare disorders in which the nerves that control muscular activity degenerate within the brain and spinal cord. The result is weakness and *atrophy* (wasting) of the muscles. The cause is unknown.

INCIDENCE AND TYPES

The most common motor neuron disease is amyotrophic lateral sclerosis (ALS), often referred to as Lou Gehrig's disease. About one or two cases of ALS are diagnosed annually per 100,000 people in the US. ALS usually affects people over 50 and is more common in men than women. About 10 percent of ALS cases are familial (run in the family).

Other motor neuron diseases include progressive muscular atrophy and progressive bulbar palsy. While these diseases start with patterns of muscle weakness different from typical ALS, they usually develop into that disease.

Two motor neuron diseases, usually inherited, affect much younger people. In infantile progressive spinal muscular atrophy (Werdnig-Hoffmann paralysis), children are affected at birth or shortly thereafter. The weakness progresses to death in several months to several years with rare exceptions. A more benign form (chronic spinal muscular dystrophy) begins any time from childhood through adolescence; it causes a progressive weakness that may never result in serious disability.

SYMPTOMS

In ALS, sufferers first note weakness in the hands and arms accompanied by wasting of the muscles. Fasciculations, an involuntary quivering of small areas of the muscle, may also occur. Many sufferers also report cramping or stiffness. Sometimes the weakness starts in the legs but, in every case, all four extremities are soon involved. There is no loss of sensation; bladder function is normal.

The diagnosis is confirmed by *EMG* (measurement of muscle electrical activity) and other tests, such as muscle *biopsy*, blood studies, *myelography*, *CT scanning*, or *MRI*, to rule out other disease.

TREATMENT AND OUTLOOK

The weakness usually progresses to involve the muscles of respiration and swallowing, leading to death in two to four years. Exceptions do occur, however, and some people have lived more than 20 years after diagnosis.

There is no means of slowing the nerve degeneration, although physical therapy can sometimes lessen disability. Wheelchairs, walkers, and other aids are available to help patients maintain independence as long as possible.

The final stages may be especially distressing for the patient and family because, although the victim is unable to speak, swallow, or move, awareness and intellect are maintained. Occasionally, life may be prolonged through the use of feeding tubes and *ventilators*. Care is generally aimed at easing discomfort.

Motor system disease

See *Motor neuron disease*.

Mountain sickness

An illness that can affect mountain climbers, hikers, or skiers who have ascended too rapidly to heights above 8,000 feet (2,400 m) or, more commonly, to above 10,000 feet (3,000 m).

CAUSES

Mountain sickness is caused by the reduced atmospheric pressure—and thus reduced oxygen—at high altitude, but the exact mechanism by which reduced pressure leads to illness is not fully understood. Broadly, reduced oxygen in the blood, along with other changes in blood chemistry, affects the nervous system, muscles, heart, and lungs.

At altitude there is a higher-than-normal blood flow through the lungs and to the brain; this, combined with an apparent increase in the permeability (leakiness) of blood vessels, can lead to *edema* (waterlogging) of these organs.

Mountain sickness is more likely the younger the person, the faster the ascent, and the higher the altitude.

PREVENTION

A person ascending to an altitude above 8,000 feet should do so gradually, stopping for a day or two's rest after each further ascent of 2,000 to 3,000 feet. Ascending higher during the rest day is permissible, provided a return to the lower level is made before night.

SYMPTOMS AND SIGNS

In most cases, mountain sickness is mild and short-lived, with symptoms such as headache, nausea, dizziness, and impaired mental processes. No further ascent should be made until the symptoms disappear. Some cases are more severe. Fluid builds up in the lungs, leading to severe breathlessness, cough, and the production of frothy sputum (phlegm). This is called high-altitude pulmonary edema. If fluid builds up around the brain (cerebral edema) the symptoms may include severe headache, seizures, vomiting, unsteadiness, hallucinations, and sometimes coma.

FIRST AID AND TREATMENT

In serious cases, the victim must be brought down from the mountain and taken to a hospital as quickly as possible. Any delay can result in brain damage and death. Administering

M

pure oxygen, if available, can help. In the hospital, *diuretic drugs* are often given to help reduce edema.

The conditions of patients with high-altitude pulmonary edema often improve rapidly after descending a few thousand feet. Patients with the cerebral form may take days or weeks in the hospital to recover.

Mouth

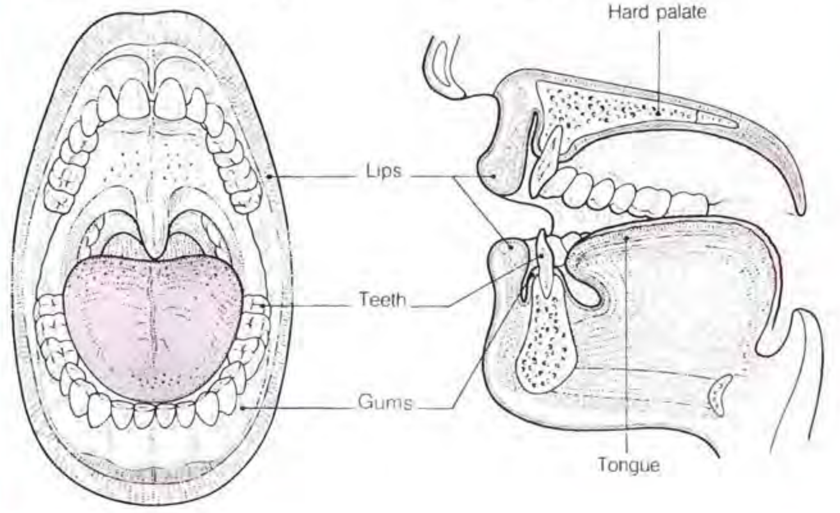
The mouth, where food is broken down for swallowing, forms the first part of the digestive tract (see *Mastication*); it converts vibrations produced by the larynx (voice box) into *speech*; and it is used in breathing.

STRUCTURE

The roof of the mouth consists of a hard bony *palate* at the front and a soft fleshy palate behind. Most of the floor of the mouth is formed by the *tongue*, which contains specialized cells, sensitive to taste, known as taste buds. Surrounding the palate and tongue are the *teeth*, which are set in the shock-absorbent tissue of the *gums*. Enclosing them all are the cheeks and *lips*, which contain a ring of muscle that helps keep food in the mouth. The inside of the mouth is lined with mucous membrane, which is lubricated with saliva produced by three pairs of *salivary glands*.

DISORDERS

The most common deformities of the mouth, other than alignment of the teeth (see *Malocclusion*), are *cleft lip and palate* (a split in the upper lip and a gap in the roof of the mouth). They may occur alone or together.



Infections of the mouth are common. They include an abscess around the root of a tooth (see *Abscess, dental*) and oral *candidiasis* (thrush), a fungal infection that produces sore, cream-colored patches on the lining of the mouth. Noninfective conditions that also cause discoloration include *leukoplakia* (marked by thickened white or gray patches) and the more rare *lichen planus* (in which a white network of raised tissue develops).

Extremely common are *mouth ulcers*, painful white or yellow open sores that may develop anywhere on the mucous membrane. *Cysts*, fluid- or semisolid-filled swellings, may also occur on the lining of the cheek or the floor of the mouth.

Any lump, sore, or ulcer in the mouth that persists for more than three or four weeks should be seen by a physician. In rare cases, the abnormality is an early sign of a malignant growth (see *Mouth cancer*).

ANATOMY OF THE MOUTH

The mouth has a complicated structure, reflecting its various functions. For example, the tongue, lips, teeth, and palate play an essential role in speech production. Together with the salivary glands, the same mouth parts play a role in eating and drinking.

Mouth cancer

Malignant tumors affecting the oral cavity; most common are *lip cancer* and *tongue cancer*. The floor of the mouth, the salivary glands, the inside of the cheeks, the gums, and the palate are less commonly affected. Most are squamous carcinomas.

CAUSES AND INCIDENCE

The main cause of oral cancer is smoking. Tobacco smoke and heat irritate the mucous membrane lining the mouth. The risk to pipe and cigar smokers is as great, or greater, than to cigarette smokers. The other chief causes are chewing tobacco, inhaling snuff, and heavy alcohol consumption. Poor oral hygiene and irritation from ill-fitting dentures or jagged teeth are predisposing factors.

Oral cancers represent about 8 percent of all malignancies. Men are twice as commonly affected as women, and most cases occur in men older than 40.

SYMPTOMS AND SIGNS

Cancer of the lip usually starts with a whitish patch on the lower lip called *leukoplakia*. The lesion is a small ulcer, or a deep, hard-edged fissure, and may be the first sign of a malignant tumor in the mouth. These initial tissue changes may be accompanied by a burning sensation, but are usually painless.

As the tumor grows, it develops into an ulcer that may bleed and that erodes surrounding tissue. If the tongue is affected, it becomes stiff, making chewing, swallowing, and speaking difficult. In its advanced stages, the tumor is usually painful.

DIAGNOSIS

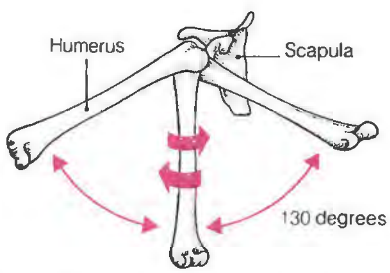
Any lump, discolored patch, or other tissue change on the lip or in the mouth that does not clear up within a month should be reported to a physician. In some cases, a dentist is the first person to detect such a change. The diagnosis is based on a *biopsy* (removal of a small sample of tissue).

TREATMENT AND OUTLOOK

Treatment consists of surgical removal of all cancerous tissue, *radiation therapy*, or a combination of both. Extensive surgery may result in facial disfigurement and problems with eating and speaking, which may require reconstructive surgery. Radiation therapy sometimes damages the salivary glands (see *Mouth, dry*).

The rate of spread of oral cancer varies according to the site. Tongue cancer is the most dangerous, spreading rapidly to nearby lymph nodes. When oral cancer in any form is detected and treated early, the outlook is good, resulting in a cure in three quarters of cases. More than half the people with oral cancer survive for more than five years after treatment.

Mouth, dry

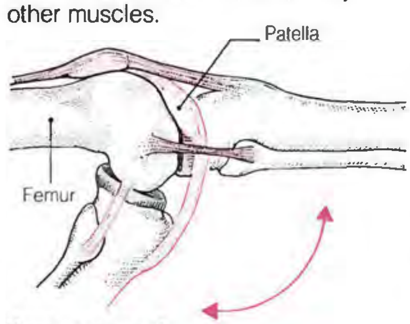


The result of inadequate production of saliva. Dry mouth is usually a temporary condition caused by fear, a salivary gland infection (see *Parotid*

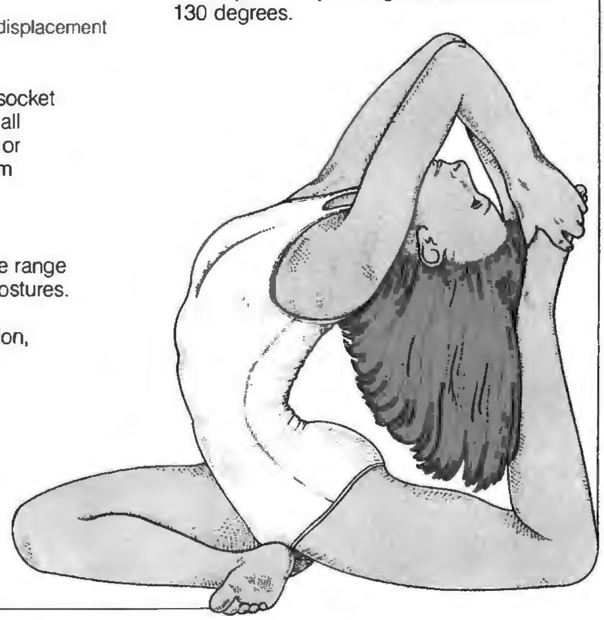
MOVEMENT

During life, movement occurs constantly throughout the body. All visible movements are caused by the shortening of muscles, usually for only brief periods at a time. This causes movement of many kinds—of bones, of blood in the vessels, of food in the intestines, of urine from the bladder, of the eye, of facial expression, and of the body as a whole. All movement is either voluntary (willed) or involuntary (automatic).

SKELETAL MOVEMENT



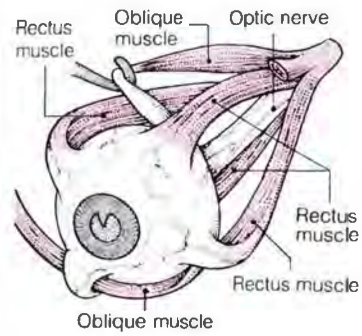
This always involves moving bones relative to one another. Many muscles are involved. Some act to brace certain bones so that different bones can be moved by other muscles.



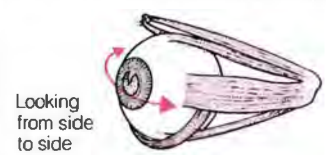
Combined rotation and displacement

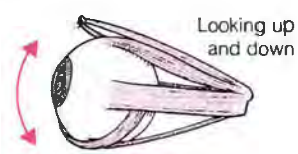
Arm movements
The shoulder—a ball-and-socket joint—allows movement in all directions. Sometimes two or more movements of the arm may be combined.

Yoga and movement
Yoga (right) teaches a wide range of body movements and postures. It helps to increase joint flexibility, to eliminate tension, and to promote relaxation.



Knee movement
A hinge joint, the knee allows movement in one plane only through an arc of about 130 degrees.

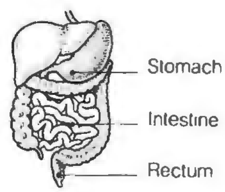


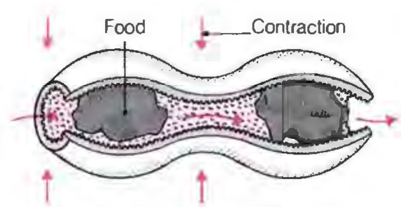


EYE MOVEMENT

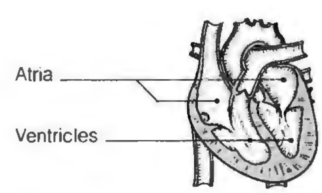
Six muscles work together on the eyeball to give a range of smooth, precise movements.

Eye muscles
The four rectus eye muscles run directly back from the eyeball; the oblique muscles are attached to and pull on the eyeball at an angle.





Actions of eye muscles
Two rectus muscles control side-to-side eye movements. The other muscles control up-and-down and rotational movements.



INVOLUNTARY MOVEMENT

Movement of internal organs is not under voluntary control but is regulated by the autonomic nervous system.

Peristalsis
This is an example of movement caused by involuntary muscle action. Waves of contraction pass along muscles in the intestinal wall, forcing the contents forward and preventing obstruction.

Heart beat
The heart differs from other muscles in that it has an impulse-conducting system that ensures contraction in sequence—the atria (upper chambers) first, then the ventricles (lower chambers).

gland), or the action of *anticholinergic drugs*. Permanent dry mouth is rare. It can occur, for unknown reasons, as part of *Sjögren's syndrome* or may result from *radiation therapy* given to treat a tumor of the mouth. In these cases, dry mouth is usually accompanied by difficulty swallowing and speaking, interference with taste, and tooth decay. Dry mouth may be partially relieved by spraying the inside of the mouth with artificial saliva.

Mouth-to-mouth resuscitation

See *Artificial respiration*.

Mouth ulcer

An open sore caused by a break in the *mucous membrane* lining the mouth. Mouth ulcers take the form of round or oval, shallow, white, gray, or yellow spots with an inflamed red border. They may occur singly or in clusters anywhere in the mouth.

TYPES

The most common type of mouth ulcer is a *canker sore*, which occurs on the inside of the cheek and lip and on the tongue. Also common are ulcers caused by the *herpes simplex* virus, which also causes *cold sores*.

Rare types of mouth ulcer include those occurring in *Behçet's syndrome*, *tuberculosis*, *syphilis*, *Vincent's disease*, *leukemia*, *anemia*, and drug allergy.

A mouth ulcer may be the first stage of *mouth cancer*. Any ulcer that fails to heal within three or four weeks, or that recurs, should be seen by a physician. *Blood tests* and/or a *biopsy* (removal of a small sample of tissue for analysis) may be required to determine the cause.

Mouthwash

A solution for rinsing the mouth. Many mouthwashes make various medicinal claims, but most do no more than leave the mouth feeling fresh and, if used vigorously, remove loose food debris from the teeth (an effect that can be achieved with water). Most antiseptic mouthwashes intended to combat *halitosis* (bad breath) are ineffective because they do not treat the cause of the problem; if used for a prolonged period, they may irritate the mouth.

Some mouthwashes, however, are useful. When the gums are too tender for proper toothbrushing, as in some types of *gingivitis* (inflamed gums), a mouthwash containing hydrogen peroxide can help clean the teeth by its foaming action. Any time routine dental hygiene is not possible (such as after oral surgery), a mouthwash with chlorhexidine used under the supervision of a dentist acts effectively against the bacteria in dental plaque, the sticky coating on the teeth responsible for decay.

Fluoride mouthwashes are helpful in preventing dental caries, probably by strengthening tooth enamel, and possibly also by acting directly against plaque. A mouthwash of warm salt water can help ease painful inflammation caused by tooth disorders, such as impacted wisdom teeth (see *Impaction, dental*) or *dry socket* (infection at the site of a tooth extraction).

Movement

Bodily movements include skeletal movements and movements of soft tissues and body organs. All movement is brought about by the actions of various types of muscles.

SKELETAL MOVEMENTS

The simplest skeletal movement consists of a change in the relative position of two bones, brought about by shortening of a muscle attached to the two bones and acting across a *joint*. Simultaneously, other muscles and soft tissues, such as skin, tendons, and ligaments, are stretched.

More complex skeletal movements involve many bones, joints, and muscles, which are arranged to allow an enormous range of possible actions, from turning a screwdriver to turning a somersault. Even in a fairly simple movement, several muscles are active, some contracting to initiate and maintain a movement while others that oppose the movement contract to help prevent sudden, uncontrolled movement.

All voluntary (willed) skeletal movements are initiated in the part of the cerebrum (the main mass of the brain) called the motor cortex. Signals are sent down the spinal cord along nerve fibers, and from there along separate nerve fibers to the appropriate muscles. Control relies on information supplied by sensory nerve receptors, in the muscles and elsewhere, that record the position of the different parts of the body and the amount of contraction in each muscle. This information is integrated in specific areas of the brain (including the cerebellum and basal ganglia) that control coordination, initiation, and cessation of movement. Learning complex sequences (such as piano playing) involves the establishment of unconscious patterns of nerve activity in the cerebellum.

Skeletal movements can also occur as simple *reflexes* in response to certain sensory warning signals. In these instances, the movement is automatic and less controlled, involving far fewer nerve connections.

OTHER MOVEMENTS

Not all body movements involve the skeleton. Movements of the eyes and tongue are brought about by contractions of muscles attached to soft tissues. Again, they may be voluntary movements (controlled from the motor cortex) or reflexes. Movements of the internal organs are involuntary; they include the *heart beat* and *peristalsis*. (See also *Muscles*.)

DISORDERS

Disorders of the nervous system, muscles, joints, or bones may impair movement. (See *Nerve injury*; *Neuropathy*; *Brain* disorders box; *Spinal cord*; *Muscles* disorders box.)

Moxibustion

A form of treatment, often used in conjunction with *acupuncture*, in which a cone (moxa) of wormwood leaves or of certain other plant materials is burned just above the skin to relieve internal pain. The burning material is thought to act as a counterirritant (that is, its irritation of nerve endings in the skin alleviates deep-seated pain in the same area). When used in conjunction with acupuncture, the cone of moxa is placed on a needle over an acupuncture point, and the moxa is lit.

MRI

Magnetic resonance imaging. MRI is a diagnostic technique that provides high quality cross-sectional images of organs and structures within the body without X rays or other radiation.

HOW IT WORKS

During the imaging, the patient lies inside a massive, hollow, cylindrical magnet and is exposed to short bursts of a powerful magnetic field. The nuclei (protons) of the body's hydrogen atoms normally point randomly in different directions, but, in a magnetic field, they line up parallel to each other, like rows of tiny magnets. If the hydrogen nuclei are then knocked out of alignment by a strong pulse of radio waves, they produce a detectable radio signal as they fall back into alignment.

Magnetic coils in the machine detect these signals and a computer changes them into an image based on the strength of signal produced by different types of tissue. Tissues that

contain a lot of hydrogen (such as fat) produce a bright image; those that contain little or no hydrogen (such as bone) appear black.

WHY IT IS DONE

MRI allows images to be constructed in any plane; it is particularly valuable in studying the brain and spinal cord. This technique reveals tumors vividly, indicating their precise extent, and produces impressive images of the internal structure of the eye and ear.

MRI also produces detailed images of the heart and major blood vessels, provides images of blood flow, and is useful for examining joints and soft tissues, particularly in the knee. The role of MRI in imaging the abdominal organs is becoming established.

Images from MRI are similar in many ways to those produced by *CT scanning*, but MRI generally gives much greater contrast between normal and abnormal tissues.

HOW IT IS DONE

MRI is usually an outpatient procedure. During the examination the patient must lie still; children may be given a general anesthetic. A scan usually takes about half an hour.

RISKS

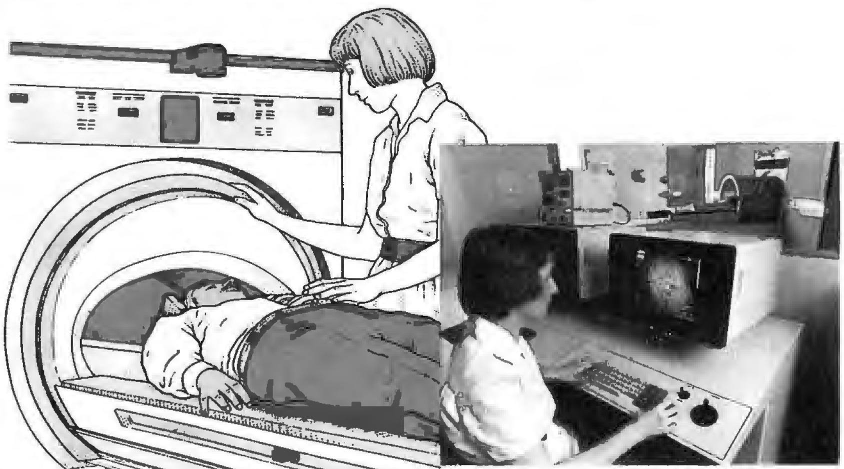
There are no known risks or side effects to MRI. The technique does not use radiation and can therefore be performed repeatedly with no known adverse effects.

However, any person fitted with a pacemaker, hearing aid, or other electrical device should tell his or her physician before undergoing MRI, since the scanner may interfere with these devices.

OUTLOOK

MRI is a costly test that is not yet widely available; it is still the subject of continuing research. A future application of MRI, known as magnetic resonance spectroscopy, relies on the properties of other chemical elements in the body (such as phosphorus and calcium) and is able to provide information on organ function.

MS



The abbreviation for *multiple sclerosis*.

Mucocele

A swollen sac or cavity within the body that is filled with mucus secreted from cells in its inner lining. An example is a mucocele of the appendix, caused by constriction of the opening of the appendix into the intestine. A mucocele of the gallbladder (*hydrops*) may be caused by a gallstone obstructing its outlet.

MAGNETIC RESONANCE IMAGING (MRI)

A valuable diagnostic technique, MRI has been in use since the early 1980s. The patient lies down surrounded by electromagnets and is exposed to short bursts of powerful magnetic fields and radio waves. The bursts stimulate hydrogen atoms in the patient's tissues to emit signals, which are detected and analyzed by computer to create an image of a "slice" of the patient's body.

MRI computer

A computer linked to the MRI scanner creates an image of the area being scanned and displays it on a monitor.

Mucolytic drugs

Mucolytic drugs (including *acetylcysteine*) make sputum (phlegm) less sticky and easier to cough up.

Mucopolysaccharidosis

Any of a group of inborn errors of *metabolism*. The best known is *Hurler's syndrome*; others include Hunter's, Sanfillippo's, Morquio's, Maroteaux-Lamy, and Scheie's syndromes. They are rare, collectively affecting about one child in 10,000.

All are *genetic disorders* in which there is an abnormality of a specific *enzyme* in body tissues. The enzyme abnormality affects the way carbohydrates are handled within body cells, leading to an accumulation of unwanted substances called mucopolysaccharides in the tissues.

Depending on the disease, features include abnormalities of the skeleton and/or the central nervous system (brain and spinal cord) with mental retardation and, in some cases, a characteristic facial appearance. There may also be corneal clouding, liver enlargement, and joint stiffness. No specific treatment is available; death often occurs during the childhood or teenage years. However, there are also mild varieties that may allow a reasonably normal life. Some children with Hurler's syndrome have been successfully treated by bone marrow transplantation, which provides a continuing source of the enzyme.

Parents with a seriously affected child should receive *genetic counseling* concerning the risk of any future child being affected.

Mucosa

Another term for a *mucous membrane*.

Mucous membrane

The soft, pink, skinlike layer that lines many of the cavities and tubes in the body, including the respiratory tract, alimentary canal, the urinary and genital passages, and eyelids. The mucous membrane secretes a fluid that contains *mucus* to keep such structures moist and well-lubricated. The fluid is produced and released onto the surface of the mucous membrane by millions of specialized cells (goblet cells) within the membrane.

Mucus

The thick, slimy fluid secreted by *mucous membranes*. Mucus moistens, lubricates, and protects those parts of the body lined by mucous membrane, such as the alimentary and digestive tracts. Mucus prevents stomach acid from damaging the stomach wall and

prevents enzymes from digesting the intestine, it eases swallowing and lubricates food as it passes through the alimentary tract, it moistens inhaled air and traps smoke and other foreign particles in the airways (to keep them out of the lungs), and it facilitates sexual intercourse.

Mucus method of contraception

See *Contraception.*

Multiple myeloma

A malignant condition of middle to old age, also called myelomatosis. Multiple myeloma is characterized by the uncontrolled proliferation and disordered function of cells called plasma cells in the bone marrow.

Plasma cells are a type of B-*lymphocyte* (class of white blood cell) responsible for making *antibodies,* or *immunoglobulins,* that normally help protect against infection. In multiple myeloma, the proliferating plasma cells produce excessive amounts of a single type of immunoglobulin while the production of other types is impaired, making the patient particularly prone to infection.

Multiple myeloma is rare, with about three new cases annually per 100,000 population.

SYMPTOMS

As the abnormal plasma cells expand within bone, they cause pain and destruction of bone tissue. If the bones in the spine are affected, they may collapse and compress nerves, causing symptoms such as numbness or paralysis. The level of calcium in the blood may increase markedly as bone is destroyed, as may the level of a breakdown product of the immunoglobulin secreted by the plasma cells. These changes in blood chemistry may damage the kidneys, leading to *renal failure.*

In addition to the increased risk of infection, patients may suffer from *anemia* and a bleeding tendency if healthy bone marrow becomes replaced by malignant plasma cells.

DIAGNOSIS, TREATMENT, AND OUTLOOK

The disease is diagnosed from the appearance of a *bone marrow biopsy* specimen, the excess of the single type of immunoglobulin in the blood or urine, and the presence of areas of destroyed bone, as shown by X rays.

Treatment includes the use of *anticancer drugs* to reduce the number of abnormal plasma cells, *radiation therapy* to diseased areas of bone, and supportive measures (including blood transfusions to correct anemia, antibiotics to combat infections, and analgesics to relieve pain).

The severity and prognosis of the illness varies, but only about one fifth of patients survive for four years or longer from the time of diagnosis.

Multiple personality

A rare disorder in which a person has two or more distinct personalities, each of which dominates at different times. The personalities are almost always very different from each other and are often total opposites, as in the story of Dr. Jekyll and Mr. Hyde. They may have no awareness of each other, but are aware of lost periods of time.

Although multiple personality is often called split personality, a phrase also used to describe *schizophrenia,* the two disorders are unrelated. The split in schizophrenia is between thought and feeling.

Multiple pregnancy

See *Pregnancy, multiple.*

Multiple sclerosis

A progressive disease of the central nervous system in which scattered patches of myelin (the protective covering of nerve fibers) in the brain and spinal cord are destroyed. This causes symptoms ranging from numbness and tingling to paralysis and incontinence. The severity of multiple sclerosis (MS) varies markedly among sufferers.

CAUSES

The cause of multiple sclerosis remains unknown. It is thought to be an *autoimmune* disease in which the body's defense system begins to treat the myelin in the central nervous system as foreign, gradually destroying it, with subsequent scarring and damage to some of the underlying nerve fibers.

There seems to be a genetic factor since relatives of affected people are eight times more likely than others to contract the disease. Environment may also play a part—it is five times more common in temperate zones (such as the US and Europe) than in the tropics. Spending the first 15 years of life in a particular area seems to determine future risk. It is thought that a virus picked up by a susceptible person during this early period of life may be responsible for the disease's later development.

INCIDENCE

Multiple sclerosis is the most common acquired (not present at birth) disease of the nervous system in young adults. In relatively high-risk temperate areas the incidence is about one in every 1,000 people. The ratio of women to men sufferers is 3 to 2.

SYMPTOMS AND SIGNS

Multiple sclerosis usually starts in early adult life. It may be active briefly and then resume years later. The symptoms vary with which parts of the brain and spinal cord are affected.

Spinal cord damage can cause tingling, numbness, or a feeling of constriction in any part of the body. The extremities may feel heavy and become weak. *Spasticity* (stiffness) sometimes develops. The nerve fibers to the bladder may be involved, causing incontinence.

Damage to the white matter in the brain may lead to fatigue, vertigo, clumsiness, muscle weakness, slurred speech, unsteady gait, blurred or double vision, and numbness, weakness, or pain in the face.

These symptoms may occur singly or in combination and may last from several weeks to several months. In some sufferers, relapses may be precipitated by injury, infection, or physical or emotional stress.

Attacks vary considerably in their severity from person to person. In some, the disease may consist of mild relapses and long symptom-free periods throughout life, with very few permanent effects. Others have a series of flare-ups, leaving them with some disability, but further deterioration ceases. Some become gradually more disabled from the first attack and are bedridden and incontinent in early middle life. A small group suffers gross disability within the first year.

A person disabled with multiple sclerosis may have problems in addition to the paralysis, such as painful muscle spasms, urinary tract infections, constipation, skin ulceration, and changes of mood between euphoria and depression.

DIAGNOSIS

There is no single diagnostic test for multiple sclerosis; confirmation of the disease is usually by exclusion of all other possible conditions. A neurologist may perform tests to help confirm the diagnosis, including *lumbar puncture* (removal of a sample of fluid from the spinal canal for laboratory analysis), tracing electrical activity in the brain (see *Evoked responses*), *CT scanning,* and *MRI.*

TREATMENT

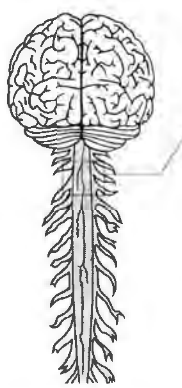
The search for a cure is still in progress. Patients are encouraged to

adopt as positive an outlook as possible, and to lead as active a life as their disabilities allow. *Corticosteroid drugs* may be prescribed to alleviate the symptoms of an acute episode; other drugs may be given to control specific symptoms, such as incontinence and depression. *Physical therapy* often helps strengthen muscles and various aids can help patients maintain mobility and independence.

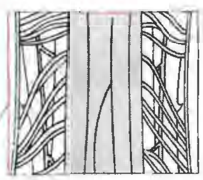
Multivitamin

A group of over-the-counter preparations containing a combination of *vitamins* and used to supplement the intake of vitamins in the diet. (See *Vitamin supplements*.)

Mumps



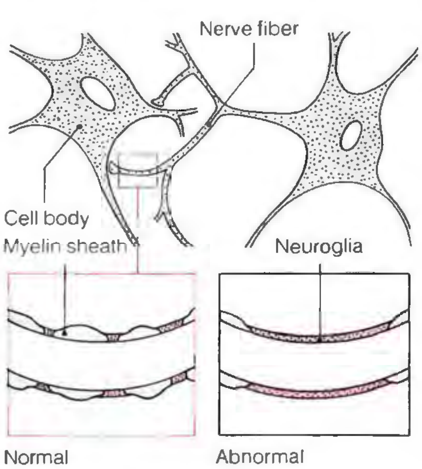
An acute viral illness, mainly of childhood. The chief symptom is inflammation and swelling of the parotid (salivary) glands on one or both sides. Serious complications are uncommon. However, in teenage and adult males, mumps can be a highly uncomfortable illness in which one or both testes become inflamed and swollen. One attack of mumps confers lifelong immunity.



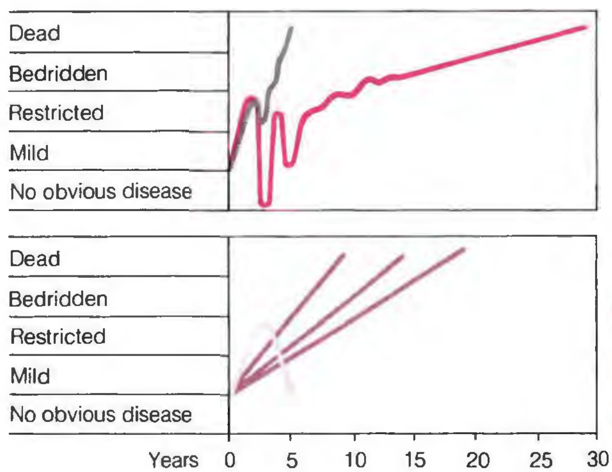
CAUSES AND INCIDENCE

The mumps virus is spread in airborne droplets. There is an incubation

FEATURES OF MULTIPLE SCLEROSIS



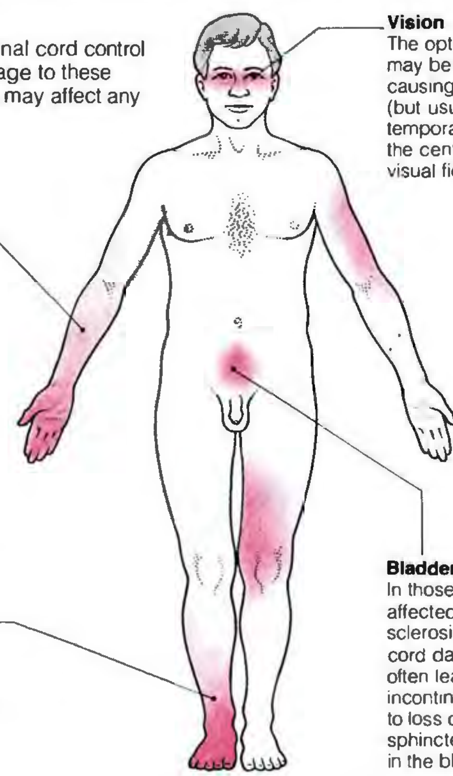
This disease can affect any area of the white matter of the brain and spinal cord. The plaques of demyelination are areas in which the fatty myelin sheaths of the nerve fibers have been destroyed. Affected fibers cannot conduct nerve impulses, so functions such as movement and sensation may be lost. The patchy distribution of plaques causes very varied effects.



Multiple sclerosis and the spine
Multiple sclerosis often affects nerve fibers in the spinal cord, thus blocking impulses to and from the brain.

Effects of multiple sclerosis
The fiber of the nerve tract is not usually destroyed. But the loss of insulating myelin and its replacement by neuroglia alters normal ion movements, so that the fiber can no longer conduct impulses.

RANGE OF OUTLOOKS IN MULTIPLE SCLEROSIS



Progress of multiple sclerosis
Multiple sclerosis is characterized by periods when symptoms are present, alternating with remissions (when symptoms are mild or absent).

AFFECTED AREAS

Because the brain and spinal cord control all parts of the body, damage to these parts by multiple sclerosis may affect any function or any organ.

Vision
The optic nerves may be involved, causing severe (but usually temporary) loss of the center of the visual field.

Sensation
The nerve tracts that carry impulses for sensation are often involved. This causes areas of numbness, or a feeling of pins and needles in the skin

Coordination
When the nerve fibers in the brain stem are involved, there may be incoordination, loss of balance, and double vision

Movement
Plaques on the long motor nerve tracts in the brain or spinal cord may affect walking, sometimes causing dragging of one leg or a feeling of weakness

Bladder
In those severely affected by multiple sclerosis, spinal cord damage often leads to incontinence due to loss of sphincter control in the bladder

period of two to three weeks between infection and the appearance of symptoms. An affected person may spread the virus to others for about a week before and up to two weeks after symptoms appear. Most infections are acquired at school or from infected family members.

In the US, where many states require proof of mumps vaccination for school entry, the incidence has dropped markedly over the last 20 years, from a peak incidence of more than 185,000 cases in 1967 to a few thousand cases per year currently. In countries where immunization is not given routinely in early childhood, the infection remains common, affecting a large proportion of the population at some time between ages 5 and 10.

SYMPTOMS AND COMPLICATIONS

Many infected children have no symptoms or no more than mild sickness and discomfort in the region of the salivary glands (just inside the angle of the jaw). In more serious cases, the child first complains of pain in this region and has difficulty chewing; the glands on one or both sides then become swollen, painful, and tender. Fever, headache, and difficulty swallowing may develop, but the temperature falls after two to three days and the swelling subsides within a week to ten days. When only one side is affected, the second gland often swells as the first is subsiding.

An occasional complication is *meningitis*, which can cause headache, photophobia, drowsiness, fever, and stiff neck. However, these symptoms also resolve without long-term effects in most cases. A less common complication is *pancreatitis*, causing abdominal pain and vomiting.

In males after puberty, *orchitis* (inflammation of the testis) develops in about one quarter of cases. Only one testis is usually affected, becoming swollen, tender, and painful for two to four days. Subsequently, the affected testis shrinks to smaller than normal size. Uncommonly, both testes are affected; extremely rarely this can lead to sterility.

There is no evidence that mumps in pregnancy has any effect on the fetus.

DIAGNOSIS AND TREATMENT

Mumps is usually diagnosed from the patient's symptoms; the diagnosis may be confirmed by culturing the virus from saliva or urine or by measuring antibodies to mumps virus in the blood.

There is no specific treatment, but an affected child may be given

Appearance of mumps
The swelling, especially if present on both sides, may give the affected child a somewhat hamsterlike appearance.

analgesics (painkillers) and plenty to drink. In moderate to severe cases, the child may need to stay in bed during the first few days of the illness and should not go to school until symptoms have subsided.

For males with severe orchitis, a physician may sometimes prescribe a stronger painkiller, and *corticosteroid drugs* to reduce inflammation.

IMMUNIZATION

A safe and effective mumps vaccine is available and routinely given in the US to children in their second year, usually in combination with measles and rubella vaccines. The vaccine should not be given to children under 1, or to anyone with risk factors for vaccination (see *Immunization*).

Males who have already gone through puberty who have never been immunized against mumps or had the infection should avoid contact with any infected person. If symptoms of mumps do develop, passive immunization with antimumps *immunoglobulin* can provide some protection against the development of orchitis.

Münchausen's syndrome

A form of chronic *factitious disorder* in which the sufferer complains of physical symptoms that are pretended or self-induced. Sufferers are not *malingering*, they simply want to play the patient role. Most afflicted people are repeatedly hospitalized for investigations and treatment.

Pain in the abdomen, bleeding, neurological symptoms (such as dizziness and blackouts), skin rashes, and fever are the usual complaints. Sufferers typically invent dramatic, but often plausible, false histories and, once in the hospital, behave in a disruptive manner. Many show evidence of self-injury or of previous treatment (such as numerous scars or detailed medical knowledge).

It is difficult to determine the causes of the disorder; when challenged, the sufferers deny any allegations of deception or immediately discharge themselves from the hospital. Treatment is aimed at protecting these people from unnecessary operations and treatments.

Murmur

A sound caused by turbulent blood flow through the heart, as heard by a physician through a *stethoscope*. Murmurs are a separate phenomenon from other types of normal or abnormal *heart sounds*, which are caused mainly by sudden acceleration or deceleration of blood movement.

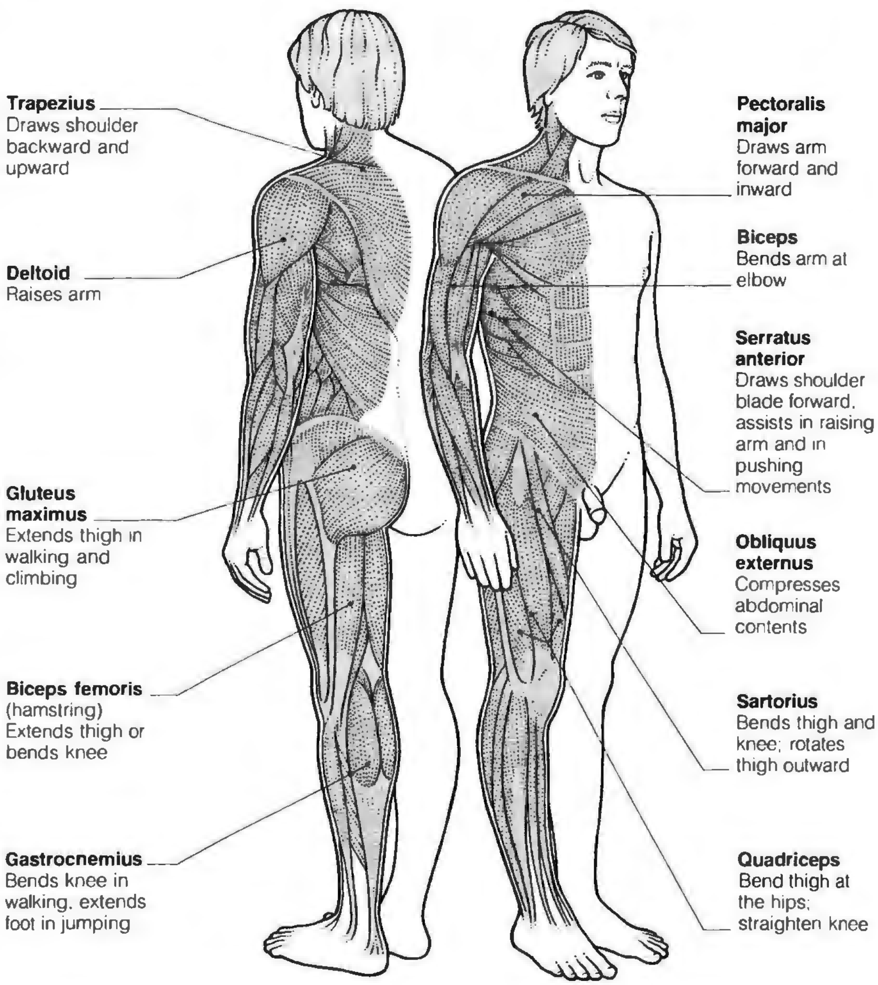
Heart murmurs are not necessarily a sign of disease, but an unusual sound is regarded as an indication of possible abnormality in the blood flow. Apart from "innocent" murmurs, the most common cause of extra blood turbulence is a disorder of the heart valves, such as stenosis (narrowing) or insufficiency (leakage) with regurgitation. Murmurs can also be caused by some types of congenital heart disease such as *septal defects* (holes in the heart) or *patent ductus arteriosus*, by *pericarditis* (inflammation of the membrane around the heart), or by other, rarer, conditions, such as a *myxoma* in a heart chamber.

By noting the location on the chest wall at which the murmur is best heard and the timing of the murmur in relation to the basic heart sounds, and by considering these factors in conjunction with other signs and symptoms, the physician can usually arrive at a diagnosis, which may be confirmed by *echocardiography*.

Muscle

A structure composed of bundles of specialized cells capable of contraction and relaxation to create movement, both of the body itself in relation to the environment and of the organs within it. There are three different types of muscle in the body—skeletal, smooth, and cardiac.

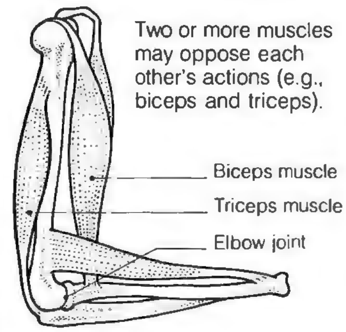
SKELETAL MUSCLE



The largest part of the musculature consists of skeletal (voluntary) muscles; the body contains more than 600 such muscles.

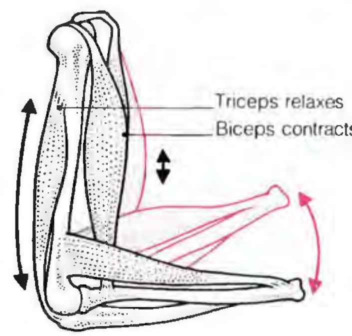
Skeletal muscles are classified according to the type of action each muscle performs. An extensor muscle opens out a joint, a flexor closes it; an adductor muscle draws a part of the body inward, an abductor moves it outward; a levator raises it, a

M



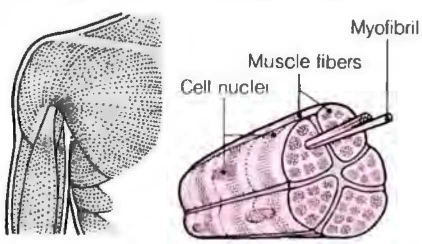
THE BODY'S MUSCLES

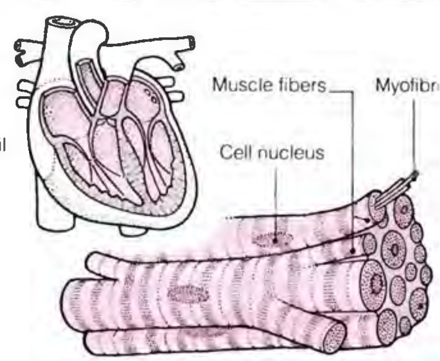
The most prominent muscles in the body are the skeletal muscles, which account for 40 to 45 percent of body weight. These muscles are called voluntary because they are under conscious control; some important voluntary muscles are indicated on the illustration below. Many internal organs, such as the heart and intestines, also consist partly or entirely of involuntary muscle, which is not under conscious control.



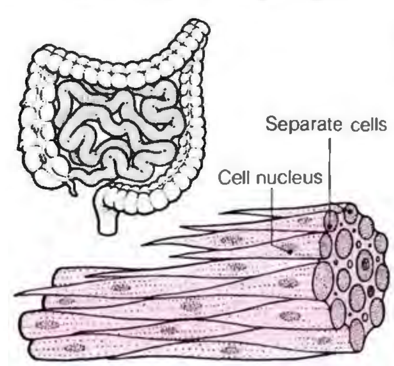
MUSCLE MOVEMENT

Contraction makes a muscle shorter and draws together the bones to which the muscle is attached.





Controlled movement at the elbow relies on coordinated relaxation and contraction of the biceps and triceps.



MUSCLE TYPES

Skeletal and cardiac muscles appear striped under the microscope, unlike smooth muscles.

Skeletal muscle
Skeletal muscle consists of bundles of fibers (muscle cells), each containing contractile elements (myofibrils).

Cardiac muscle
Cardiac muscle contains short, branching cells that interconnect to help spread the signals that cause contraction.

Smooth muscle
Smooth muscle consists of more loosely woven, tapering cells. Contraction is slower than in other muscle types.

depressor lowers it; and constrictor or sphincter muscles surround and close body orifices.

Skeletal muscles are composed of groups of muscle fibers in an orderly arrangement.

A small muscle may be made up of only a few bundles of fibers, while the major muscles in the body (such as the gluteus maximus that forms the bulk of the buttock) are made up of hundreds of bundles. A muscle fiber is made up of even smaller longitudinal units called myofibrils, the basic working units of which are microscopic filaments called actin and myosin; these are proteins that control contraction.

Movement of the skeletal muscles is under the voluntary control of the brain. Each muscle fiber is supplied with a nerve ending that receives impulses from the brain. The nerve impulse stimulates the muscle by releasing a *neurotransmitter* called acetylcholine. This starts a chain of chemical and electrical events, involving sodium, potassium, and calcium ions, which results in the filaments of myosin sliding over the actin filaments in much the same way as an extendable ladder moves when it is closed. This movement of myosin over actin filaments causes the muscle to shorten in length.

Each muscle contains a set of specialized nerve fibers that registers the force of contraction; another set in the tendon gauges the stretch. The information received by these fibers is transmitted to the brain and is vital in limiting muscle action.

Skeletal muscle is maintained in partial contraction—called muscle tone. *Spasticity* is one form of abnormally increased muscle tone.

Skeletal muscle activity is affected by changes in chemical composition of the fluid surrounding the muscle cells. A fall in potassium ions causes muscle weakness; a decrease of calcium ions causes muscle spasm.

DISORDERS OF MUSCLE

The most common muscle disorder is injury, followed by symptoms caused by a lack of blood supply to a muscle (including the heart). In addition, there are a number of other rarer disorders of muscle.

GENETIC DISORDERS

The *muscular dystrophies* cause progressive weakness and disability. Some types appear at birth, some in infancy, and some develop as late as the fifth or sixth decade.

One type of *cardiomyopathy*, a general term for disease of the heart muscle, is inherited.

INFECTION

The most important infection of muscle is *gangrene*, which may complicate deep wounds (especially those contaminated by soil). *Tetanus* is acquired in a similar way, causing widespread muscle spasm through the release of a powerful toxin.

Viruses (especially influenza B) may also infect muscles (causing *myalgia*), as may the organism causing *toxoplasmosis*. *Trichinosis* is an infestation of muscle with the worm *TRICHINELLA SPIRILIS*, which is acquired by eating undercooked meat (usually pork).

INJURY

Muscle injuries, such as tears and *sprains*, are very common; they cause bleeding into the muscle tissue. Healing leads to formation of a scar in the muscle, which shortens its natural length. Blunt muscle injury may result in *hematoma* formation from bleeding into the muscle. Rarely, bone may form in the hematoma causing *myositis* ossificans.

TUMORS

Primary muscle tumors may or may not be cancerous. Noncancerous tumors are called *myomas*, those affecting smooth muscle are *leiomyomas*, and those affecting skeletal muscle are rhabdomyomas. Myomas of the uterus (see *Fibroids*) are among the most common of all tumors. Cancerous tumors are called myosarcomas and are very rare; cancers of the skeletal muscle are known as *rhabdomyosarcomas*.

Secondary tumors, which spread from a primary site of cancer elsewhere in the body, very rarely involve muscle.

HORMONAL AND METABOLIC DISORDERS

Muscle contraction depends on the maintenance of proper levels of sodium, potassium, and calcium in and around muscle cells. Any alteration in the concentration of these substances affects muscle function. For example, a severe drop in the level of potassium (hypokalemia) causes profound muscle weakness and may stop the heart. A drop in blood calcium (hypocalcemia) causes increased excitability of muscles and, occasionally, spasms.

Thyroid disease is often associated with muscle disorders, the most common being a swelling of the small muscles that move the eyes, causing a bulging eyeball (see *Exophthalmos*).

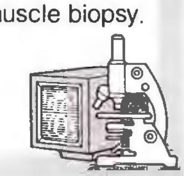
Adrenal failure causes general muscle weakness.

IMPAIRED BLOOD SUPPLY

Muscles depend on a good blood supply for normal function. *Cramp* is usually caused by a lack of blood flow, sometimes associated with severe exertion. *Peripheral vascular disease*, which restricts the blood supply, causes *claudication* (muscle pain on exercise). *Angina pectoris* (chest pain caused by lack of blood supply to heart muscle) occurs in *coronary heart disease*.

The *compartment syndrome* is pain in muscles as a result of swelling that limits the blood supply. It is brought on by injury or exercise, occurring often in athletes with well-developed muscles.

POISONS AND DRUGS



Several toxic substances can damage muscle. They include alcohol, which can cause damage following a prolonged drinking bout. Other substances that may cause muscle damage include aminocaproic acid, chloroquine, clofibrate, emetine, and vincristine.

AUTOIMMUNE DISORDERS

Myasthenia gravis is a disorder of transmission of nerve impulses to muscles; it usually begins by causing drooping of the eyelids and double vision. Other diseases with an autoimmune basis that may affect muscles are *lupus erythematosus*, *rheumatoid arthritis*, *scleroderma*, *sarcoidosis*, and *dermatomyositis*.

INVESTIGATION

Muscle disorders are investigated by *EMG* (electromyography), which measures the response of muscles to electrical impulses, and by muscle biopsy.

SMOOTH MUSCLE

This type of muscle is concerned with the movements of internal organs, such as *peristalsis* in the intestine and contractions of the uterus during childbirth. Many other parts of the body, such as the bronchi of the lungs, the bladder, and the walls of the blood vessels, also contain smooth muscle.

Smooth muscle is composed of long, spindle-shaped cells. In most hollow organs, these cells are arranged in bundles organized in an outer longitudinal layer and an inner circular one. However, the mechanism of contraction relies on the same sliding action of actin and myosin as in skeletal muscle.

The nerve supply to smooth muscle comes from the *autonomic nervous system*, which is not under conscious control. Hence, its alternative name—involuntary muscle. Nerves from the autonomic nervous system penetrate into the muscle. There, they divide into many branches from which the neurotransmitter is released to initiate the process that leads to contraction.

In addition to neurotransmitters, smooth muscle responds to a variety of hormones, to the stretch of individual muscle fibers, and to changes in the chemical composition of the fluid surrounding the fibers, such as oxygen levels and acidity.

CARDIAC MUSCLE

This type of muscle, also called myocardium, is found only in the heart; it has unique properties that enable it to contract rhythmically about 100,000 times a day to propel blood through the circulatory system. The structure of cardiac muscle resembles that of skeletal muscle.

Contraction of cardiac muscle is stimulated by the autonomic nervous system, hormones, and stretching of the muscle fibers.

To act as an efficient pump, the muscles of the heart must contract in an orderly, regular manner. Separate muscle fibers are joined end to end by areas of extensive folds that allow contractions to be transmitted rapidly from one fiber to another. The stimulus for cardiac muscle contraction is initiated in an area of the right atrium (called the sinoatrial node), which stimulates a regular rate of contraction. Specialized conducting cells in cardiac muscle form a network capable of transmitting nerve impulses throughout the cardiac muscle fibers, spreading the contraction through both atria and then both ventricles alternately (see *Heart*).

Muscle-relaxant drugs

COMMON DRUGS

Baclofen Carisoprodol
Cyclobenzaprine Dantrolene
Diazepam Methocarbamol Orphenadrine

A group of drugs used to relieve *muscle spasm* and *spasticity*. They are often used in combination with an *analgesic* (painkiller) to relieve muscle stiffness caused by types of *arthritis*, back pain, or a disorder of the nervous system, such as *stroke* or *cerebral palsy*. Muscle-relaxant drugs are occasionally used to relieve muscle rigidity caused by injury.

HOW THEY WORK

With the exception of *dantrolene*, muscle-relaxant drugs partially block nerve signals from the brain and spinal cord that stimulate different muscles to contract.

Dantrolene acts directly on muscles by interfering with the chemical activity in muscle cells necessary for muscle contraction.

POSSIBLE ADVERSE EFFECTS

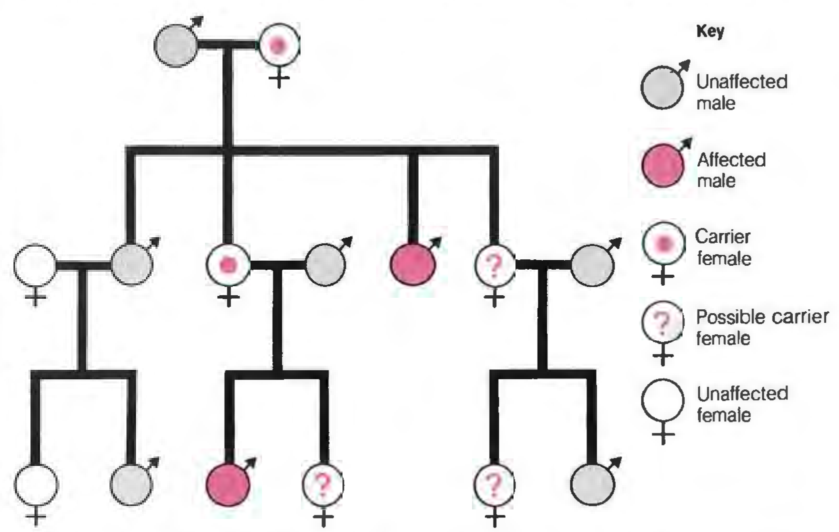
Because muscle-relaxant drugs reduce the strength of muscle contraction, they may cause weakness that is noticed when performing certain activities. Some muscle relaxants affect the brain and spinal cord, causing drowsiness. In rare cases, dantrolene causes liver damage.

Muscle spasm

Abnormal rigidity of a muscle. Causes include brain damage due to *stroke*, *cerebral palsy*, and severe *head injury*; brain disorders, such as *Parkinson's disease*; and pressure on a nerve from a *disk prolapse*. Other causes include muscle *strain* or injury.

Muscular dystrophy

An inherited muscle disorder of unknown cause in which there is slow but progressive degeneration of muscle fibers. Different forms are classified according to the age at which the symptoms appear, the rate at which the disease progresses, and the way in which it is inherited. (See box at right for main types.)



INCIDENCE

All forms of muscular dystrophy are rare. Duchenne muscular dystrophy is the most common type, affecting about one or two in 10,000 boys. It is inherited through a recessive, sex-linked gene (see *Genetic disorders*) so that only males are affected and only females can pass on the disease.

DIAGNOSIS

Often the diagnosis is suggested to the physician from observing the patient, but tests are needed for confirmation. A blood test may be performed to look for high levels of certain enzymes released from the damaged muscle cells. A test of electrical activity in the

DUCHENNE MUSCULAR DYSTROPHY: A TYPICAL FAMILY TREE

Affected males always inherit the gene for the disorder from their mothers, who are carriers of the gene, although unaffected themselves. About half the sons of carriers are affected; the other sons are neither affected nor carriers. The daughters of carriers have a 50 percent chance of being carriers themselves; complex blood tests provide the only means of knowing whether or not a certain daughter (or granddaughter) is a muscular dystrophy carrier.

M

muscles (see *EMG*) and muscle *biopsy* may be performed.

TREATMENT AND OUTLOOK

There is no effective treatment for muscular dystrophy. Affected children should be active for as long as possible to keep the healthy muscles in good condition. The children should not be allowed to become overweight; surgery to the heel cords may assist walking in some cases. The long-term outlook varies.

PREVENTION

Parents or siblings of an affected child should receive *genetic counseling*. Carriers of sex-linked forms of muscular dystrophy (see box, previous page) can be detected because their blood contains high levels of a particular enzyme.

It is now possible to diagnose some types of muscular dystrophy before birth by *chorionic villus sampling* or *amniocentesis*.

Musculoskeletal

Relating to muscle and/or bone. The musculoskeletal system is the bony skeleton of the body and the hundreds of muscles that are attached to it.

Mushroom poisoning

There are many species of poisonous mushrooms and toadstools in the US, but only some of them cause poisoning. Many of the others, although poisonous, have an unpleasant taste and thus are unlikely to be eaten in significant amounts.

TYPES OF MUSCULAR DYSTROPHY

Duchenne muscular dystrophy	In this type, the child is slow in learning to sit up and walk, and does so much later than normal. The condition is rarely diagnosed before the age of 3, but progresses rapidly. Affected children tend to walk with a waddle and have difficulty climbing stairs. In getting up from the floor, the child "climbs up his legs," pushing his hands against his ankles, knees, and thighs. Sometimes there is curvature of the spine. Despite their weakness, the muscles (especially those in the calves) appear bulky; this is because wasted muscle is replaced by fat. By about age 12, affected children are no longer able to walk; few survive their teen years, usually dying from a chest infection or heart failure. Affected boys often have below-average intelligence.
Becker's muscular dystrophy	This type produces the same symptoms as the Duchenne type, but starts later in childhood and progresses much more slowly. Patients often reach the age of 50. Both types of dystrophy have sex-linked inheritance.
Myotonic dystrophy	This form affects muscles of the hands and feet. Infants are floppy and slow to develop. The main feature is that the muscles contract strongly but do not relax easily. Myotonic dystrophy is associated with cataracts in middle age, baldness, mental retardation, and endocrine problems. The condition has an autosomal dominant pattern of inheritance.
Limb-girdle muscular dystrophy	This type takes different forms. It starts in late childhood or early adult life, and progression is slow. The muscles of the hips and shoulders are mainly affected. Other nerve and muscle conditions must be eliminated before this form of dystrophy can be diagnosed confidently.
Facioscapulohumeral muscular dystrophy	This form usually appears first between the ages of 10 and 40; it affects only the muscles of the upper arms, shoulder girdle, and face. It is inherited in an autosomal dominant pattern. In this form of muscular dystrophy, progression of the weakness is slow, and severe disablement is rare.

TYPES, SYMPTOMS, AND TREATMENT

Most fatal cases of mushroom poisoning in the US are caused by *AMANITA PHALLOIDES* (the death cap) and its relatives. This mushroom looks innocuous, bearing a resemblance to the edible field mushroom. However, there are some clear differences. The death cap grows in deciduous woods (mainly beech and oak), has a yellow-olive colored cap, and, most importantly, has white gills on the underside of its cap (not pink-brown as on the edible field mushroom).

The death cap and one or two related species such as *AMANITA VIROSA* (destroying angel) contain highly poisonous peptides called amanitins, which attack cells in the lining of the small intestine, the liver, and, occasionally, the kidneys. Symptoms such as severe abdominal pain, vomiting, and diarrhea usually develop eight to 14 hours after eating the mushroom. Later, there may be liver enlargement and jaundice; about 10 to 15 percent of victims die of liver failure (this stage of the poisoning resembles acute viral hepatitis). There is no effective antidote. Treatment consists of supportive measures in the hospital. For those who survive the poisoning (after about one week), recovery is usually fairly rapid.

Another species, *AMANITA MUSCARIA*, or fly agaric, is very similar in shape to the death cap but has a red cap flecked with white. Symptoms of poisoning, which appear within 20 minutes to two hours, may include drowsiness, visual disturbances, delirium, muscle tremors, and nausea and vomiting. Treatment of this type of mushroom poisoning, and of other types in which symptoms develop rapidly, is by gastric lavage (see *Lavage, gastric*) and the administration of activated charcoal. Full recovery usually occurs within 24 hours. Fatal poisoning by fly agaric has never been reported in the US.

"Magic" mushrooms are a species containing the hallucinogenic substance psilocybin. In addition to hallucinations, they may cause high fever in children, which requires medical attention. The effects usually subside within four to six hours; occasionally they persist longer.

Mutagen

Any physical or chemical agent that, when applied to a group of living cells, increases the rate of *mutation* in those cells. A mutation is a change in the genetic material within a cell, which,

under certain circumstances, can give rise to a cancer or a hereditary disease.

The most important mutagens are ionizing radiation and some chemicals. The former includes X rays and various types of emission from nuclear explosions, radioactive fallout, and leaks from nuclear reactors, including gamma rays and alpha and beta particles (see *Radiation hazards*). Similar types of radiation are also emitted (at a low intensity) from rocks and from the sky (cosmic rays).

Many chemical *carcinogens* are thought to cause cancers by altering the genetic material within cells, thus acting as mutagens. Chief among them are chemicals in tobacco smoke.

Mutation

A change in the genetic material within a living cell—that is, in the *DNA*, the main constituent of a cell's *chromosomes* that provides the coded instructions for the cell's activities.

Many mutations are neutral or harmless; some are harmful, giving rise to cancers, birth defects, and hereditary diseases. Very rarely, a mutation may be beneficial.

CAUSES AND TYPES

A mutation results from a fault in the copying of a cell's DNA to its daughter cells when the cell divides. One of the offspring cells inherits some faulty DNA, and the fault is copied each time the cell divides, creating a population of cells containing the altered DNA.

The change may be a point mutation, affecting only a small part of a section of DNA (called a *gene*). This type may lead to production of defective enzymes or other proteins in the affected cells, thus disrupting their activities. In other cases, entire chromosomes or bits of chromosomes are deleted, added, or rearranged in affected cells, which can produce greater disruptive effects.

The term *mutagen* refers to any physical or chemical agent that makes mutations more likely. The most important mutagens are types of high-energy radiation, and certain chemicals, including some *carcinogens* (cancer-inducing agents).

EFFECTS

The effects of a harmful mutation depend on whether the affected cell is a "germ" cell in an ovary or testis (capable of giving rise to an egg or sperm) or whether it is one of the other cells in the body (somatic cells).

A mutated somatic cell can, at worst, multiply to form a group of abnormal cells within a particular body region. Often these cells die out, are destroyed by the body's immune system, or have only a minor local effect. Sometimes, however, they may form the basis for a tumor.

A mutation in a germ cell can have a dramatically different effect. It may be passed on, via egg or sperm, to a child, who then carries the mutation in all of his or her cells. This may lead to an obvious birth defect or abnormality in body chemistry. Furthermore, the child may pass on the mutation to some of his or her descendants. *Genetic disorders* (such as *hemophilia* and *achondroplasia*) stem originally from point mutations that have occurred to the germ cell of a parent, grandparent, or more distant ancestor. Some of these mutations occur frequently; about one third of all cases of hemophilia are caused by new mutations. *Chromosomal abnormalities* (such as *Down's syndrome*) generally result from mutations in the formation of a parental egg or sperm.

PREVENTION

Some mutations are unavoidable, occurring by chance or as the result of natural background radiation from the sky and from radioactivity in rocks. This background radiation causes random mutations in the population.

Minimizing any further risk of a mutation depends on avoiding known mutagens. It is particularly important for people exposed to radiation in the course of their work to have their exposure closely monitored to ensure that it does not exceed safe limits (see *Radiation hazards*). Younger people and those of reproductive age should have their reproductive organs shielded when undergoing X rays or radiation therapy.

Radioactive leaks or explosions from nuclear reactors can cause a rise in mutation rates that affects large populations. This may lead to an increase in the incidence of various cancers and birth defects in succeeding generations.

The chances of a mutation can also be lessened by avoiding exposure to carcinogens (which are a class of mutagen), the most obvious of which are the chemicals in tobacco smoke.

BENEFICIAL MUTATIONS

Very rarely, a mutation occurs in a germ cell that confers a survival advantage in the face of some environmental stress. People who inherit this mutation tend to survive longer than their peers; some of their children in turn inherit the mutation and pass it on to succeeding generations. Such mutations tend to become more common in a population over many generations as long as the original environmental stress persists.

An example is the mutation that causes sickle cell trait. Carrying this mutation protects against malaria, so it enhances a child's survival chances where malaria is prevalent. The mutation is prevalent in Africa (along with malaria) and affects many people of African origin. A double dose of the mutation (inheriting it from both parents) can lead to *sickle cell anemia*.

Mutism

Refusal or inability to speak. Mutism may occur as a symptom of severe *manic-depressive illness*, catatonic *schizophrenia*, and a rare form of *conversion disorder*. The term may also be applied to those who have taken a vow of silence for religious reasons.

Elective mutism describes a rare childhood disorder usually starting before age 5. The child understands language and speaks properly, but refuses to speak most of the time, preferring to use nods or gestures. A shy, withdrawn personality and anxiety over leaving home for school are important factors, but mild mental retardation or language problems may be the cause. This condition rarely lasts more than a few months.

Akinetic mutism describes a state of inert passivity that is caused by certain deep-seated tumors of the brain or by *hydrocephalus*. Though conscious and able to follow movements with their eyes, these people are incontinent, require feeding, and respond at most with a whispered "yes" or "no."

Treatment of mutism depends on the underlying cause.

Myalgia

The medical term for muscle pain. Myalgia is common in viral illnesses (such as influenza) and also occurs in a number of rheumatic disorders, such as *rheumatoid arthritis*, systemic *lupus erythematosus*, and *polymyalgia rheumatica*. Myalgia is the main symptom of *polymyositis* and *dermatomyositis*, disorders that cause inflammation of muscle tissue.

Myasthenia gravis

A disorder in which the muscles become weak and tire easily. The eyes, face, throat, and limb muscles are most commonly affected. Typically, the sufferer has drooping eyelids, a blank facial expression, and weak, hesitant speech.

CAUSES AND INCIDENCE

Myasthenia gravis is an *autoimmune disorder* in which, for unknown reasons, the body's *immune system* attacks and gradually destroys the receptors in muscles that are responsible for picking up nerve impulses. As a result, affected muscles fail to respond, or respond only weakly, to nerve impulses.

Myasthenia gravis is a rare disease; two to five new cases per 100,000 people are diagnosed annually. It affects more women than men (in a ratio of 3 to 2). Although it can occur at any age, myasthenia gravis usually appears between the ages of 20 and 30 in women and 50 and 70 in men.

SYMPTOMS AND SIGNS

The disease may develop suddenly or gradually. It is extremely variable in the way it affects different people and in how it affects the same person from day to day. The affected muscles become worse with use but may recover completely with rest. Symptom-free periods typically alternate with relapses of the condition.

The eye muscles are the most commonly affected, and most sufferers have drooping eyelids and double vision. Weakness is also common in the muscles of the face, throat, larynx (voice box), and neck. This causes difficulty speaking, so that the voice becomes weak, hoarse, nasal, and slurred toward the end of a conversation. Chewing and swallowing become increasingly difficult as a meal progresses, so that the sufferer may choke or regurgitate food through the nose. Sometimes the jaw must be supported to prevent it from hanging.

In some people, the arm and leg muscles are also affected, producing difficulty combing the hair and climbing stairs. In severe cases of myasthenia gravis, respiratory muscles in the chest may be weakened, causing breathing difficulty.

Infection, stress, menstruation, medications, and other factors can exacerbate the condition.

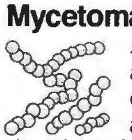
Abnormalities in the thymus gland are present in about three quarters of affected people and, in about 10 to 15 percent of them, a *thymoma* (tumor of the thymus gland) is found.

DIAGNOSIS

The disease is diagnosed by a physical examination, the patient's history, and various tests. The most commonly used diagnostic test involves the injection of a drug called edrophonium into a vein. Within a minute, power is temporarily restored to the weak muscles. Electromyography (see *EMG*), which detects muscle weakness by measuring the muscle's electrical activity, and blood tests that reveal the presence of certain antibodies may also be carried out.

In some patients, mainly those over 40, *CT scanning* may be performed to look for a thymoma.

TREATMENT



In mild cases of myasthenia gravis, regular medication with drugs to facilitate the transmission of nerve impulses to the muscles is often enough to restore the patient's condition to near normal.

In severe myasthenia gravis, thymectomy (removal of the thymus gland) often considerably improves, and sometimes cures, the condition. Otherwise, regular exchanges of the patient's antibody-containing plasma for antibody-free plasma may be carried out; high doses of *corticosteroid drugs*, which block the immune process, may be given.

OUTLOOK

In mild cases the sufferer is able to live a comparatively normal life. In a minority of patients, progression of the disease cannot be halted and paralysis of the throat and respiratory muscles may lead to death.

Mycetoma

A rare tropical infection affecting skin and bone, caused by fungi or by actinomycetes (bacteria that form long chainlike colonies).

The infection is usually confined to one limb and can be highly disfiguring. It produces a hard swelling covered by the openings of multiple drainage channels, through which pus is discharged. The disease organisms form into visible "grains," which are found in the discharge.

Antibiotic drugs are the main treatment if the disease is caused by actinomycetes. Mycetoma caused by fungal infections may be difficult to treat with drugs; surgical removal of diseased tissue may be necessary.

Mycology

The study of *fungi* and *fungal infections*.

Mycoplasma

Any of a group of microorganisms that are the smallest capable of free existence. Mycoplasmas are about the same size as viruses and, like viruses, have no cell wall. However, unlike viruses, mycoplasmas can reproduce outside living cells.

Most types of mycoplasma are harmless to humans, although many cause respiratory diseases in animals such as cattle, sheep, and poultry. One of the species, *MYCOPLASMA PNEUMONIAE*, causes a special form of *pneumonia* (primary atypical pneumonia) in humans. The pneumonia is treated effectively with antibiotics such as tetracyclines.

Mycosis

Any disease caused by a fungus. (See *Fungi; Fungal infections.*)

Mycosis fungoides

A type of *lymphoma* (cancerous spread of lymphoid tissue) that primarily affects the skin of the buttocks, back, or shoulders but can also occur in other sites. The cause of this rare disorder is unknown.

The mildest form appears as a red, scaly, nonitching rash; it may spread slowly or remain unaltered for many years. In the more severe forms of the disease, thickened patches of skin and ulcers may develop and lymph glands may enlarge.

DIAGNOSIS, TREATMENT, AND OUTLOOK

A skin *biopsy* (removal of a small sample of tissue for microscopic examination) is carried out. In mild cases, patients are treated with *PUVA* (*psoralen drugs* plus long-wave ultraviolet light treatment in the A range) or nitrogen mustard applied to the skin. In more severe cases, *anticancer drugs* may be needed.

Mydriasis

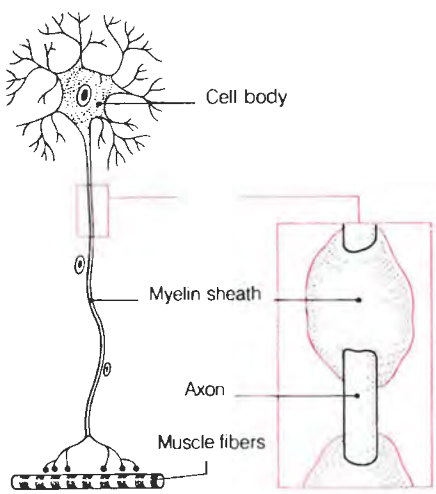
Dilation (widening) of the pupil of the eye. Mydriasis, which occurs naturally in the dark, also occurs if a person is emotionally aroused, after the use of eye drops (such as atropine), and after consumption of alcohol. Adie's syndrome is a benign condition in which one pupil constricts slowly in response to light. The condition may last for years.

Myectomy

Surgical removal of part or all of a muscle. Myectomy may be performed to alter the power of an eye muscle to correct *strabismus* (squint), or to remove a fibroid in an operation called a *myomectomy*. Myectomy is also part of the treatment of severely injured and infected muscles.

Myel-

A prefix that denotes a relationship to bone marrow (as in myeloma, a tumor consisting of bone marrow cells) or to



the spinal cord (as in myelitis, inflammation of the spinal cord). The prefix myelo- is synonymous with myel-.

Myelin

The fatty material, composed of lipid (a fat) and protein, that forms a protective sheath around some types of nerve fiber. Myelin gives the characteristic appearance to the white matter of the brain, which is composed largely of myelinated nerve fibers.

In addition to having a protective function, myelin acts as an electrical insulator, thereby increasing the efficiency of nerve impulse conduction.

Abnormal breakdown of myelin is called *demyelination*. It occurs in some diseases of the nervous system, notably *multiple sclerosis*.

The myelin nerve sheath
The axon is the long conducting fiber of a nerve. To transmit impulses, each nerve requires an insulating myelin sheath

Myelitis

Inflammation of the spinal cord. Myelitis may be the result of a viral infection—for example, *poliomyelitis* (commonly called polio), *measles*, or *herpes simplex*. The illness starts suddenly with headache, fever, neck stiffness, and pain in the back and limbs, which are followed in some cases by muscle pain and weakness, and eventually paralysis.

Transverse myelitis is a type of myelitis in which there is inflammation of the spinal cord around the middle of the back. It may follow a viral illness but often occurs without obvious cause. Common symptoms are back pain and gradual paralysis of the legs. Many people recover, but some are left with spastic paralysis of the involved limbs.

Myelocele

A protrusion of the spinal cord and its meninges (protective coverings) under the skin due to a congenital defect in the vertebral column (see *Spina bifida*).

Myelography

X-ray examination of the spinal cord, nerves, and other tissues within the spinal canal after injection of a substance opaque to X rays.

WHY IT IS DONE

In the past, myelography was often performed to examine the lower spinal nerves when a disk prolapse was suspected; it was also important in diagnosing tumors of the spinal cord, and in looking for damaged nerves after certain injuries. The procedure is being replaced today by newer imaging techniques, such as *CT scanning* and *MRI*.

HOW IT IS DONE

The patient lies facedown on the X-ray table. Using local anesthesia, a *lumbar puncture* is performed; X-ray control is used to guide a fine needle into the fluid-filled space that surrounds the spinal cord and spinal nerves. A small sample of fluid is withdrawn for testing, and the radiopaque dye is introduced. By tilting the patient headdown, the dye can be moved up the spinal canal, and X-ray pictures are taken of areas where damage is suspected. The procedure usually takes 15 to 20 minutes. Afterward, the patient must lie down for a few hours with the head slightly raised.

Myeloma, multiple

See *Multiple myeloma*.

Myelomeningocele

See *Myelocele*.

Myelopathy

A term that refers to any disease of the *spinal cord* or of the bone marrow, such as *multiple myeloma* or *leukemia*.

Myelosclerosis

An increase of fibrous tissue within the bone marrow. It is also known as osteosclerosis or myelofibrosis. Myelosclerosis may occur without any obvious cause (primary myelosclerosis) or may result from some other bone marrow disease (such as *polycythemia* or chronic myeloid *leukemia*). The ability of the bone marrow to produce blood components is impaired. However, this function can be partly taken over by the spleen and the liver.

Primary myelosclerosis is a disease of middle age with a gradual onset. The main symptoms are those of *anemia*, which is caused by impaired red blood cell production by the bone marrow. Enlargement of the spleen, night sweats, itching, loss of appetite, and weight loss are other common symptoms of myelosclerosis. In secondary myelosclerosis, there may be other symptoms connected with the underlying disease.

TREATMENT

Treatment of primary myelosclerosis is aimed at the relief of symptoms, mainly through blood transfusions. Anticancer drugs are of little or no use. Only half of patients survive for more than three years, and acute leukemia develops in a small number.

In secondary myelosclerosis, treatment is of the underlying cause.

Myiasis

An infestation of the skin, deeper tissue, or intestines by fly larvae. Myiasis is primarily restricted to the tropical regions of the world.

TYPES AND SYMPTOMS

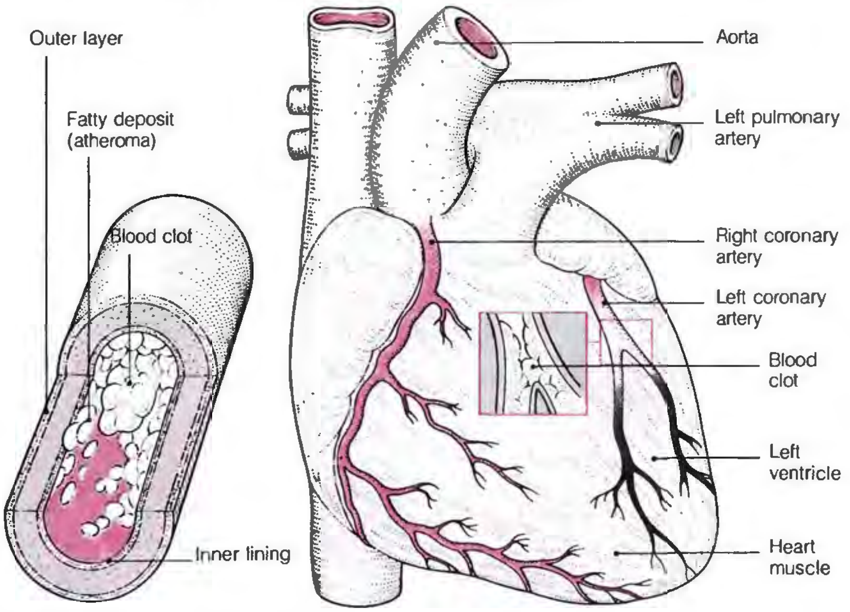
In Africa, the tumbu fly lays eggs on clothing left outside to dry; the larvae that hatch from these eggs penetrate the skin to cause boillike swellings. Various other flies may lay eggs in open wounds, on the skin, or in the ears or nose. Sometimes the larvae penetrate deeply into the tissues, causing considerable destruction. Intestinal infestation can occur after eating contaminated food.

PREVENTION AND TREATMENT

Myiasis can largely be prevented by keeping flies away from food, by covering open wounds, and, in Africa, by thoroughly ironing clothes dried outdoors.

Cutaneous myiasis is treated by placing drops of oil over the swelling caused by the larva. The oil suffocates the larva, which is forced to come to the surface and can be removed with a needle. Infestation in deeper tissues may require surgical treatment. Intestinal myiasis can be adequately treated with a laxative.

Myo-

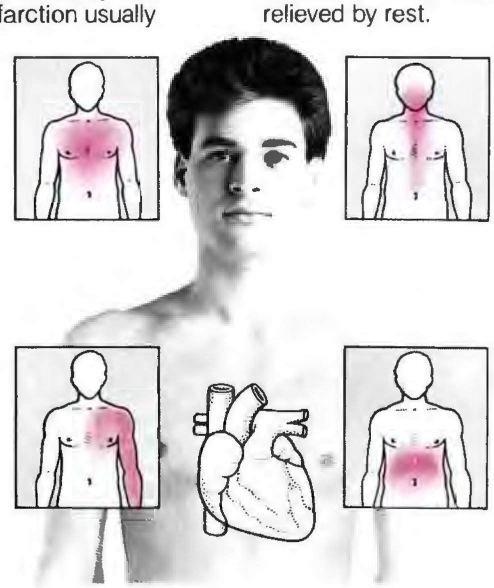


A prefix that denotes a relationship to muscle (as in myocarditis, inflammation of the heart muscle).

Myocardial infarction

Popularly known as a heart attack, sudden death of part of the heart muscle characterized, in most cases,

FEATURES OF MYOCARDIAL INFARCTION



Myocardial infarction, in which an area of heart muscle is deprived of blood supply and suffers tissue death as a result, is a major cause of death in developed countries. Atherosclerosis of the coronary arteries is the cause in most cases of myocardial infarction.

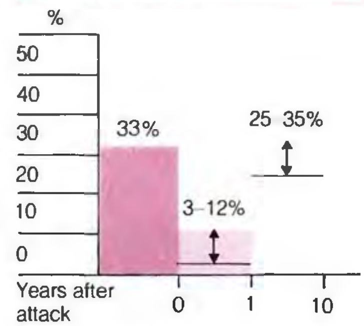
Atherosclerosis
Like all other arteries, the coronary arteries may be affected by atherosclerosis. Patchy plaques of atheroma develop on the inner lining of the arteries, restricting the blood flow and encouraging the formation of blood clots. The clotting results in a sudden stoppage of blood flow to the heart.

PAIN

Many victims of myocardial infarction have a history of angina pectoris, in which the chest pain is relieved by rest. The pain of infarction usually comes on suddenly, and ranges from a tight ache to intense crushing agony. It lasts for 30 minutes or more, and is not relieved by rest.

A central chest pressure, ranging from mild to severe, is common to almost every attack of myocardial infarction from coronary obstruction.

In some cases, pain radiates up into the jaw and through to the back. Sometimes, it occurs only in these places.



In many cases, the pain radiates down the left arm; it may cause a sensation of weakness in the arm muscles.

More rarely, pain may be felt in the upper abdomen. If it occurs only here, it may be mistaken for another disorder.

OUTLOOK AFTER AN ATTACK

Myocardial infarction is fatal within 20 days in about one third of cases, and another 3 to 12 percent of patients die between 20 days and one year of the attack. Some further risk persists for several years, but a significant number of patients (about 30 percent) are still alive 10 years after an attack.

FATALITY RATES

Death within the first 20 days after the attack

Death between 20 days and 1 year after the attack

Death between 1 year and 10 years after the attack

RISK FACTORS

Uncontrollable factors include a family history of heart disease, old age, and being male.

Habitual cigarette smokers have a substantially increased risk of dying from myocardial infarction.

High blood pressure is a major risk factor, and the risk increases the higher the pressure.

The risk of atherosclerosis and coronary heart disease increases dramatically in those who are more than 30 percent overweight.

A raised blood cholesterol content (for which there may be a genetic tendency) increases the risk. A high-fat diet is also a factor.

Physical inactivity is also a major risk factor.

by severe, unremitting chest pain. Each year in the US about 1 million people have a heart attack; attacks are fatal in about one third of cases and are the single most common cause of death in developed countries.

Men are more likely to suffer heart attacks than women, smokers more than nonsmokers, and the children of someone who has died of a heart attack are more likely to die from this cause. Other risk factors include increased age, unhealthy diet, stress, obesity, and disorders such as *hypertension* (high blood pressure), *diabetes mellitus*, and *hyperlipidemia*.

SYMPTOMS AND COMPLICATIONS

The characteristic symptom is sudden pain in the center of the chest (see box on previous page). The victim may also be short of breath, restless, and apprehensive, have cold clammy skin, feel nauseated or vomit, or lose consciousness.

In mild cases, pain and other symptoms are slight or do not develop at all (in which case the attack is known as a silent infarct). The episode passes unnoticed and may be discovered only by subsequent tests.

Damage to the heart muscle may be so severe that it leads immediately to *heart failure* (reduced pumping efficiency of the heart). *Arrhythmias* (abnormal heart rhythms) are common. Most people who die of a myocardial infarction do so within the first few hours due to a type of arrhythmia called ventricular fibrillation, which seriously interferes with the pumping action. However, if the person can be brought to a hospital, arrhythmias can be controlled with drugs or electrical *defibrillation*.

Possible long-term complications include damage to the mitral valve, leading to *mitral insufficiency*, or the development of a weak area in the wall of the heart or in the muscle dividing the two sides of the heart. Complications may require surgery.

DIAGNOSIS

The diagnosis is made from the patient's history and from special tests. Those performed immediately include *ECG* and the measurement of certain enzymes released into the blood from damaged heart muscle. Emergency coronary artery *angiography* may be performed if surgery is being considered.

TREATMENT

If someone is thought to be having a heart attack, a physician or ambulance should be called immediately. Initial treatment may include strong *analgesics* (painkillers) and *oxygen therapy*. *Diuretic drugs* may be given to treat heart failure, which can lead to accumulation of fluid in the lungs. Intravenous fluids may need to be given for shock, and *antiarrhythmic drugs* may be given to control arrhythmias. *Beta-blocker drugs* are given in some cases to reduce the risk of further muscle damage.

In many hospitals, patients who arrive within three to six hours of a heart attack are now treated with *thrombolytic drugs* to dissolve any blood clot. Other new methods of treatment include *angioplasty* (widening of narrowed coronary arteries), which may follow the thrombolytic treatment. *Coronary artery bypass* surgery may be considered.

In the past, it was recommended that patients rest in bed for two weeks or more following an attack. Today, patients are encouraged to be out of bed within four or five days.

It is increasingly common for heart attack patients to be supervised in special hospital coronary care units. The nursing and medical staff are trained to recognize and institute early treatment for arrhythmias, and many patients find the environment reassuring. However, some specialists believe coronary care units are actually more stressful and prefer that some patients, particularly the very elderly, be cared for elsewhere in the hospital or at home.

OUTLOOK

Anyone who has suffered a heart attack has an increased risk of suffering another one in the following few years. The chances of surviving for many years can be improved by attention to risk factors (see table on previous page).

It is important for patients to have their conditions assessed by their physicians at regular intervals for life.

Myocarditis

Inflammation of the heart muscle. The diagnosis of myocarditis is sometimes made after death when a young person has died unexpectedly during vigorous exercise. In such cases the pathologist finds evidence of inflammation, which is usually assumed to be due to a virus infection sometimes preceded by a sore throat or a cold. Myocarditis is a feature of *rheumatic fever*, which is rare today. It may also, in rare cases, be caused by drugs or radiation therapy.

People with virus infections affecting the lungs often have mild myocarditis, which may be detected only by an *ECG*. Rarely, the inflammation causes a serious disturbance of the heart beat, breathlessness, chest pain, *heart failure* (reduced pumping efficiency), and cardiac arrest leading to death. Acute *pericarditis* (inflammation of the outer lining of the heart) often accompanies myocarditis.

Most cases clear up without treatment, although occasionally *corticosteroid drugs* are prescribed to reduce inflammation. It is generally believed that exercise is dangerous for people with myocarditis; most physicians recommend that exercise be avoided until a patient's electrocardiogram results have returned to normal. Anyone with symptoms of a viral infection (such as a sore throat) should avoid strenuous exercise to reduce the risk of myocarditis developing.

In Central and South America, the most common cause of myocarditis is the parasitic infection *Chagas' disease*. Many years after the initial infection, the parasitic organisms can cause extensive damage to the heart muscle, leading to progressive and often fatal heart failure.

Myoclonus

Rapid, uncontrollable jerks or spasm of a muscle or muscles that occur at rest or during movement. Myoclonus may be associated with disease of nerves and muscles. It may occur during an epileptic seizure (see *Epilepsy*) or as a symptom of a brain disorder such as *encephalitis* (inflammation of the brain).

Myoclonus also occurs in healthy people, an example being the limb jump that is sometimes experienced just before falling asleep.

Myofacial pain disorder

See *Temporomandibular joint syndrome*.

Myoglobin

The oxygen-carrying pigment in muscles. It consists of a combination of iron and protein, and gives muscles their red color. Like *hemoglobin* (the oxygen-carrying pigment in red blood cells), myoglobin takes up and then stores oxygen, which it releases when the muscle tissues are in need of oxygen to contract.

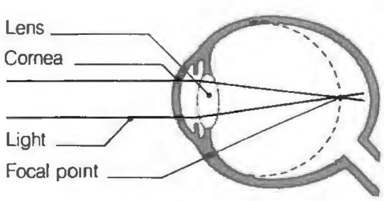
Myoglobinuria is the presence of myoglobin in the urine. Small amounts of myoglobin in the urine may occur when taking prolonged, vigorous exercise. However, severe myoglobinuria is usually caused by the release of myoglobin from a large

area of damaged muscle (which can occur in *crush syndrome*, for instance) and may cause *renal failure*.

Myoma
A noncancerous tumor of muscle. The most common type is a *leiomyoma*, which affects the smooth muscle of the intestine, uterus, and stomach.

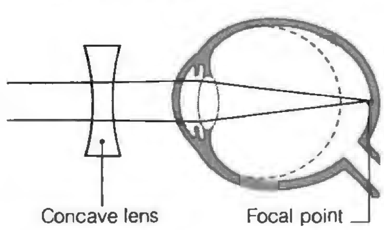
Myomectomy
Surgical removal of a *myoma* (a noncancerous tumor of muscle). The term is commonly applied to the removal of *fibroids* of the uterus.

Myopathy
A disease of muscle, usually degenerative (see *Muscle* disorders box), but sometimes caused by chemical poisoning, by a drug side effect, or by a chronic disorder of the *immune system*. A myopathy is not caused by disease of the nervous system. An example is *muscular dystrophy*.



Myopia
An error of *refraction* in which near objects can be seen clearly while those in the distance appear blurred. Commonly known as nearsightedness, myopia is caused by the eye being too long from front to back. As a result, the corneal lens focuses images of distant objects in front of the retina.

Myopia, which tends to be inherited, usually appears around puberty and increases progressively until the early 20s, when it stabilizes. Myopia that starts in early childhood often progresses into adult life, and may become very severe.



If myopia is detected during a *vision test*, *glasses* or *contact lenses* may be prescribed to reduce the focusing power of the cornea.

THE CAUSE OF MYOPIA

Myopia is caused by the combined power of the cornea and lens being too great in relation to the length of the eyeball.

Uncorrected myopia
With uncorrected myopia, the images of distant objects are focused in front of the retina and appear blurred.

Corrected myopia
To see distant objects clearly, the power of the eye must be reduced by a concave (negative) lens.

Myositis
Inflammation of muscle tissues that causes pain, tenderness, and weakness. Types of myositis include *pleurodynia* (a viral infection affecting muscles around the rib cage), myositis ossificans (in which the damaged muscle is replaced by bone), *polymyositis* (inflammation of muscles throughout the body), and *dermatomyositis* (inflammation of muscles and the presence of a rash). Polymyositis and dermatomyositis are rare *autoimmune disorders*.

Myotomy
A procedure that involves cutting into a muscle. An example is pyloromyotomy—cutting into the muscle surrounding the lower end of the stomach to treat *pyloric stenosis* (narrowing of the stomach's exit).

Myotonia
A rare symptom that describes the inability of a muscle to relax after the need for contraction has passed. Myotonia occurs primarily in two neurological diseases. Myotonia congenita is an inherited condition in which muscle stiffness starts during infancy and usually improves as the person grows older. In myotonic dystrophy, myotonia is combined with muscle weakness. Drugs may help reduce myotonia.

Myringitis
Inflammation of the eardrum. Myringitis occurs, to some degree, in every case of *otitis media*.

Myringoplasty
Surgical closure of a perforation (hole) in the eardrum (see *Eardrum, perforated*) by means of a tissue graft. Myringoplasty is done to improve hearing and, sometimes, to stop a recurrent discharge from the ear. The graft material is usually muscle fascia (fibrous lining) taken from the temple or the thigh.

Myringotomy
A surgical opening made through the eardrum to allow drainage of the middle-ear cavity.

WHY IT IS DONE

Myringotomy is usually performed on children to treat persistent *middle-ear effusion*, in which a sticky secretion fills the middle-ear cavity. The fluid causes hearing loss, which may become permanent if the condition is not treated.

Before the advent of antibiotics, myringotomy was performed to treat acute *otitis media* (middle-ear infection) by releasing the pus and thereby relieving pressure on the eardrum.

HOW IT IS DONE

Using a general anesthetic, a small incision is made in the eardrum and most of the fluid is removed by suction. At the same time, a small tube may be inserted in the hole to allow any remaining and subsequently produced fluid to drain into the outer ear. In most cases the child can leave the hospital the following day. The tube usually falls out a few months later as the hole in the eardrum closes. If the condition has not cleared up, a second operation may be required to insert another tube.

Myxedema
A condition in which there is thickening and coarsening of the skin and other body tissues (most noticeable in the face, where the lips become swollen and the nose thickened). Other symptoms usually include weight gain, hair loss, sensitivity to cold, and mental dullness. Myxedema results from *hypothyroidism* and is most common in adults (especially women) over 40. The term myxedema is sometimes used interchangeably with adult hypothyroidism.

Myxoma
A benign, jellylike tumor composed of soft mucous material and loose fibrous strands. Myxomas usually occur singly, and may grow very large. They usually occur under the skin (typically in the limbs or neck), but may also develop in the abdomen, bladder, or bone. Very rarely, a myxoma may grow inside the heart, which can lead to the formation of thrombi (blood clots) and obstruct blood flow through the heart. In most cases, a myxoma can be successfully removed by surgery. Myxomatosis is a highly infectious viral disease of rabbits in which many myxomas develop throughout the rabbit's body; this disease does not affect humans.

M

N

Nadolol
A *beta-blocker drug* used in the treatment of *hypertension* (high blood pressure), *angina pectoris* (chest pain due to impaired blood supply to heart muscle), certain types of *arrhythmia* (irregularity of the heart beat), and *hyperthyroidism* (overactivity of the thyroid gland).

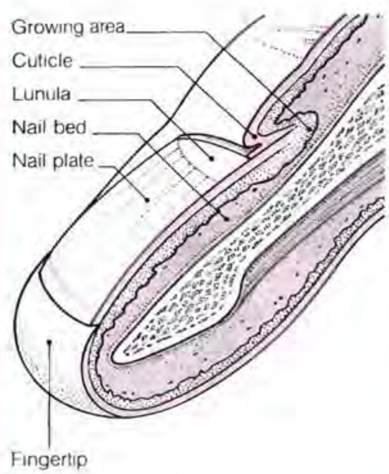
Possible adverse effects are typical of other beta-blocker drugs.

Nail
A hard, curved plate on the fingers and toes composed of *keratin* (a tough protein that is also the main constituent of skin and hair). A fingernail takes about six months to grow from base to tip, although there are seasonal growth variations. Toenails take twice as long to grow.

DISORDERS

The nails are susceptible to damage through injury, usually as a result of crushing or pressure on the nail. Sometimes the nails become abnormally thick and curved—a condition called *onychogryphosis* that mainly affects the big toes of elderly people.

Nails may be damaged by bacterial or fungal infections, especially *tinea* and *candidiasis*. In *paronychia*, the nail folds are infected. The nails may also be affected by skin disease or by more generalized illnesses.



Examples of the effects of skin disease on the nails include pitting of the nails in *alopecia* areata, pitting and *onycholysis* (separation of the nail from its bed) in *psoriasis*, and scarring and onycholysis in *lichen planus*.

Nail abnormalities may be signs of more generalized disease. Brittle, ridged, concave nails are a sign of iron-deficiency *anemia*, onycholysis is seen in *thyrotoxicosis*, and fibrous growths on the nails are a sign of *tuberous sclerosis*. Splinterlike black marks develop beneath the nails (denoting bleeding into the nail bed) in *endocarditis* and *bleeding disorders*.

Abnormalities of nail color may also signify disease. A greenish discoloration may be caused by bacterial infection under the nail, blue nails may be a sign of heart or respiratory disease, and yellow nails that are hard and curved develop in *bronchiectasis* and *lymphedema*. The nails may also be discolored by the color in nail polish and by nicotine staining.

ANATOMY OF A NAIL

The nail bed is the area from which the nail grows. At the base of each nail, a half-moon shape, the lunula, is crossed by a flap of skin, the cuticle. The skin that surrounds the nail is the nail fold. The nail is composed of keratin, a tough protein also found in skin and hair.

DIAGNOSIS AND TREATMENT

Nail disorders are usually diagnosed by inspecting the nails and skin, along with a physical examination if necessary. Laboratory examination of nail clippings may be performed.

Treatment of nail disorders is difficult. Creams and lotions seldom penetrate sufficiently; oral medication may take months to be effective.

Nail-biting
A common activity that does not indicate any underlying medical condition. Many children bite their nails during their first years at school, but most grow out of it. Nail-biting sometimes continues as a nervous habit in adolescents and adults. Persistent nail-biting may make the nails unsightly and cause pain and sometimes bleeding.

Various preparations with an unpleasant taste can be painted on the nails, but many people become accustomed to the taste.

Nalidixic acid
An *antibiotic drug* used to treat and, occasionally, to prevent *urinary tract infection*. Nalidixic acid is effective against some types of bacteria that are resistant to other antibiotics.

Adverse effects include nausea, vomiting, increased sensitivity to sunlight, blurred vision, drowsiness, and dizziness.

Naloxone
A drug that blocks the action of *narcotic drugs*. Naloxone reverses breathing difficulty caused by a narcotics overdose. It is also given to newborn babies affected by narcotics used to aid childbirth and to people who have received high doses of a narcotic drug during surgery.

Possible adverse effects include abdominal cramps, diarrhea, nausea, vomiting, and tremors.

Naltrexone
A drug that blocks the euphoric effects of *narcotic drugs*. Naltrexone is given to addicts who have stopped taking narcotics as part of a supervised detoxification program. It helps prevent the recurrence of *drug dependence*.

Possible adverse effects include nausea, loss of energy, depression, and, in rare cases, liver damage.

Nandrolone
An anabolic steroid (see *Steroids, anabolic*) sometimes used with *growth hormone* in the treatment of *short stature*. Nandrolone is also used to treat certain types of *anemia*.

Possible adverse effects include swollen ankles, nausea and vomiting, jaundice, and aggressive behavior. In men, nandrolone may cause difficulty passing urine; in women, irregular menstruation and abnormal hair growth may occur.

Naphazoline
A *decongestant drug* used in the treatment of allergic *rhinitis*, *sinusitis*, or a common *cold*. Naphazoline is also given to clear bloodshot eyes and to relieve minor eye irritation.

Overuse of nasal preparations containing naphazoline may lead to palpitations, headache, drowsiness, restlessness, and "rebound" congestion (worsening of congestion after drug use is stopped).

Naproxen
A *nonsteroidal anti-inflammatory drug* (NSAID) that is used as an *analgesic* (painkiller) in the treatment of

headache, menstrual pain, and injury to soft tissues (such as muscles or ligaments). It is also used to reduce joint pain and stiffness in *arthritis*.

Possible adverse effects are nausea, abdominal pain, and *peptic ulcer*.

Narcissism

Intense self-love. The term is derived from the Greek myth of Narcissus, who so loved to stare at his own reflection in the water that he fell in and drowned. In *psychoanalytic theory* there is an early stage in childhood development when the ego (self) feels omnipotent. Failure to deal with the frustrations of discovering that this is not so may result in neurosis later.

A narcissistic personality disorder is characterized by an exaggerated sense of self-importance, constant need for attention or praise, inability to cope with criticism or defeat, and poor relationships with other people.

Narcolepsy

A *sleep* disorder characterized by chronic, excessive daytime sleepiness with recurrent episodes of sleep occurring several times per day. Attacks may last from a few seconds to more than an hour and may be mildly inconvenient or severely disabling, often interfering with work and daily life. *Cataplexy* (sudden loss of muscle tone without loss of consciousness) occurs in about three quarters of cases. Other symptoms may include *sleep paralysis* and vivid hallucinations at the onset of sleep or on awakening.

In narcolepsy, the REM (rapid eye movement) state, which normally occurs only during sleep, intrudes into wakefulness. Narcolepsy is often inherited. Treatment usually involves regular naps, along with *stimulant drugs* to control drowsiness and sleep attacks and *antidepressant drugs* to suppress cataplexy.

Narcosis

A state of stupor usually caused by a drug (see *Narcotic drugs*) or other chemical. Narcosis resembles sleep, being marked by reduced awareness and by diminished ability to respond to external stimulation. However, unlike a sleeper, a person in narcosis cannot be roused completely.

Narcotic drugs

COMMON DRUGS	
Codeine	*Meperidine*
Morphine	*Propoxyphene*

A type of *analgesic* (painkiller) used in the treatment of moderate and severe pain. Abuse of narcotic drugs for their euphoric effects often causes *tolerance* (the need for greater amounts to have the same effects) and physical and psychological *drug dependence*.

Nasal congestion

Partial blockage of the nasal passage caused by inflammation of the mucous membrane that lines it. Congestion can be caused by an infection of the nasal passage itself (such as a cold), by an infection that has spread from the sinuses (see *Sinusitis*), or by an allergy (see *Rhinitis, allergic*).

A simple, effective, and time-honored method of alleviating nasal congestion is to inhale the steam from a pot of hot water. This loosens the mucus, which enables the sufferer to blow it out through the nose. *Decongestant drugs* in the form of nasal drops and sprays should be used sparingly since extensive use can make congestion worse. Decongestant tablets and syrups are of doubtful value and may cause drowsiness.

Persistent nasal congestion should be investigated by a physician.

Nasal discharge

The spontaneous emission of fluid from the nose. Nasal discharge is commonly caused by inflammation of the mucous lining and is often accompanied by *nasal congestion*.

In allergic *rhinitis*, the discharge consists of runny, clear mucus. Infection of the nasal passage itself (such as a cold) or infection that has spread from the sinuses (see *Sinusitis*) usually causes a thicker discharge of mucus, often mixed with pus. A newly developed persistent runny discharge may be an early sign of a tumor (see *Nasopharynx, cancer of*).

Bleeding from the nose is usually caused by injury or a foreign body in the nose; it may also be a sign of an underlying bleeding disorder or a tumor (see *Nosebleed*). In rare cases, cerebrospinal fluid may be discharged from the nose as a result of a fracture at the base of the skull.

Nasal obstruction

Blockage of one or both sides of the nasal passage, which interferes with breathing. The most common cause is inflammation of the mucous membrane that lines the passage (see *Nasal congestion*). Other causes include severe deviation of the *nasal septum*, nasal *polyps*, a *hematoma* (a collection of clotted blood) usually caused by injury, and, rarely, a malignant tumor. In children, enlargement of the adenoids is the most common cause of nasal obstruction.

Nasal septum

The central partition inside the nose that divides it into two cavities. The nasal septum consists of cartilage at the front and bone at the rear, both covered by *mucous membrane*.

DISORDERS

Deviated septum (twisting of the septum to one side) may be present from birth or may be caused by a blow to the nose. It is rarely troublesome, but, if breathing is obstructed, the septum can be straightened by surgery.

Injury can also cause a *hematoma* (a collection of clotted blood) to form between the cartilage of the septum and the wall of one nasal cavity, again sometimes obstructing breathing. The hematoma may become infected, causing an *abscess*, which may require surgical drainage. Occasionally, an abscess develops on a child's septum without prior injury.

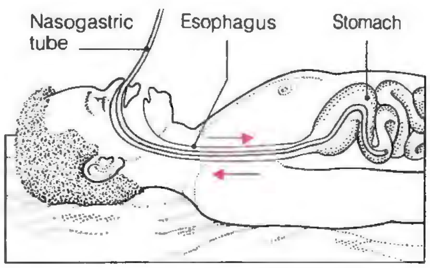
Rarely, a hole may be eroded in the septum by *tuberculosis, syphilis, cocaine*, or *Wegner's granulomatosis*.

Destroyed nasal septum
This photograph of the left nostril was taken with a light shined into the right nostril. There is a hole in the septum.

Nasogastric tube

A narrow plastic tube that is passed through the nose, down the esophagus, and into the stomach.

WHY IT IS USED



One of its most common uses is to suck or drain digestive juices from the stomach when the intestine is blocked (as in *pyloric stenosis*) or is not working properly (as may occur after an abdominal operation). The tube is also used to give liquid nourishment to very ill patients who cannot eat (see *Feeding, artificial*), to obtain specimens of stomach secretions for examina-

N

tion, and to wash out the stomach after a drug overdose or after swallowing a poison (see *Lavage, gastric*).

HOW IT IS USED

Inserting the tube is a quick, simple procedure that causes little discomfort and does not require an anesthetic. The tube is lubricated and passed into one nostril; while the patient swallows, it is slid down the throat and into the stomach. To ensure that the tube is in the stomach, a sample of fluid is withdrawn through a syringe and tested on litmus paper for acidity. The stomach contents may then be sucked out through the syringe or through a suction device, or they may be allowed to drain freely into a container. Fluids for lavage or feeding are introduced through a funnel. If the nasogastric tube is to be left in place for some time, the protruding end of the tube is taped to the face.

Using a nasogastric tube
The tube is passed via a nostril and the esophagus into the stomach. Substances may be delivered into the stomach via the tube, or the stomach contents may be removed through it.

Nasopharynx

The passage connecting the nasal cavity behind the nose to the top of the throat behind the soft *palate*. Part of the respiratory tract, the nasopharynx forms the upper section of the *pharynx*. During swallowing, the nasopharynx is sealed off (to prevent food from entering it) by the action of the soft palate pressing against the back of the throat.

The nasopharynx contains the openings to the *eustachian tubes* (passages connecting the back of the nose to the middle ear) and, in children, the *adenoids*. The adenoids can enlarge to such an extent that the nasopharynx becomes completely blocked, forcing the child to breathe through his or her mouth.

Nasopharynx, cancer of

A malignant tumor that originates in the *nasopharynx* (uppermost part of the throat, behind the nose) and usually spreads to the nasal cavity, nasal sinuses, base of the skull, and lymph nodes in the neck. Cancer of the nasopharynx is rare in the West but common in the Far East; it is most common between the ages of 40 and 50 and affects twice as many men as women. One cause is believed to be the *Epstein-Barr virus*.

SYMPTOMS AND SIGNS

Common first signs are recurrent nosebleeds, a persistently runny nose, and voice change. As the tumor spreads, there may be a bloody discharge from the nose, loss of smell, double vision, deafness, paralysis of one side of the face, and severe facial pain.

DIAGNOSIS AND TREATMENT

The diagnosis is made from a *biopsy* (removal of a small sample of tissue for analysis). X rays may be taken to determine to what extent the cancer has spread.

Treatment is with *radiation therapy*. The outlook depends on when treatment began; one third of sufferers survive for more than five years.

Natural childbirth

See *Prepared childbirth*.

Naturopathy

A form of *alternative medicine* based on the principle that disease is due to the accumulation of waste products and toxins in the body, and that symptoms reflect the body's attempt to rid itself of these substances. Practitioners of naturopathy believe that health is maintained by avoiding anything artificial or unnatural in the diet or in the environment.

Nausea

The sensation of needing to vomit. Although nausea may occur independently of vomiting, the causes are the same (see *Vomiting*).

Navel

A popular term for the *umbilicus*, the depression in the abdomen that marks the point at which the umbilical cord was attached to the fetus.

Nearsightedness

See *Myopia*.

Nebulizer

A device used to administer a drug in aerosol form through a face mask. Nebulizers are used to administer *bronchodilator drugs*, especially in the emergency treatment of an attack of

Using a nebulizer
An electric or hand-operated pump sends a stream of air or oxygen across a chamber containing the required drug. This stream of air disperses the drug into a fine mist, which is then conveyed to the face mask and inhaled by the user.

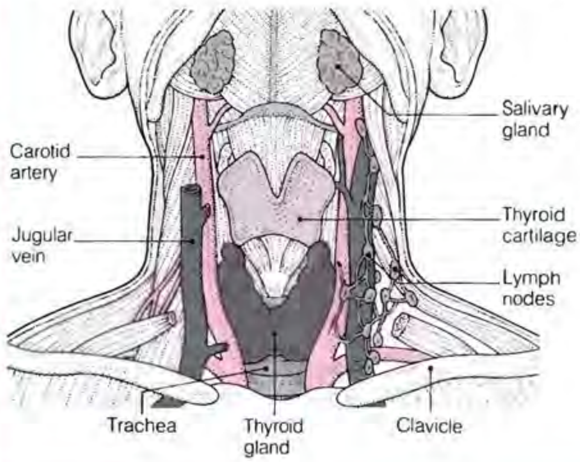
asthma. A nebulizer is much easier to use than a conventional *inhaler* (pressurized aerosol canister).

Neck

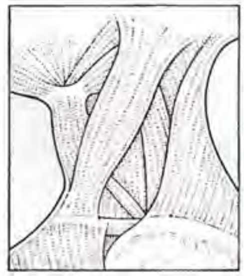
In addition to supporting the head, the neck is the passageway between the head and brain and the body. It thus contains a number of vital structures. Decapitation kills because it cuts through the *spinal cord* (which carries nerve impulses to and from the brain) and because it severs the *trachea* (windpipe), the *esophagus*, and major blood vessels leading to and from the head. Strangulation kills by compressing major blood vessels and by cutting off the air supply to the lungs.

DISORDERS

INJURY *Torticollis* (wryneck), in which the head is twisted to one side, may result from birth injury to a neck muscle or from skin *contracture* after burns or other injuries.



Fractures and *dislocations* of any of the vertebrae in the neck can injure the spinal cord, causing paralysis or even death; *whiplash injuries* can also severely damage the spinal cord.



DEGENERATION The joints between vertebrae may be affected by *cervical osteoarthritis*, causing neck pain, stiffness, and sometimes tingling and weakness in the arm and hand. Similar symptoms may be caused by a *disk prolapse*. In *ankylosing spondylitis*, fusion of the vertebrae may result in permanent neck rigidity.

CONGENITAL DEFECT *Cervical rib* (a small extra rib in the neck) often causes no symptoms until middle age, when it may result in pain, numbness, and a pins and needles sensation in the forearm and hand.

ANATOMY OF THE NECK

The neck contains many important structures, including the larynx, the thyroid and parathyroid glands, many lymph nodes, and the carotid arteries. The upper seven vertebrae of the spine are in the neck; a complex system of muscles is connected to these vertebrae, the clavicles, the upper ribs, and the lower jaw. Contraction of these muscles allows the head to turn and the jaw to open and close.

Muscles of the neck
Muscles on the back and side of the neck support and move the head.

OTHER DISORDERS Because structures in the neck are so closely packed, any condition that causes swelling (such as inflammation, allergy, bleeding, or tumors) may, if large enough, interfere with breathing or swallowing. Enlargement of the lymph nodes usually results from infection, but may be due to other conditions.

Neck pain of unknown origin is very common. As long as neurological symptoms (such as loss of sensation or muscle power) are absent, it is unlikely to be serious. Most sufferers recover within a few weeks.

Neck dissection, radical

A surgical procedure for removing cancerous lymph nodes in the neck. The operation is commonly required as part of the treatment of cancer of the tongue, tonsils, or other structures in the mouth and throat.

A flap of skin on the affected side of the neck is raised (using a general anesthetic) to expose the underlying sternomastoid muscle. The muscle is cut through just above the clavicle (collarbone) and lifted up. The entire lymphatic system in the neck (the vessels as well as the nodes) is then removed, along with the internal jugular vein, lower salivary gland, and other surrounding tissue.

Neck rigidity

Marked stiffness of the neck caused by spasm of the muscles in the neck and spine. Neck rigidity is an important clinical sign of *meningitis* (inflammation of the membranes surrounding the brain and spinal cord). Severe neck rigidity may cause the head to arch backward, especially in babies.

Necrolysis, toxic epidermal

A severe, blistering rash in which the surface layers of the skin peel off, exposing large areas of red raw skin over the body. The effects of toxic epidermal necrolysis are similar to those of a severe third-degree burn, with the same potentially serious risks of widespread infection and loss of body fluid and salts from the exposed body surface.

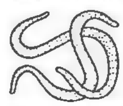
In newborn babies, the condition is usually caused by staphylococci (a type of bacteria) and is called the scalded skin syndrome. Treatment is with antibiotic drugs and sometimes intravenous fluid replacement.

In adults, the most common cause of toxic epidermal necrolysis is an adverse reaction to a drug, particularly a barbiturate, sulfonamide, or penicillin. The condition usually clears up when use of the drug is discontinued. Intravenous fluid replacement is sometimes necessary.

Necrophilia

A rare sexual perversion in which orgasm is achieved by sexual acts, either heterosexual or homosexual, with dead bodies.

Necropsy



A little-used alternative medical term for an *autopsy* (postmortem examination of a body).

Necrosis

The death of tissue cells. Necrosis can occur as a result of *ischemia* (inadequate blood supply), which may lead to *gangrene*; infection (such as *tuberculosis*); or damage by extreme heat or cold, noxious chemicals (such as acids), or excessive exposure to X rays or other forms of radiation.

The appearance of dead tissue depends on the cause of the necrosis and, usually, on the type of tissue affected. For example, in necrosis due to tuberculosis, the dead tissue is soft, dry, and cheeselike; fatty tissue beneath the skin that has died as a result of damage or infection develops into tough scar tissue that may form a firm nodule.

Nematodes

The scientific name for a group of cylindrically shaped worms, some of which can be parasites of humans. (See *Roundworms*.)

Neologism

The act of making up new words that have a special meaning for the inventor. The term also refers to the invented words themselves. While inventing words is often considered a creative act in novelists and poets, persistent neologism is a sign of *schizophrenia*, in which it occurs with other disordered thoughts.

Neomycin

An *antibiotic drug* used in the treatment of ear, eye, and skin infections, often in combination with other drugs. Neomycin is given to treat and sometimes prevent some infections of the intestine. It is also used in the treatment of *hyperlipidemia* (high lipid levels in the blood).

Possible adverse effects include rash, itching, diarrhea, nausea and vomiting, hearing loss, dizziness, and ringing in the ears.

Neonate

A newly born infant (see *Newborn*).

Neonatologist

A specialist in the care of newborn babies and their special problems. Problems may be short-term (such as those associated with premature or low-weight babies) or lifelong (such as

N

spina bifida). The neonatologist cares for the baby for the first four weeks of life. After this time, the child's medical care becomes primarily the responsibility of a *pediatrician*.

Neonatology
The branch of *pediatrics* concerned with the care of newborn infants and the treatment of their disorders. (See also *Neonatologist*.)

Neoplasia
A medical term for *tumor* formation, characterized by a progressive, abnormal multiplication of cells. The term neoplasia does not necessarily imply that the new growth is *malignant*; *benign* tumors also develop as a result of neoplasia.

Neoplasm
A medical term for a *tumor* (any new, abnormal growth). Neoplasms may be *malignant* or *benign*.

Neostigmine
A drug used in the treatment of *myasthenia gravis* (a rare autoimmune disorder that causes muscle weakness). Neostigmine is also given to treat abnormal retention of urine (see *Urine retention*) and paralytic *ileus* (temporary paralysis of the intestine).

Neostigmine works by increasing the activity of *acetylcholine*, a *neurotransmitter* (chemical released from nerve endings) that stimulates the contraction of muscles.

Possible adverse effects include nausea and vomiting, increased salivation, blurred vision, diarrhea, abdominal cramps, sweating, muscle cramps, twitching, and rash.

N

Nephrectomy
Surgical removal of one or both of the *kidneys*.

WHY IT IS DONE
One of the most common reasons for nephrectomy is to remove a malignant tumor (see *Kidney cancer*). A kidney may also be removed if it is not functioning normally due to infection or the presence of stones (see *Calculus, urinary tract*), or is causing severe *hypertension* (high blood pressure). Nephrectomy may also be necessary if a kidney is so badly injured that bleeding cannot be stopped.

HOW IT IS DONE
Nephrectomy is carried out using general anesthesia. The patient lies on his or her side, bent sharply at the waist over an angled operating table. An incision is made along the lower edge of the ribs, from the spine at the back to the front of the abdomen to expose the kidney. The *ureter* and renal blood vessels are tied off, and the kidney is removed. The incision is stitched up after insertion of a drainage tube, which is left in position for 24 to 48 hours.

OUTLOOK
A person's kidney function becomes virtually normal about six months after removal of a single kidney because the remaining kidney (providing it is healthy) takes over the entire work load. If both kidneys are removed, the patient requires *dialysis* or a *kidney transplant*.

Nephritis
Inflammation of one or both kidneys. Nephritis may be caused by infection (see *Pyelonephritis*), by abnormal responses of the *immune system* (see *Glomerulonephritis*), and by metabolic disorders, such as gout. (See also *Kidney* disorders box.)

Nephroblastoma
See *Kidney cancer*.

Nephrocalcinosis
The deposition of calcium within the substance of one or both kidneys. Nephrocalcinosis is not the same as kidney stones (see *Calculi, urinary tract*), in which calcium particles develop within the drainage channels of the kidney.

Nephrocalcinosis may occur in any condition in which the blood level of calcium is raised. These conditions include *hyperparathyroidism* (overactivity of the parathyroid gland) and *renal tubular acidosis* (in which the kidney produces urine of lower than normal acidity). Nephrocalcinosis may also develop as a result of taking excessive amounts of certain *antacid drugs* or *vitamin D*.

Treatment is of the underlying cause to prevent further calcification.

Nephrolithotomy
The surgical removal of a *calculus* (stone) from the kidney by cutting through the body of the kidney. Nephrolithotomy can be achieved through an abdominal incision, or through a puncture incision made through the skin in the back and directly into the kidney (percutaneous nephrolithotomy). Instruments allow the stone to be grasped or fragmented and withdrawn.

A more straightforward method of stone removal is *pyelolithotomy*, in which the stone is removed through a cut at the junction between the kidney and ureter.

An alternative approach to dealing with kidney stones is to pulverize them by means of ultrasonic waves (see *Lithotripsy*). Pulverization may also be achieved with an ultrasonic wand passed through the skin (percutaneous *lithotripsy*).

Nephrologist
A specialist in the diagnosis and treatment of kidney disease.

Nephrology
The medical specialty concerned with the normal functioning of the *kidneys*, and with the causes, diagnosis, and treatment of kidney disease.

Methods of investigating the kidneys include kidney *biopsy*, *kidney function tests*, and *kidney imaging* techniques (such as intravenous *pyelography*). Treatment of kidney disorders includes drugs (to control high blood pressure, inflammation, or infection), surgical intervention (for the treatment of stones and tumors), and *dialysis* or, in some cases, a *kidney transplant* (for the treatment of advanced kidney disease).

Nephron
The microscopic unit of the *kidney* that consists of a glomerulus (filtering funnel) and a tubule. There are about 1 million nephrons in each kidney. The nephrons filter waste products from the blood and modify the amount of salts and water excreted in the urine according to the body's needs.

Nephropathy
Any disease or damage to the kidneys (see *Kidney* disorders box).

Obstructive nephropathy refers to kidney damage caused by a urinary tract *calculus* (stone), tumor, scar tissue, or pressure from an organ blocking urine flow and creating back pressure within the kidney.

Reflux nephropathy refers to kidney damage caused by backflow of urine from the bladder toward the kidney. It is caused by failure of the valve mechanism at the lower end of each ureter.

Toxic nephropathy refers to damage caused by various poisons or minerals (such as carbon tetrachloride or lead).

Nephrosclerosis
A process in which normal kidney structures are replaced with scar tissue composed of *collagen*. Nephro-

sclerosis usually represents the final healing stage of any of the conditions that cause inflammation within the kidney. Such conditions include *diabetes mellitus*, *glomerulonephritis*, and chronic *pyelonephritis*.

Nephrosis

See *Nephrotic syndrome*.

Nephrostomy

The introduction of a small tube into the kidney to drain urine to the abdominal surface, thus bypassing the ureter. Nephrostomy is sometimes performed after an operation (typically, removal of a *calculus*) on the ureter or kidney-ureter junction to allow healing to take place.

Nephrotic syndrome

A collection of symptoms and signs that results from damage to the glomeruli (filtering units of the *kidney*) causing severe *proteinuria* (loss of protein from the bloodstream into the urine). Loss of large amounts of protein in the urine lowers the protein content of the blood and results in edema (fluid retention).

CAUSES

Nephrotic syndrome may be caused by *diabetes mellitus*, *glomerulonephritis* (inflammation of the glomeruli), *amyloidosis* (a condition in which amyloid, an abnormal protein, collects in the tissues and organs), severe *hypertension* (high blood pressure), reactions to poisons (including lead, carbon tetrachloride, and poison ivy), and adverse drug reactions.

SYMPTOMS

Edema causes marked swelling of the legs and face. Fluid may also collect in the chest cavity (producing *pleural effusion*) or within the abdomen (causing *ascites*). Anorexia, lethargy, and diarrhea may also occur.

TREATMENT

Treatment is of the underlying condition. A low-sodium diet may be recommended, and *diuretic drugs* may be given to reduce edema. If the plasma protein concentration is particularly low, protein may need to be given intravenously.

Nerve

A bundle of nerve fibers that travels to a common location. Nerve fibers, also called axons, are the filamentous projections of many individual *neurons* (nerve cells).

The most obvious nerves in the body are the peripheral nerves, which extend from the central nervous system (CNS), consisting of the brain and spinal cord, to other parts of the body. Apart from the *optic nerves*, most nerve fiber bundles within the brain and spinal cord are referred to as nerve tracts or nerve pathways rather than simply "nerves."

STRUCTURE

Including optic nerves, there are 12 pairs of *cranial nerves* (which link directly to the brain) and 31 pairs of *spinal nerves* (which join the spinal cord)—all are peripheral nerves.

In the shoulder and hip regions, the spinal nerves join to form the main nerves to the limbs, such as the median nerve in the arm and the sciatic nerve in the leg. Most nerves divide at numerous points along their length to send branches to all parts of the body, particularly to the sense organs, skin, skeletal muscles, internal organs, and glands.

FUNCTION

Nerve fibers may have a sensory function, carrying information from a receptor or sense organ at the far end of the nerve toward the CNS, or a motor function, carrying instructions from the CNS to a muscle or a gland. Messages are carried by electrical impulses propagated along the fibers. Some nerves carry only sensory or motor fibers, but most carry both.

Nerve functioning is sensitive to cold, pressure, and to a wide variety of injuries (see *Nerve injury*). The peripheral nerves can be damaged by infection, inflammation, poisoning, nutritional deficiencies, and metabolic disorders (see *Neuropathy*).

Nerve block

The injection of a local anesthetic into or around a nerve to produce anesthesia (loss of sensation) in a part of the body supplied by that nerve.

WHY IT IS DONE

A nerve block is performed when it is not possible to inject anesthetic directly into the tissues that are being treated because the area is painfully inflamed or because there is a risk of spreading infection. Nerve block may also be used to anesthetize a large area, or an area not suited for injection because it is deep within the body or is covered with bone.

HOW IT IS DONE

The local anesthetic is injected at an accessible area into or around the nerve at a point remote from the area to be treated (e.g., the palm of the hand may be anesthetized by injecting points up the arm, thus blocking the ulnar and median nerves).

A nerve may be blocked as it leaves the spinal cord, such as in *epidural anesthesia* (used in childbirth) and in *spinal anesthesia* (used mainly for surgery of the lower abdomen and limbs). In a caudal block, anesthetic is injected into nerves leaving the lowest part of the spinal cord; it produces anesthesia in the buttock and genital areas. A caudal block is occasionally used for childbirth, especially a forceps delivery. A pudendal nerve block involves injection of nerves passing under the pelvis into the floor of the vagina; it is used for forceps delivery. (See also *Anesthesia, local*.)

Nerve injury

A cut or crush injury to a nerve that severs some or all of its individual conducting fibers. Surgical repair is the only treatment for a severed nerve, and only the peripheral nerves (those outside the brain and spinal cord) are amenable to such repair. (See *Neuropathy* for nerve damage from causes other than injury.)

CRUSH INJURIES

In a crush injury, individual fibers within a peripheral nerve may be severed while the nerve trunk itself remains intact. The severed fibers degenerate on both sides of the injury, leading to loss of power in the muscles and loss of sensation in the skin area supplied by the fibers. However, if the ends are still aligned, new fibers can regenerate along the channels left by the degenerated fibers. These fibers begin to grow within a few days after an injury and advance at a rate of about 1 inch (2.5 cm) per month.

COMPLETE SEVERANCE

Total severance of a nerve can result from accidental contact with powered devices (such as rotary saws and propellers), from knife and bullet wounds, or from other penetrating injuries (such as from flying glass).

If the ends of the cut nerve are separated, the fibers try to regenerate but, in the absence of directing channels, they simply bunch up to form a lump of tissue; there is no recovery of function. It is therefore essential in the surgical repair of cut nerves to ensure that the ends are meticulously brought together and stitched into place. This is achieved with *microsurgery* and delicate sutures and needles.

Even with the best surgical repair, recovery is rarely complete. While the fibers with a motor function are regenerating, the paralyzed muscles are kept healthy and free from *contractures* by constant *physical therapy*.

N

Regenerating nerve fibers sometimes pass down the wrong channels; as a result, when function is restored, actions may differ from what was intended (for example, an attempt to move the index finger may move the middle finger as well). Movement skills and the interpretation of sensations may need to be relearned.

BRAIN AND SPINAL CORD INJURY

Nerve tracts within the brain and spinal cord are structurally different from the peripheral nerves, and severed fibers there do not regenerate. For example, it is impossible for vision to be restored if the *optic nerves* are cut.

Nerve, trapped

Compression or stretching of a nerve, causing numbness, tingling, weakness, and sometimes pain in the area supplied by the nerve.

Common examples of a trapped nerve include *carpal tunnel syndrome*, in which symptoms appear in the thumb, index, and middle fingers as a result of pressure on the median nerve as it passes through the wrist; a prolapsed disk (see *Disk prolapse*), in which pressure on the nerve root leading from the spinal cord produces symptoms in the back and legs; and *crutch palsy*, in which the radial nerve is pressed against the humerus (upper arm bone), producing symptoms in the wrist and hand.

A damaged nerve may take some time to heal, causing symptoms to persist. Surgical decompression to relieve pressure on the nerve may be necessary in severe cases.

Nervous breakdown

A popular term used to describe unusual behavior that is thought to be part of a crisis of severe anxiety or tension or a psychiatric illness. The term has no technical meaning, but is often applied to people suffering from sudden tearfulness, episodes of shouting and screaming, marked social withdrawal, and concerns about the possibility of illness.

Nervous habit

A nontechnical term for a minor repetitive movement or activity. Sometimes these are involuntary twitches and facial tics, such as in *Gilles de la Tourette's syndrome* and some forms of *dyskinesia*.

Voluntary nervous habits, such as *thumb-sucking* and nose-picking, are common in young children, but usually disappear naturally with time. Also common is *nail-biting*, which often persists into adult life (20 percent of adults bite their nails). Such habits are thought to be a means of releasing inner tension.

All nervous habits increase during tension or anxiety. They may be severe in some forms of *depression*, an *anxiety disorder*, or drug withdrawal.

Nervous system

The body's information-gathering, storage, and control system.

The overall function of the nervous system is to gather information about the external environment and the body's internal state, to analyze this information, and to initiate appropriate responses aimed at satisfying certain drives. The most powerful drive is for survival. Many survival responses, which range from running away from danger to shivering in response to cold, are initiated unconsciously and automatically by the nervous system.

Other drives are more complex, revolving around a need to experience positive emotions (pleasure, excitement) and avoid negative ones (pain, anxiety, frustration).

In carrying out its functions, the nervous system has access to many built-in programs, but it can also improve its performance through *learning*, which relies on *memory*.

STRUCTURE

The nervous system is organized like a computer system that controls a highly complex machine. The central processing unit for the system is the central nervous system (CNS), comprising the brain and spinal cord, which consists of billions of interconnecting *neurons* (nerve cells).

Input of information to the CNS comes from the sense organs. Output (motor) instructions go to the skeletal muscles, muscles controlling speech, internal organs and glands, and the sweat glands in the skin. The cables along which this information is carried are the *nerves* that fan out from the CNS to the entire body. Each nerve is a bundle of the axons (filamentous projections) of many neurons.

In addition to these anatomical divisions of the nervous system, there are various functional divisions. Two of the most important are the *autonomic nervous system*, which is specifically concerned with the automatic (unconscious) regulation of internal body functioning, and the somatic nervous system, which controls the skeletal muscles responsible for voluntary movement.

FUNCTION

The nervous system functions largely through automatic responses to various stimuli (see *Reflex*), although voluntary (willed) actions can also be initiated through the activity of higher, conscious areas of the brain. Certain higher functions (such as visual perception, memory storage, thought, and speech production) are extremely complex and not understood in detail. Overall, however, all nervous activity is based on the transmission of impulses through complex networks of neurons.

DISORDERS

Disorders of the nervous system may result from damage to or dysfunction of its component parts (see *Brain* disorders box; *Spinal cord*; *Neuropathy*; *Nerve injury*). Disorders may also be due to impairment of sensory, analytical, or memory functions (see *Vision, disorders of*; *Deafness*; *Numbness*; *Smell, loss of*; *Agnosia*; *Amnesia*) or of motor functions (see *Aphasia*; *Dysarthria*; *Ataxia*).

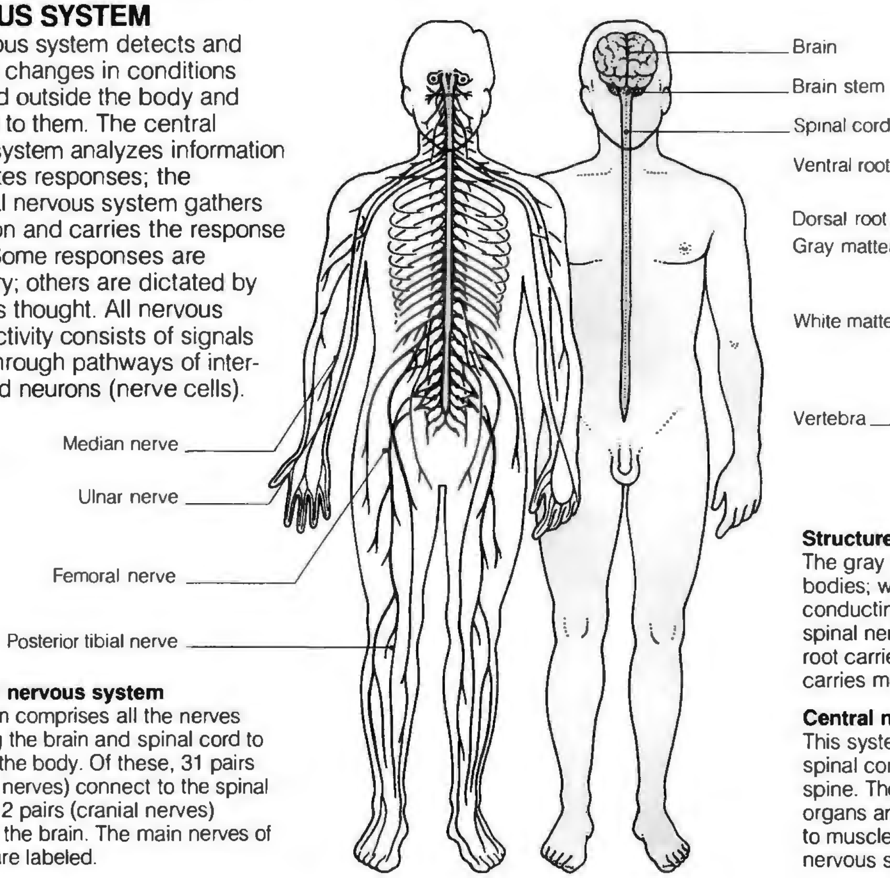
Netilmicin

An *antibiotic drug* used in the hospital to treat serious infection, usually when other antibiotic drugs have been ineffective. Netilmicin is often used to enhance the effects of other antibiotics. In rare cases, it causes damage to the inner ear and the kidneys.

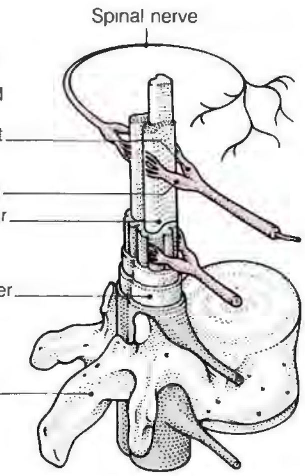
Neuralgia

Pain caused by irritation of, or damage to, a nerve. The pain usually occurs in brief bouts, may be very severe, and can often be felt shooting along the affected nerve.

The neuralgia that often occurs in *migraine* consists of attacks of intense, radiating pain around the eye that can last for up to an hour. Postherpetic neuralgia is a burning pain that may recur at the site of an attack of *herpes zoster* (shingles) for months or even years after the illness.



In glossopharyngeal neuralgia, intense pain is felt at the back of the tongue and in the throat and ear. The structures in this area are served by the glossopharyngeal nerve. The pain may occur spontaneously or be brought on by talking, eating, or swallowing; its cause is generally unknown. The same is true of *trigeminal neuralgia*, a severe paroxysm of pain affecting one side of the face supplied by the trigeminal nerve.

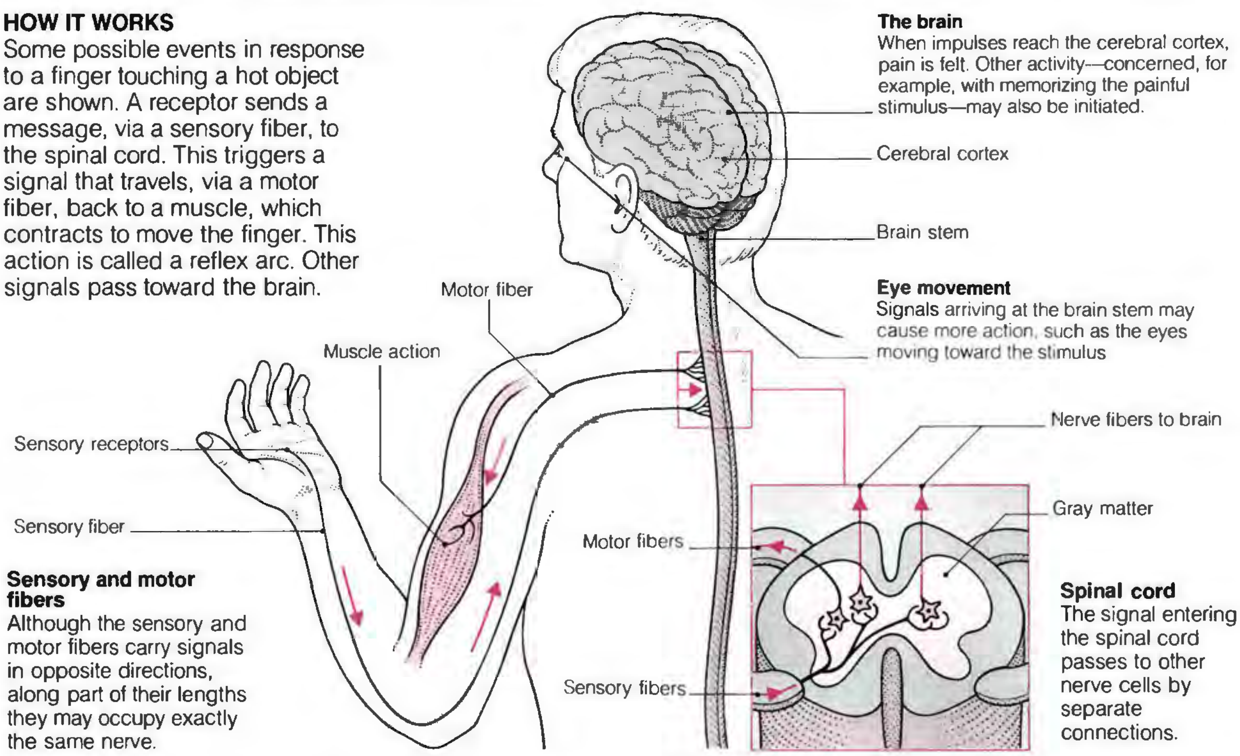


TREATMENT

Glossopharyngeal, trigeminal, and postherpetic neuralgia sometimes re-

NERVOUS SYSTEM

The nervous system detects and interprets changes in conditions inside and outside the body and responds to them. The central nervous system analyzes information and initiates responses; the peripheral nervous system gathers information and carries the response signals. Some responses are involuntary; others are dictated by conscious thought. All nervous system activity consists of signals passed through pathways of interconnected neurons (nerve cells).



Peripheral nervous system
This system comprises all the nerves connecting the brain and spinal cord to the rest of the body. Of these, 31 pairs (the spinal nerves) connect to the spinal cord and 12 pairs (cranial nerves) connect to the brain. The main nerves of the limbs are labeled.

Structure of the spinal cord
The gray matter contains nerve cell bodies; white matter contains their conducting fibers. On joining the cord, spinal nerves split into two. The dorsal root carries sensory fibers; the ventral root carries motor fibers.

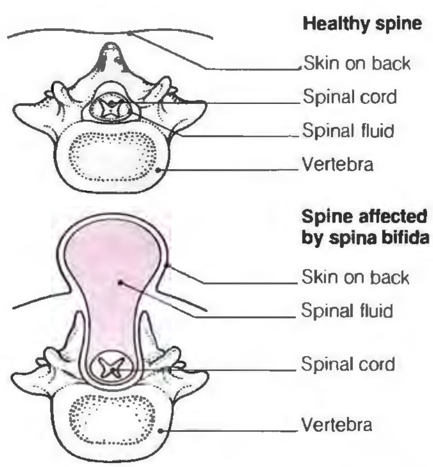
Central nervous system
This system consists of the brain and spinal cord, protected by the skull and spine. The CNS receives input from sense organs and receptors and sends signals to muscles and glands, via the peripheral nervous system.

HOW IT WORKS

Some possible events in response to a finger touching a hot object are shown. A receptor sends a message, via a sensory fiber, to the spinal cord. This triggers a signal that travels, via a motor fiber, back to a muscle, which contracts to move the finger. This action is called a reflex arc. Other signals pass toward the brain.

The brain
When impulses reach the cerebral cortex, pain is felt. Other activity—concerned, for example, with memorizing the painful stimulus—may also be initiated.

Eye movement
Signals arriving at the brain stem may cause more action, such as the eyes moving toward the stimulus



Sensory and motor fibers
Although the sensory and motor fibers carry signals in opposite directions, along part of their lengths they may occupy exactly the same nerve.

Spinal cord
The signal entering the spinal cord passes to other nerve cells by separate connections.

spond to carbamazepine. They may also be relieved by analgesics (painkillers) such as acetaminophen.

Neural tube defect

A developmental failure affecting the spinal cord or brain in the embryo. Very early in fetal development, there is a ridge of neural-like tissue along the back of the embryo. As the fetus develops, this material differentiates into both the spinal cord and body nerves at the lower end and the brain at the upper end. At the same time, the bones that make up the back gradually surround the spinal cord on all sides. If any part of this sequence goes awry, many defects can appear. The worst is total lack of brain (*anencephaly*). Much more common is *spina bifida*, in which the back bones do not form a complete ring to protect the spinal cord. One to two babies per 1,000 born alive in the US have a neural tube defect; many more fetuses are affected but do not survive birth.

Neural tube defect
This defect leads to failure of the bony arch to fuse over the back of the spinal cord, thus causing spina bifida.

Neurapraxia

A type of *nerve injury* in which the outward structure of a nerve appears intact, but in which some of the conducting fibers have been damaged or have degenerated and thus do not transmit signals to muscles.

Neurasthenia

An outdated term, meaning literally "nervous exhaustion." It was once used to describe a number of mental and physical symptoms, including loss of energy, insomnia, aches and pains (especially in the chest and abdomen), *depression*, irritability, and reduced concentration.

Neuritis

Literally, inflammation of a nerve. True nerve inflammation may be caused by infection (e.g., by a virus in *herpes zoster* or a bacterium in *leprosy*). The term neuritis is also often applied to nerve damage or disease from causes other than inflammation. Thus, it has become virtually synonymous with *neuropathy*, a term for all disorders of peripheral nerves.

Neuroblastoma

A tumor of the adrenal glands or sympathetic nervous system (the part of the nervous system responsible for certain automatic body functions, notably the *fight or flight response*). Most neuroblastomas develop in the adrenal glands or in the sympathetic nerves along the back wall of the abdomen. Less commonly, they develop in the sympathetic nerves of the chest or neck, or, very rarely, in the brain.

Neuroblastomas are the most common extracranial (outside the skull) solid tumor of childhood. About 80 percent of cases develop during the first 10 years of life, most commonly in the first four years. The incidence is 8.3 cases per 1 million children.

SYMPTOMS AND SIGNS

The symptoms vary according to the site of the tumor and the extent to which it has spread. Common symptoms include weight loss, general aches and pains, paleness, and irritability. There may also be tumors of the abdomen, neck, eyes, or skin. In some cases, the tumor secretes the hormones *epinephrine* and *norepinephrine*, which may cause diarrhea, high blood pressure, and flushing of the skin.

DIAGNOSIS

The condition is diagnosed from the symptoms and signs, and from X rays, blood tests, and urine tests. In some cases, it may be necessary to perform a biopsy (removal of a small sample of tissue for examination) of the bone marrow and any accessible tumors.

TREATMENT AND OUTLOOK

Treatment consists of surgical removal of the tumor, followed by *radiation therapy* and possibly *anticancer drugs*.

The outlook varies greatly because neuroblastomas range from being relatively harmless to highly malignant. Overall, about one third of those affected survive for at least five years after treatment.

Neurocutaneous disorders

A group of conditions characterized by abnormalities of the skin as well as abnormalities of the nerves and/or the central nervous system.

The best known of these disorders is *neurofibromatosis*, in which there are brown patches on the skin and numerous fibrous nodules on the skin and nerves. Another example is *tuberous sclerosis*, characterized by small skin-colored swellings over the cheeks and nose, mental deficiency, and epilepsy.

Neurodermatitis

An itchy, eczemalike skin condition caused by repeated scratching. (See also *Lichen simplex*.)

Neuroendocrinology

The study of the interactions between the *nervous system* and the *endocrine system*. These systems control internal body functions and the way in which the body responds to the external environment. However, the two systems do not act separately. Hormones produced by the endocrine system can affect nervous system functions, including behavior (for example, sex hormones affect mood and sexual motivation). Similarly, special nerve cells, called neurosecretory cells (found mainly in the *hypothalamus*), can release hormones in response to stimulation by the nervous system; these hormones can, in turn, affect various endocrine glands. Stress is initially perceived by the nervous system but ultimately causes the release of hormones by the pituitary and adrenal glands.

Neuroendocrinological investigations range from recording the electrical activity of neurosecretory cells to experiments showing the relationship between hormones and behavior.

Neurofibromatosis

An uncommon inherited disorder, also called von Recklinghausen's disease. Neurofibromatosis is characterized by numerous soft, fibrous swellings (called neurofibromas) that grow from nerves in the skin and sometimes elsewhere in the body. In addition, there are *café au lait spots* (pale, coffee-colored patches) on the skin of the trunk and pelvis.

SYMPTOMS AND SIGNS

In most cases, neurofibromatosis affects only the skin. However, the swellings and spots may be unsightly. If neurofibromas occur in the central nervous system, they can cause *epilepsy* and other complications, sometimes affecting vision and hearing. Rarely, bone deformities occur.

TREATMENT
Surgical removal of neurofibromas is necessary only if they are causing complications. Anyone who has the disorder, and parents of an affected child, should seek *genetic counseling*.

Neurologist
A specialist in the diagnosis and treatment of diseases and disorders of the nervous system. Neurologists conduct examinations of the patient's nerves, reflexes, motor and sensory functions, and muscles to determine the cause and extent of a problem.

Neurology
The study of the nervous system and its disorders, particularly their diagnosis and treatment (the specialty of *neuropathology* is concerned with the causes and effects of neurological conditions). In addition to a detailed knowledge of the structure and function of the brain, spinal cord, and nerves, neurologists must understand the many conditions that can affect them. To aid in the diagnosis of such conditions, extensive use is made of modern imaging techniques (such as *CT scanning* and *MRI*). Because the nervous system is profusely supplied with blood vessels that may be involved in a neurological disorder, *angiography* (an X-ray imaging technique to show blood vessels) is often used in diagnosis.

In the past, relatively few disorders of the nervous system could be treated effectively. Today, however, with better understanding of the biochemical and structural bases of neurological disorders, new treatments are being developed, including the surgical removal of tumors, repair of damaged nerves (see *Neurosurgery*), transplantation of adrenal tissue in *Parkinson's disease*, and drug treatment of some forms of *dementia*.

Neuroma
A benign tumor of nerve tissue that may affect any nerve in the body. In most cases, the cause is unknown; rarely, a neuroma develops as a result of damage to a nerve.

The symptoms vary according to the nerve involved. In general, there is intermittent pain in parts of the body supplied by the nerve. The same areas may also become numb and weak if the neuroma develops in a confined space and presses on the nerve.

If the symptoms are troublesome, the tumor may be surgically removed. (See also *Acoustic neuroma*.)

Neuron
A nerve cell. There are billions of neurons in the nervous system; they act in various combinations to do everything from writing a symphony to scratching a fleabite. The neurons are analogous to the wires in a complex electrical machine.

There are three main types of neuron—interneurons, motoneurons, and sensory neurons (see illustrated box, overleaf).

FUNCTION
The function of a neuron is to signal, or "fire" (that is, to transmit an electrical impulse along its axon), under certain specific conditions. The electrical impulse causes the release of a neurotransmitter from the axon terminals, which in turn may cause a muscle cell to contract, cause an endocrine gland to release a hormone, or affect the next neuron in a circuit.

Different stimuli excite different types of neurons to fire. Sensory neurons may be excited by physical stimuli, such as light of a certain wavelength, pressure, or cold. The activity of most neurons is controlled by the effects of neurotransmitters released from adjacent neurons.

The ability of a neuron to fire depends on a small difference in electric potential between the inside and outside of the cell. Under the direct influence of an excitatory neurotransmitter, a sudden change occurs in this potential at one point on the cell's membrane. The change, called an "action potential," then flows along the membrane (and thus along the axon of the cell) at speeds up to several hundred miles per hour. A neuron may be able to fire in this way several times every second.

There are also neurotransmitters that stabilize neuronal membranes, preventing an action potential. Thus, the firing pattern of a neuron depends on the balance of excitatory and inhibitory influences acting on it.

LIFE SPAN
If the cell body of a neuron is damaged or degenerates, the cell dies and is never replaced. A baby starts life with the maximum number of neurons; their number decreases continuously thereafter. We seem to be born with an excess number of neurons, so problems arise only when disease, injury, or persistent alcohol abuse affects the central nervous system, dramatically increasing the rate of neuron loss.

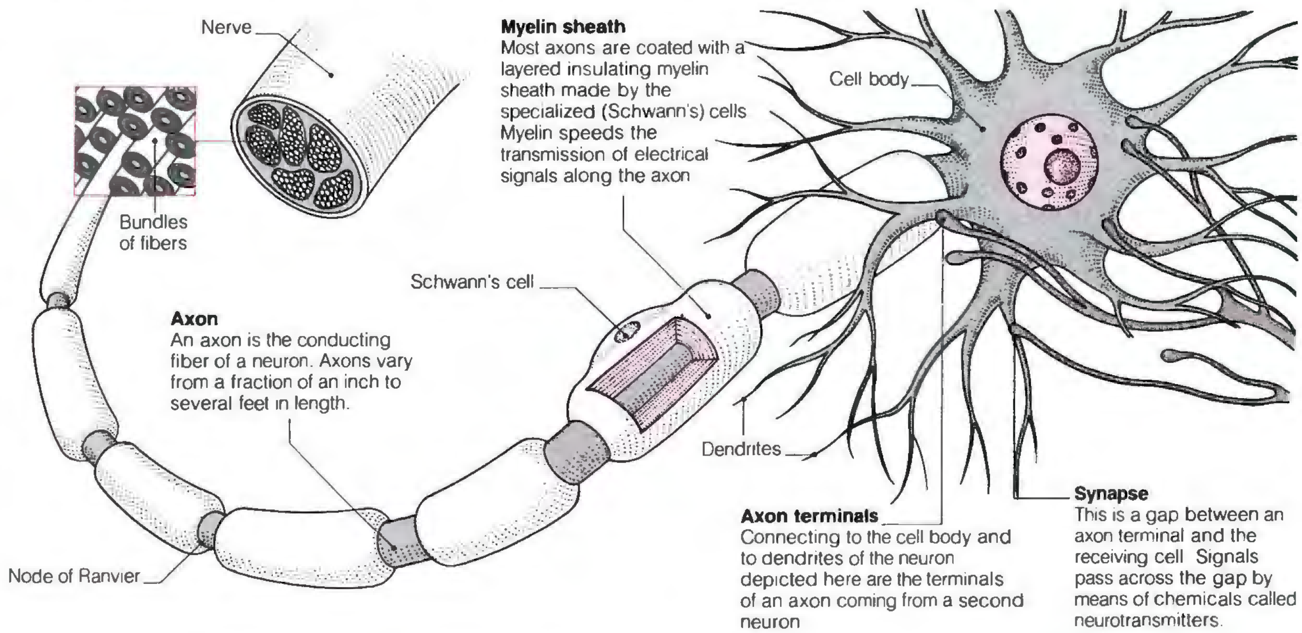
If a peripheral nerve is damaged, its individual fibers can regenerate (see *Nerve injury*; *Neuropathy*).

Neuropathic joint
A joint damaged by a series of injuries, which pass unnoticed because of neuropathy (loss of sensation) affecting that joint. Neuropathic joints develop in a number of conditions, including *diabetes mellitus* and untreated *syphilis*.

When sensation to pain is lost, abnormal stress and strain on a joint do not stimulate the protective reflex spasm of the surrounding muscles; this allows exaggerated movement that can damage the joint. Severe recurrent damage to a joint may lead to *osteoarthritis*, swelling, and deformity; there is minimal pain because of the lack of sensation.

DIAGNOSIS AND TREATMENT
Severe joint degeneration and deformity are visible on X rays. A brace or caliper splint may be necessary to restrict abnormal joint movement. Occasionally, an arthrodesis (joint fusion) is performed. The nerve damage is irreversible.

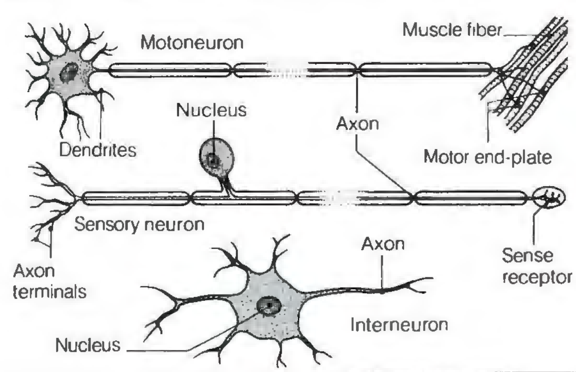
Neuropathology
The study of diseases and disorders of the nervous system. Neuropathologists are concerned principally with the causes and effects of neurological conditions rather than with their diagnosis and treatment (usually handled by a *neurologist* or *neurosurgeon*).



Neuropathy
Disease, inflammation, or damage to the peripheral nerves, which connect the central nervous system, or CNS (brain and spinal cord), to the sense organs, muscles, glands, and internal organs. Symptoms caused by neuropathies include numbness, tingling, pain, or muscle weakness, depending on the nerves affected.

TYPES
Most nerve cell axons (the conducting fibers that make up nerves) are insulated within a sheath of a fatty substance called *myelin*, but some are unmyelinated. Most neuropathies arise from damage or irritation either to the axons or to their myelin sheaths. An axon may suffer thinning, complete loss of, or patchy loss of its myelin sheath. This may cause a slowing or a complete block to the passage of electrical signals.

Various types of neuropathy are described according to the site and distribution of damage. For example, a distal neuropathy starts with damage at the far end of a nerve (farthest from the brain or spinal cord). A symmetrical neuropathy



STRUCTURE OF A NEURON

A neuron (nerve cell) consists of a cell body and several branching projections called dendrites. Every neuron has a filamentous projection called an axon (nerve fiber). Axons vary in length from a fraction of an inch to several feet. An axon branches at its end to form terminals, via which signals are transmitted to target cells, such as the dendrites of other neurons, muscle cells, or glands. Bundles of the axons of many neurons are known as nerves or, within the brain or spinal cord, as nerve tracts or pathways.

BASIC TYPES OF NEURON

Sensory neurons carry signals from sense receptors along their axons into the CNS. Motoneurons carry signals from the CNS to muscles or glands; the axon terminals form a motor end-plate. Interneurons form all the complex interconnecting electrical circuitry within the CNS itself. For each sensory neuron in the body, there are about 10 motoneurons and 99 interneurons.

Brain neurons
Electron micrograph of interneurons in the brain.

affects nerves at the same places on each side of the body. Some neuropathies are described according to their underlying cause (e.g., diabetic neuropathy and alcoholic neuropathy).

The term neuritis is now used virtually interchangeably with neuropathy. Polyneuropathy (or polyneuritis) literally means damage to several nerves; mononeuropathy (or mononeuritis) indicates damage to a single nerve. *Neuralgia* describes pain caused by irritation or inflammation of a particular nerve.

CAUSES

In some cases of neuropathy there is no obvious or detectable cause. Among the many specific causes are *diabetes mellitus*, dietary deficiencies (particularly of B vitamins), persistent excessive alcohol consumption, and metabolic upsets such as *uremia*. Other causes include *leprosy*, *lead poisoning*, or poisoning by drugs.

Nerves may become acutely inflamed. This often occurs after a viral infection (for example, in *Guillain-Barré syndrome*). Neuropathies may result from autoimmune disorders such as *rheumatoid arthritis*, systemic *lupus erythematosus*, or *periarteritis nodosa*. In these disorders, there is often damage to the blood vessels supplying the nerves. Neuropathies may occur secondarily to malignant tumors such as *lung cancer*, or with *lymphomas* and *leukemias*. Finally, there is a group of inherited neuropathies, the most common being *peroneal muscular atrophy*.

SYMPTOMS

The symptoms of neuropathy depend on whether it affects mainly sensory nerve fibers or motor nerve fibers. Damage to sensory nerve fibers may cause numbness and tingling, sensations of cold, or pain, often starting in the hands and feet and spreading toward the body center. Damage to motor fibers may cause muscle weakness and muscle wasting.

Damage to nerves of the autonomic nervous system may lead to blurred vision, impaired or absent sweating, episodes of faintness associated with falls in blood pressure, and disturbance of gastric, intestinal, bladder, and sexual functioning, including incontinence and impotence. Some neuropathies are linked with particular symptoms (for example, very painful neuropathies may arise in diabetes mellitus and in *alcohol dependence*).

DIAGNOSIS

To determine the extent of damage, studies of nerve conduction are performed, along with *EMG* tests, which record the electrical activity in muscles. To determine the cause of neuropathy, *blood tests*, X rays, nerve or muscle *biopsy* (removal of tissue for analysis), and various other tests may be required.

TREATMENT

When possible, treatment is aimed at the underlying cause. For example, in diabetes mellitus, scrupulous attention to the control of the blood sugar level affords the best chances for recovery. Other people may need to stop drinking alcohol, or, if a nutritional deficiency has been diagnosed, may be given injections of vitamins such as thiamine (vitamin B_1).

If treatment is successful and the cell bodies of the damaged nerve cells have not been destroyed, a full recovery from the neuropathy is possible.

Neuropsychiatry

The branch of medicine that deals with the relationship between psychiatric symptoms and distinct neurological disorders. These conditions are usually forms of brain disease, such as *temporal lobe epilepsy*, tumors, or infections. Research and brain imaging are revealing evidence that subtle forms of brain damage underlie certain psychotic illnesses.

Neurosis

A term commonly used to describe a range of relatively mild psychiatric disorders in which the sufferer remains in touch with reality.

Neurotic symptoms are distressing to the afflicted person, who is aware of a change from his or her usual psychological state. By contrast, people suffering from psychotic illnesses do not recognize that they are sick (see *Psychosis*). Neurotic symptoms generally do not lead to distinctly abnormal behavior, although they can severely limit work or social activities. They tend to fluctuate in intensity, often in response to social or personal stresses. No physical abnormality has been shown to underlie them.

The major neurotic disorders are *depression* (the mild form); *anxiety disorders*, including *phobias* and *obsessive-compulsive behavior*; *somatization disorder*; and *dissociative disorders*. *Psychosexual disorders* have recently been included in this category.

Neurosurgeon

A surgeon who operates on the brain, spinal cord, or other parts of the nervous system (see *Neurosurgery*).

Neurosurgery

The specialty concerned with the surgical treatment of disorders of the nervous system. Many generalized nervous system disorders do not respond to surgical treatment, but neurosurgery can deal with most conditions in which a localized structural change interferes with nerve function.

Conditions treated by neurosurgery include tumors of the brain, spinal cord, or meninges (membranes that surround the brain and spinal cord), certain abnormalities of the blood vessels that supply the brain, such as an *aneurysm* (a bulge in a weak point of an artery), bleeding inside the skull (see *Extradural hemorrhage*; *Intracerebral hemorrhage*; *Subdural hemorrhage*), *brain abscess*, some birth defects (such as *hydrocephalus* and *spina bifida*), certain types of *epilepsy*, and nerve damage caused by illness or accidents. Neurosurgeons are also concerned with the surgical relief of otherwise untreatable pain.

Neurosyphilis

Infection of the brain or spinal cord that occurs in untreated *syphilis* many years after the initial infection.

Damage to the spinal cord due to neurosyphilis may cause tabes dorsalis, characterized by poor coordination of leg movements when walking, urinary incontinence, and intermittent pains in the abdomen and limbs. Damage to the brain may cause *dementia*, muscle weakness, and, in rare cases, extensive neurologic damage (when it is called general paralysis of the insane).

Neurotoxin

A chemical that damages nervous tissue. The principal effects of neurotoxic nerve damage are numbness, weakness, or paralysis of the part of the body supplied by the affected nerve. Neurotoxins are present in the venom of certain snakes (see *Snakebites*), and are released by some types of bacteria (such as those that cause *tetanus* and *diphtheria*). Some chemical poisons, such as arsenic and lead, are also neurotoxic.

Neurotransmitter

Although nerve impulses are electrical, the transmission of these impulses from one neuron (nerve cell) to another, or to a muscle cell, is achieved chemically rather than electrically. The chemical that transmits the message is a neurotransmitter. Scores of different chemicals fulfill this function in different parts of the nervous system (see box, overleaf).

Many neurotransmitters are similar to, or identical to, substances used by our bodies as hormones. These neurotransmitters also act as messenger molecules, but are released into the bloodstream to act on their target cells at a distance.

TYPES

One of the most important neurotransmitters is *acetylcholine*. It is released by neurons connected to skeletal muscles (causing them to contract) and by neurons that control the sweat glands and the heart beat. It also transmits messages between neurons in the brain and spinal cord.

Interference with the action of acetylcholine on skeletal muscles is the cause of the disease *myasthenia gravis*; depletion of the nerve cells that release acetylcholine in the brain may be a cause of *Alzheimer's disease*.

Another transmitter, *norepinephrine*, is important in nerve pathways controlling heart beat, blood flow, and response to stress. In addition to being produced in the body by neurons, norepinephrine is made by the *adrenal glands*. Dopamine plays an important role in parts of the brain that control movement, and malfunction of the neurons that respond to dopamine is thought to be important in causing *Parkinson's disease*. *Serotonin* is one of the primary neurotransmitters in parts of the brain concerned with conscious processes.

Over the last 20 years, a whole new family of transmitters, called the neuropeptides, has been discovered. Neuropeptides are small proteins; they are larger molecules than the previously known neurotransmitters, which are all very small molecules. The best studied of these neuropeptides are the *endorphins*, which are used by the brain to control sensitivity to pain.

Nevus

A skin blemish that can be flat, raised slightly above the skin's surface, or on a stalk; a nevus can be colored or not colored, and with or without hair growth. Some nevi are present at birth, others develop at any age.

TYPES

There are two main types of nevus: melanocytic (pigmented) nevi, caused by abnormality or overactivity of skin cells producing the pigment *melanin*, and vascular nevi, caused by an abnormal collection of blood vessels.

The most common type of pigmented nevi are *freckles*, which are small, flat, light to dark brown areas found on any part of the body that is exposed to the sun. A *lentigo* is a pale to brown spot very similar to a freckle. *Café au lait spots* are another type of light brown pigmented nevus.

A mole (a brown to dark brown spot that is not usually present at birth) is another common type of nevus. As a child grows, moles may spread, forming an average number of 15 to 20 per person by adulthood. In rare cases these moles become cancerous (see *Melanoma, malignant*).

Unusual types of moles include hairy, pigmented nevi found on the shoulders of some young men, halo nevi (in which the skin surrounding the nevus lightens in color to give a characteristic "halo" appearance), and juvenile melanomas (see *Melanoma, juvenile*), which are red-brown nevi that occur in childhood.

Some nevi have a bluish coloration; these so-called blue nevi are often found on the backs of the hands of young girls. Most black and Asian infants are born with one or more blue-black spots on their lower backs (see *Mongolian spot*).

Another type of nevus is a vascular nevus (*hemangioma*), caused by an abnormal collection of blood vessels; a port-wine mark is an example.

TREATMENT

Most nevi are harmless and do not require treatment. However, if a nevus suddenly appears, grows, bleeds, or changes color, medical advice should be sought without delay to exclude the possibility of cancer. (See also *Spider nevus*.)

Newborn

An infant at birth and during the first few weeks of life.

INITIAL EXAMINATION

Immediately after birth, the newborn baby is briefly checked by the nurse, midwife, or physician in attendance. This examination includes checking the heart rate with a *stethoscope* and establishing that breathing is normal. The *Apgar score* and other tests are performed to check the baby's health. The baby's sex is noted and a check made for any obvious *birth defect*.

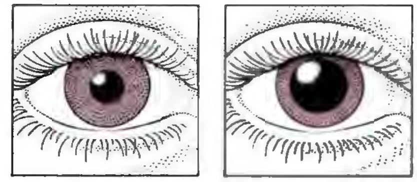
NURSING PROCEDURE

The baby is labeled with his or her name and date of birth; the birth weight, length, and head circumference are recorded. Usually a handprint or footprint is recorded along with the mother's fingerprint or thumbprint for identification.

At birth, the baby is usually covered with vernix, a greasy, white substance that protects it in the uterus. It is wiped off and the baby is wrapped in a blanket and given to the mother to hold and to feed, or placed in a warm crib. If very small or sick, the baby is kept in an *incubator* and treated in a neonatal intensive-care unit or other intensive-care unit.

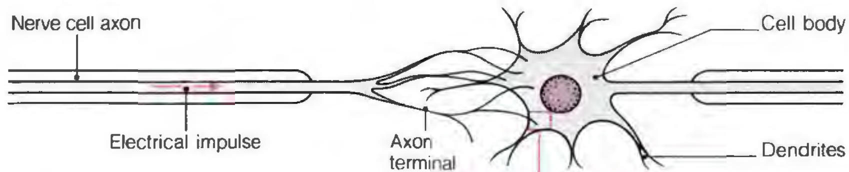
The frequency of the baby's urine and *meconium* (the newborn stool) is recorded. During the second week of life, two special blood tests are performed. The *Guthrie test* is performed on all babies to check for *phenylketonuria*. The other test done at this time checks for *hypothyroidism*.

MEDICAL EXAMINATION



Within 24 hours of birth, the baby is usually given a complete medical examination by his or her physician. This examination assesses the baby's general health and identifies any birth defects (such as cleft palate). The skull, eyes, face, abdomen, heart, spine, hips, genitals, and limbs are checked, and the baby's posture, movements, behavior, cry, reflexes, and responsiveness are noted (see *Reflexes, primitive*).

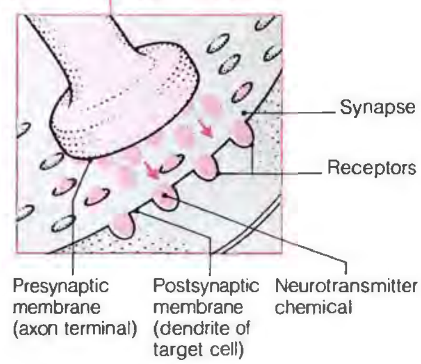
ABNORMALITIES IN THE NEWBORN



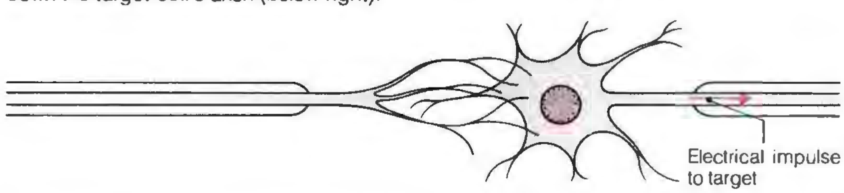
The newborn baby may have a swollen or misshapen head due to pressure during labor. Less com-

HOW NEUROTRANSMITTERS WORK

When an electrical impulse travels down a nerve cell axon, it causes the release of a chemical neurotransmitter at the axon terminals. The chemical is not the same in every case; acetylcholine, norepinephrine, dopamine, and serotonin are all important examples.



Example of neurotransmitter activity
Neurotransmitters enable the pupil to change size in different light conditions.



1 The impulse travels down the neuronal axon (above), from the cell body toward the axon terminals; neurotransmitter is released from tiny swellings, called synaptic knobs, at the axon terminals.

2 The neurotransmitter crosses the gap, or synapse, to the surface membrane of the target cell (right), where it binds to a protein called a receptor.

3 If sufficient target cell receptors are activated by neurotransmitter binding, an impulse is initiated and passes in turn down the target cell's axon (below right).

monly, there may be more notable evidence of *birth injury*, such as *cephalhematoma* (swelling of the scalp caused by bruising around the skull). Most problems caused by the pressure of delivery resolve themselves within a few days.

Jaundice is extremely common in the newborn, especially if the baby is breast-fed. Usually appearing on the second or third day, the jaundice generally disappears over the next few days. In most cases, jaundice in the newborn is harmless. However, it may be serious if it appears during the first 24 hours or occurs in a very premature infant.

Some newborn girls have slight vaginal bleeding or discharge, and babies of either sex may have enlargement of the breasts. These harmless conditions are caused by maternal sex hormones that reached the fetus through the placenta. Any extra hormones soon leave the baby's body.

The umbilical cord, which may be painted with a dye to prevent infection, usually dries and drops off within a week or so of birth. Serious infections of the cord stump can occur.

Minor, harmless abnormalities of the newborn include *milia* (tiny, white spots on the face), *hemangioma*, *mongolian spot*, and *urticaria* of the newborn (a blotchy, red rash that occurs around the second day). See also *Prematurity*; *Postmaturity*.

Niacin
See *Vitamin B*.

Nickel
A metallic element that is present in the body in minute amounts. Its exact role is poorly understood. Nickel is thought to activate certain *enzymes* (substances that promote biochemical reactions). It also may play a part in stabilizing chromosomal material in the nuclei of cells.

Disease due to a deficiency of nickel is unknown. However, excessive exposure to it—which occurs most commonly in industrial workers—may cause *dermatitis* (inflammation of the skin) or, rarely, *lung cancer*.

Niclosamide
An *antihelmintic drug* used in the treatment of *worm infestation*. Niclosamide acts on tapeworms in the intestine, causing them to loosen their grip and be passed out of the body in the feces.

Adverse effects are uncommon and are typical of those produced by other antihelmintic drugs.

Nicotine

A drug in tobacco that acts as a stimulant and is responsible for dependence on tobacco. The drug has no medical use, but certain of its derivatives are used as pesticides.

After inhalation, the nicotine in tobacco smoke passes rapidly into the bloodstream. Nicotine in chewing tobacco is absorbed more slowly through the lining of the mouth. Once in the bloodstream, the drug acts on the nervous system until it is eventually broken down by the liver and excreted in the urine.

EFFECTS
Nicotine acts primarily on the *autonomic nervous system*, which controls involuntary body activities such as the heart rate. The effects of the drug vary from one person to another, and also depend on dosage and past usage. In someone unused to smoking, even a small amount of nicotine may slow the heart rate and cause nausea and vomiting. However, in habitual smokers, the drug increases the heart rate, narrows the blood vessels (the combined effect of which is to raise blood pressure), and stimulates the central nervous system, thereby reducing fatigue, increasing alertness, and improving concentration.

Regular tobacco smoking results in tolerance to nicotine, so that a higher intake is needed to bring about the same effect. However, this process is much less notable with tobacco than with other addictive drugs.

NICOTINE AND DISEASE
Although it is the tar in tobacco smoke that damages lung tissue and causes lung cancer, tobacco smoking is also clearly associated with *coronary heart disease*, *peripheral vascular disease*, and other cardiovascular disorders. It is uncertain whether these disorders are caused by the nicotine or by the carbon monoxide content of the smoke.

Excessively large amounts of nicotine can cause poisoning, which may result in vomiting, seizures, and, very occasionally, death.

WITHDRAWAL
Because most smokers are physically dependent on nicotine, stopping smoking often causes withdrawal symptoms, such as drowsiness, headaches, fatigue, and difficulty concentrating. To reduce these symptoms in a person who is trying to stop smoking, a physician may prescribe nicotine chewing gum, which has a less harmful effect on the circulatory system. (See also *Tobacco smoking*.)

Nicotinic acid
See *Vitamin B*.

Nifedipine
A *calcium channel blocker* used mainly to prevent and treat *angina pectoris*. It is also often used to treat *hypertension* (high blood pressure) and disorders affecting the circulation, such as *Raynaud's disease*.

Possible adverse effects are *edema* (fluid retention), flushing, headache, and dizziness.

Night blindness
The inability to see well in dim light. Many people with night blindness show no discernible eye disease. In other people, the condition may be an inherited functional defect of the retina or an early sign of *retinitis pigmentosa*. Night blindness is sometimes caused by vitamin A deficiency.

Nightmare
An unpleasant vivid dream, often accompanied by a sense of suffocation. Nightmares occur during REM (rapid eye movement) *sleep*, in the middle and later parts of the night, and are often clearly remembered if the dreamer awakens completely.

Nightmares are very common, especially in children aged 8 to 10. They are particularly likely to occur when the child's breathing is slightly difficult because of a cold or illness, or when there is anxiety over separation from parents or home. In adults, nightmares may be a side effect of certain drugs, including *beta-blocker drugs* and *benzodiazepine drugs*. Traumatic events (such as accidents, torture, or prolonged imprisonment) seem to be particularly associated with disturbing and repeated nightmares. However, there is no specific relationship to psychiatric illness.

Nightmares should not be confused with hypnagogic *hallucinations*, which occur while falling asleep, or with *night terror*, which occurs in NREM (nonrapid eye movement) sleep and is not remembered the next day.

Night terror
A disorder, occurring mainly in children, consisting of abrupt arousals from sleep in a terrified state. Night terror (also called sleep terror) usually starts between the ages of 4 and 7, and gradually disappears in early adolescence. Episodes occur during NREM (nonrapid eye movement) *sleep*, usually half an hour to three and a half hours after falling asleep.

Sufferers awaken screaming in a semiconscious state and remain frightened for some minutes. They do not recognize familiar faces or surroundings, and usually cannot be comforted. Physical signs of agitation, such as sweating or an increased heart rate, are also common. Gradually, the sufferer falls back to sleep and has no memory of the event the next day.

Though distressing to parents, night terror in children has no serious significance. In adults, it is likely to be associated with an *anxiety disorder*.

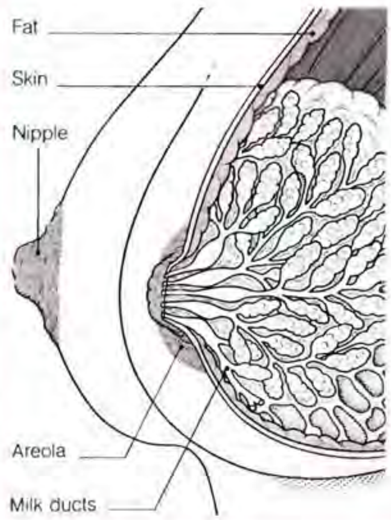
NIH

The abbreviation for the National Institutes of Health. The institutes are a part of the Department of Health and Human Services and comprise a research hospital, a computerized medical library, and 11 of the largest and best-financed research organizations in the world. One of them concentrates on cancer; the others have broader charters—the National Institute of Allergy and Infectious Diseases, for example, and the National Heart, Lung, and Blood Institute. The major focus of medical and dental research in the US, the NIH finance additional research programs in universities, hospitals, and other nongovernment institutions.

Nipple

The small prominence at the tip of each breast. Each of a woman's nipples contains tiny openings through which milk can pass. The nipple and the surrounding areola are darker than the surrounding skin, darkening more and increasing in size during pregnancy. Muscle in the nipple allows it to become erect.

DISORDERS



Structural defects of the nipple are rare. One or both nipples may be absent, or there may be additional nipples along a line extending from the armpit to the groin.

An inverted nipple is usually an abnormality of development. It can be corrected by drawing out the nipple between finger and thumb daily for several weeks. Inversion of a previously normal nipple in an adult is much more significant and may be due to *breast cancer*.

Cracked nipples are common during the last months of pregnancy and during breast-feeding. Daily washing, drying, and moisturizing of the nipple can help prevent it. In addition to causing discomfort, cracks may lead to infective *mastitis*.

LOCATION OF THE NIPPLE

The protrusion at the tip of the breast, surrounded by the areola. Milk ducts emerge at the nipple.

Papilloma of the nipple is a benign swelling attached to the skin by a stalk. *Paget's disease of the nipple* appears initially as persistent eczema of the nipple. It is caused by a slowly growing cancer arising in a milk duct, and surgical treatment is required.

Discharge from the nipple occurs for a variety of reasons. A clear, straw-colored discharge may develop in early pregnancy. A milky discharge may occur after the period of breast-feeding is over. *Galactorrhea* (discharge of milk in someone who is not pregnant or breast-feeding) may be caused by a hormone imbalance; rarely, it may be due to a galactocele (a cyst under the areola). A discharge containing pus indicates a breast *abscess*. A bloodstained discharge may be due to mammary dysplasia (abnormal tissue), chronic mastitis, or cancer.

Nit

The egg of a louse. Both head lice and pubic lice produce eggs, which they glue to the base of hairs growing from their host's head or pubes. The nits are tiny—about one fiftieth of an inch (0.5 mm) in diameter—and yellow (newly laid) or white (hatched). They hatch within eight days, and the empty eggshells are carried outward as the hair grows.

Louse infestations are often diagnosed from the presence of nits. The distance from the base of hairs to the furthest nits provides a rough approximation of the duration of the infestation. (See *Lice*; *Pubic lice*.)

Nitrate drugs

COMMON DRUGS
Isosorbide dinitrate *Nitroglycerin*

A group of *vasodilator drugs* used in the treatment of *angina pectoris* (chest pain due to impaired blood supply to heart muscle) and severe *heart failure* (reduced pumping efficiency).

Possible adverse effects of nitrate drugs include headache, flushing, and dizziness. *Tolerance* (the need for greater amounts of the drug to have the same effect) may develop when the drug is used regularly.

Nitrites

Salts of nitrous acid (a nitrogen-containing acid). Some of these chemicals, notably sodium nitrite, are added to certain foods in small quantities (mainly meat products such as sausages) because they act as preservatives and destroy bacteria that cause *food poisoning*. In large amounts, nitrites can cause dizziness, nausea, and vomiting.

Within the intestine, nitrites are converted to substances called nitrosamines. In laboratory tests, nitrosamines have been shown to cause cancer in animals. However, there is no conclusive proof that they have the same effect in humans or that eating food containing nitrites is harmful to health.

Nitrofurantoin

An *antibacterial drug* used in the treatment of *urinary tract infection*.

Nitrofurantoin should be taken with food to reduce the risk of irritating the stomach, which can prompt abdominal pain and nausea. More serious adverse effects, such as breathing difficulty, numbness, and jaundice, are rare.

Nitrogen

A colorless, odorless gas that makes up 78 percent of the Earth's atmosphere. Atmospheric nitrogen has no biological action, although, in scuba diving, bubbles of nitrogen gas may form in body fluids if a diver ascends to the surface too rapidly, causing the condition commonly called the "bends" (see *Decompression sickness*).

Although nitrogen gas cannot be utilized by the body, compounds of nitrogen are essential to life. Probably

the most important of such compounds are *amino acids*, the building blocks of *proteins*, which represent the fundamental structural substances of all cells and tissues. Because humans cannot make amino acids, they must be obtained from the diet in the form of animal and plant proteins. The proteins are then broken down into their constituent amino acids so that they can be absorbed and reconstituted into the specific proteins needed by the body. These processes of protein breakdown and reconstitution produce a variety of nitrogen-containing waste products, primarily *urea*, which is excreted from the body in the urine. (See also *Nitrate drugs*; *Nitrites*.)

Nitroglycerin

A *vasodilator drug* used to treat and prevent symptoms of *angina pectoris* (chest pain due to an inadequate blood supply to the heart). Nitroglycerin may cause headache, flushing, and dizziness; adverse effects are usually relieved by a reduction in the dose.

Nitrous oxide

A colorless gas (sometimes called laughing gas) with a sweet taste that is used with oxygen to provide *analgesia* (pain relief) and light anesthesia (see *Anesthesia, general*) during dental procedures, childbirth, and minor surgery. For major surgery requiring deeper anesthesia, nitrous oxide and oxygen need to be combined with other drugs.

The advantages of the combination of nitrous oxide and oxygen over other agents are their rapid action and nonflammability. Possible adverse effects include nausea and vomiting during the recovery period.

NMR

Abbreviation for nuclear magnetic resonance. The preferred term for this technique is magnetic resonance imaging (see *MRI*).

Nocardiosis

An infection caused by a funguslike bacterium. The infection usually starts in the lung and spreads via the bloodstream to the brain and tissues under the skin. The causative organism is present in the soil in all parts of the world and is acquired by inhalation. Nocardiosis is rare except in people with *immunodeficiency disorders* or those already suffering from other serious disease.

The infection causes a pneumonia-like illness, with fever and cough. It fails to settle under normal, short-term, antibiotic treatment, and signs of progressive lung damage occur. Brain abscesses may follow. The condition is diagnosed by microscopic examination of sputum (phlegm). Treatment, which may have to be continued for 12 to 18 months, is with *sulfonamide drugs*, sometimes in conjunction with other antibiotics (such as trimethoprim).

Nocturia

The disturbance of a person's sleep at night by the need to pass urine. In most people, a moderately full bladder does not usually disturb sleep, although light sleepers are more likely to wake to empty their bladders. Drinking alcohol in the evening stimulates urine production and may result in nocturia.

A common cause of nocturia is enlargement of the prostate gland (see *Prostate, enlarged*), which obstructs the normal outflow of urine and causes the bladder to be full at night.

Another common cause is *heart failure* (reduced pumping efficiency of the heart) leading to the retention of excess fluid, which is absorbed into the bloodstream and carried to the kidneys at night to make more urine.

Also common is *cystitis* (inflammation of the bladder), in which irritation of the bladder wall increases its sensitivity so that smaller volumes of urine trigger a desire to pass urine.

Rarer causes of nocturia include *diabetes mellitus* (in which greater volumes of urine are produced both day and night) and chronic *renal failure* (in which the kidney loses its ability to produce a reduced quantity of more concentrated urine at night).

Nocturnal emission

Ejaculation that occurs during sleep, commonly called a "wet dream." Nocturnal emission is normal in male adolescents and is a common cause of unnecessary anxiety. Nocturnal emissions may also occur in adult males whose sexual activity is limited.

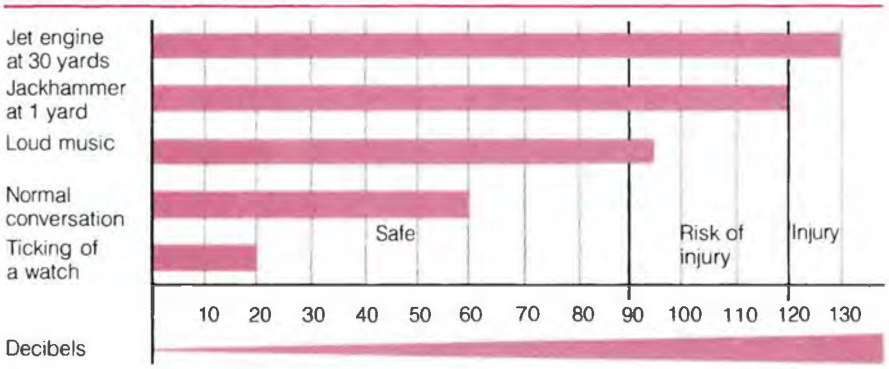
Node

A small, rounded mass of tissue that may be normal or abnormal. The term most commonly refers to a *lymph node*, which is a normal structure in the lymphatic system. Abnormal nodes are often called *nodules*.

Nodule

A small lump of tissue, usually more than one quarter of an inch (6 mm) in diameter. A nodule may protrude from the skin's surface or it may form deep under the skin. Nodules may be either hard or soft.

Noise



Sound that is disordered, unwanted, or that interferes with hearing.

Hearing may be damaged by exposure to intensely loud noise for a short period (such as an explosion at close range) or by prolonged exposure to lower levels of noise (such as might occur in a machine room or foundry). Any noise above 90 decibels may cause damage; the louder the noise, the shorter the time required for damage to occur (see chart).

HOW NOISE DAMAGES HEARING

Exposure to a sudden very loud noise, usually above 130 decibels, can cause immediate and permanent damage. Normally, muscles in the middle ear respond to loud noise by altering the stiffness of the chain of bones that pass vibrations to the inner ear, thus reducing their efficiency. But when the noise occurs without warning, these protective reflexes have no time to respond. The full force of the vibrations is carried to the inner ear, causing severe damage to delicate hair cells in the cochlea. Occasionally, loud noises can rupture the eardrum.

COMPARATIVE NOISE LEVELS

N

More commonly, damage from loud noise occurs over a period of time, with gradual destruction of the hair cells of the cochlea and permanent hearing loss.

SYMPTOMS OF NOISE DAMAGE

Sound at 90 decibels or above usually causes pain, which is a warning that hearing may be damaged unless the source of the noise is removed. Prolonged *tinnitus* (ringing or buzzing in the ears) that occurs after a noise has ceased is an indication that some damage has probably occurred.

Prolonged exposure to loud noise leads initially to a loss of ability to hear certain high tones. Later, deafness extends to all high frequencies and the perception of speech becomes impaired. Eventually, lower tones are also affected.

PREVENTION OF NOISE DAMAGE

Regulations governing maximum noise levels apply to places of work and to some other potential hazards, such as noise from low-flying aircraft. People who cannot avoid exposure to loud noise (for example, workers using pneumatic drills) should wear earplugs. People who are persistently exposed to loud noise should have their hearing monitored regularly.

N

Noma

Also known as cancrum oris, death of tissue in the lips and cheeks caused by bacterial infection. Noma is most often seen in (and largely confined to) young, severely malnourished children in developing countries. It may complicate other diseases, especially *measles*, and sometimes occurs during the last stages of *leukemia*.

SYMPTOMS

The first symptom is inflammation of the gums and the inner surface of the cheeks. Without treatment, this leads to severe ulceration (with a foul-smelling discharge) and eventual destruction of the bones around the mouth and loss of teeth. Healing occurs naturally after a time, but scarring may be severe.

TREATMENT

Penicillin drugs and improved nutrition halt the progress of the disease. Plastic surgery may be necessary to reconstruct damaged bones or to improve facial appearance.

Nonaccidental injury

See *Child abuse*.

Noninvasive

A term used to describe any medical procedure that does not involve penetration of the skin or entry into the body through any of the natural openings; examples include *CT scanning* and *echocardiography*. The term noninvasive is sometimes applied to benign tumors that do not spread throughout body tissues.

Nonspecific urethritis

Also called nongonococcal urethritis, inflammation of the urethra due to a cause or causes other than *gonorrhea*. Worldwide, nonspecific urethritis is the most common type of *sexually transmitted disease*.

CAUSES

The name nonspecific urethritis was given to the disorder at a time when few laboratory tests were available for the detection of microorganisms. Today, about 40 percent of cases are known to be caused by *CHLAMYDIA TRACHOMATIS* (see *Chlamydial infections*); others are caused by *HERPESVIRUS HOMINIS* (the virus that causes *herpes simplex*) or *TRICHOMONAS VAGINALIS* infections. In about 50 percent of cases, however, the cause remains unknown.

SYMPTOMS

Nonspecific urethritis has an incubation period of about two to three weeks. In men, the infection usually causes a clear or pus-containing urethral discharge often accompanied by pain or discomfort on passing urine. Sometimes these symptoms are very mild or even absent. Women with nonspecific urethritis may have no symptoms; some have a vaginal discharge, mild discomfort on passing urine, or pain in the pelvic region.

DIAGNOSIS AND TREATMENT

Laboratory tests are performed to find the organism responsible for the infection. Because a woman may have no symptoms, a diagnosis often rests on the fact that she has a male partner with nonspecific urethritis.

Treatment is difficult because in many cases the cause cannot be determined. The cure rate is roughly 85 percent. *Antibiotic drugs*, including oxytetracycline and erythromycin, are given. Because relapses are common, follow-up visits are necessary for three months after treatment to examine the urine and any discharge.

COMPLICATIONS

In men, *cystitis*, *epididymitis*, *prostatitis*, and urethral stricture (narrowing of the urethra) can occur as complications of nonspecific urethritis.

In women, *salpingitis* (inflammation of the fallopian tubes), cysts of the Bartholin's glands, and *cervicitis* may occur. *Ophthalmia* neonatorum, a type of conjunctivitis, sometimes develops in babies born to women with chlamydial cervicitis.

Reiter's syndrome (in which there is arthritis and conjunctivitis as well as urethritis) develops in about 5 percent of people with nonspecific urethritis.

Nonsteroidal anti-inflammatory drugs

COMMON DRUGS

Diflunisal Fenoprofen Ibuprofen Indomethacin Meclofenamate Naproxen Phenylbutazone Piroxicam Sulindac Tolmetin

WARNING
Report abdominal pain or indigestion to your physician.

A group of drugs that has an *analgesic* (painkilling) action and also reduces inflammation in joints and soft tissues, such as muscles and ligaments. The name nonsteroidal anti-inflammatory drugs is commonly abbreviated NSAIDs.

WHY THEY ARE USED

NSAIDs are widely used to relieve symptoms caused by types of arthritis, such as *rheumatoid arthritis*, *osteoarthritis*, and *gout*. They do not cure or halt the progress of disease but improve mobility of the affected joint by relieving pain and stiffness.

NSAIDs are also used in the treatment of back pain, menstrual pain, headaches, pain after minor surgery, and soft tissue injuries.

HOW THEY WORK

NSAIDs reduce pain and inflammation by blocking the production of prostaglandins (chemicals that cause inflammation and trigger transmission of pain signals to the brain).

POSSIBLE ADVERSE EFFECTS

Nausea, indigestion, diarrhea, and *peptic ulcer* may occur.

Norepinephrine

A hormone secreted by certain nerve endings (principally those of the *sympathetic nervous system*) and by the medulla (center) of the *adrenal glands*. Norepinephrine's primary function is to help maintain a constant blood pressure by stimulating certain blood vessels to constrict when the blood pressure falls below normal. For this reason, an injection of the hormone may be given in the emergency treatment of *shock* or severe bleeding. (See also *Epinephrine*.)

Norethindrone
A *progesterone drug* that is used with an *estrogen drug* in several *oral contraceptive* preparations and in *hormone replacement therapy*.

On its own, norethindrone is sometimes used to treat women who are suffering from *endometriosis*, *amenorrhea* (absent periods), or irregular menstrual bleeding (see *Menstruation, disorders of*).

Norgestrel
A synthetic *progesterone drug* used in some *oral contraceptive* preparations.

Nortriptyline
An *antidepressant drug* that also has a sedative effect. Nortriptyline is useful in the treatment of *depression* that may follow a *stroke*.

Nose
The uppermost part of the respiratory tract and the organ of *smell*.

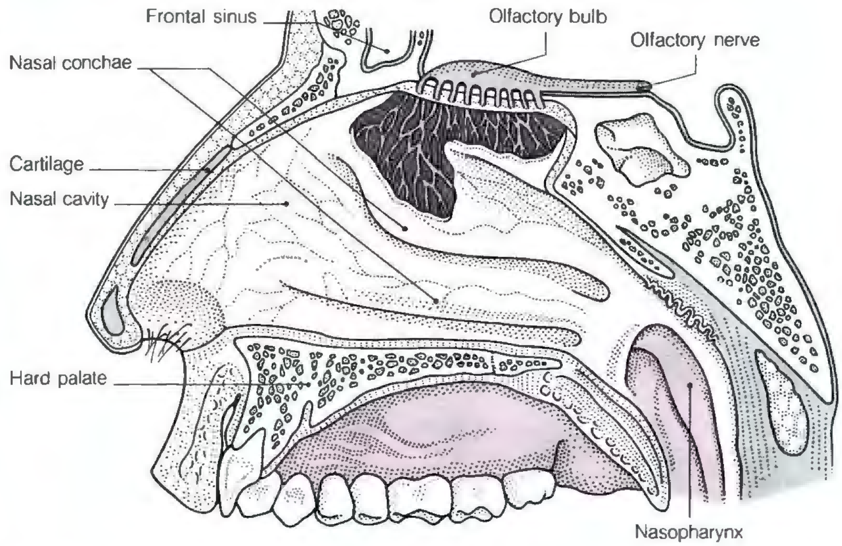
STRUCTURE

The nose is an air passage connecting the nostrils at its front to the *nasopharynx* (the upper part of the throat) at the rear. The *nasal septum*, made of cartilage at the front and bone at the rear, divides the passage.

Two small bones, the nasal bones, project from the front of the cranium and form the top of the bridge of the nose; the remainder of the bridge is cartilage. The roof of the nasal passage is formed by bones at the base of the skull, the walls by the maxilla (upper *jaw*), and the floor by the hard *palate*. Projecting from each wall are three conchae (thin, downward-curling plates of bone). The entire nasal passage is lined with *mucous membrane*, which bears tiny hairs that considerably increase the surface area.

The bones surrounding the nose contain air-filled, mucous membrane-lined cavities known as paranasal *sinuses*, which open into the nasal passage. In each wall of the nose is the opening to a nasolacrimal duct, which drains away the tears that bathe the front of the eyeball.

Projecting into the roof of the nasal passage through tiny openings are the hairlike nerve endings of the *olfactory nerves*, which are responsible for the sense of smell.



FUNCTION

One of the main functions of the nose is to filter, warm, and moisten inhaled air before it passes into the rest of the respiratory tract. Just inside the nostrils small hairs trap large dust particles and even larger foreign bodies and induce sneezing to remove them. Smaller dust particles are filtered from the air by the hairs of the conchae. All air entering the nose passes over the blood vessels and mucus-secreting cells on the surface of the conchae. The mucus on the conchae flows inward, carrying harmful microorganisms and other foreign bodies back toward the nasopharynx so that they can be swallowed and destroyed by the gastric acid in the stomach.

The nose detects smells by means of the olfactory nerve endings, which, when stimulated by inhaled vapors, transmit this information to the olfactory bulb in the brain.

The nose also is a resonator, giving each voice its characteristic tone. (See also *Nose* disorders box, overleaf.)

ANATOMY OF THE NOSE
The nose is involved in breathing and also in the sense of smell; it is a hollow passage connecting the nostrils and the top of the throat. The upper part of the nose transmits sensations of smell.

Nosebleed
Loss of blood from the mucous membrane that lines the nose, most

FIRST AID: NOSEBLEED

WARNING
If a nosebleed starts after a heavy blow to the head, it could indicate a fractured skull. Take the victim to the hospital immediately.

1 Have the victim sit, ensuring he or she leans forward slightly with the mouth held open so that blood or clots do not obstruct the airway.

2 Pinch the lower part of the nostrils for about 15 minutes. The victim should breathe through the mouth.

3 The nostrils should be released slowly and the victim should avoid touching or blowing the nose. If the bleeding has not stopped after 20 minutes, seek medical attention.

N

DISORDERS OF THE NOSE

The nose is susceptible to a wide range of disorders. Infections and allergic conditions, leading to stuffiness or sneezing and sometimes some loss of smell, are common. Because of its prominent position, the nose is also particularly prone to injury.

CONGENITAL DEFECTS

In choanal atresia, one or both nasal cavities fail to develop fully. If both sides are affected, the baby cannot breathe properly. An abnormality affecting one side may not cause any problems until later in life.

Syphilis that is transmitted to a fetus during pregnancy may lead to a failure of full development of the nasal bones, with flattening of the bridge of the nose.

INFECTION

The common *cold*, a virus infection, causes inflammation of the lining of the nasal passages and excessive production of mucus, leading to nasal congestion. Small *boils* (infected hair follicles) are common just within the nostril, where they may cause severe pain. Backward spread of infection from the nose can rarely cause *cavernous sinus thrombosis*, a serious condition that, without antibiotics, may be fatal.

TUMORS

Hemangiomas (benign tumors of blood vessels) commonly affect the nasal cavity in babies. Many disappear spontaneously before puberty.

Basal cell carcinoma and *squamous cell carcinoma* (skin cancers) may occur in and around the nostril. The nose may also be invaded by cancers originating in the surrounding sinuses.

INJURY

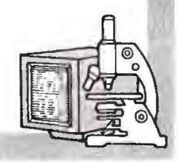
Fracture of the nasal bones (see *Nose, broken*) is a common sports injury that can lead to deformity; it may require corrective surgery. *Nosebleeds* are also common, particularly in children; they may be caused by fragile blood vessels, infection of the lining of the nose, or a blow to the nose.

DRUGS

Repeated sniffing of cocaine interferes with the blood supply to the mucous membrane lining the nose and can cause perforation of the nasal septum. Persistent inhalation of snuff can lead to nasopharyngeal cancer.

ALLERGIES

Allergic rhinitis (hay fever) is one of the most common allergies. Common causative allergens include pollens, animal dander, house mites, and fungal spores. (See *Rhinitis, allergic*.)



OBSTRUCTION

A nasal *polyp* (a projection of swollen mucous membrane) may block a nostril, causing a sensation of congestion.

Young children frequently insert foreign bodies, such as beads, peas, or pebbles, into their nostrils. They often become stuck, causing obstruction and a discharge.

INVESTIGATION

To inspect the inside of the nose, the physician uses a speculum to open up the nostrils. If a fracture is suspected, *X rays* are taken. For suspected cancer, nasal endoscopy and a *biopsy* are done.

often from inside one nostril only. Nosebleeds are most common in childhood, when they are usually insignificant and easily stopped. They are infrequent in healthy young adults, but become more common and more serious in old age.

CAUSES

The most common causes of a nosebleed are a blow to the nose, fragile blood vessels, or dislodging crusts that form in the mucous membrane as a result of a cold or other infection. Rarely, recurrent nosebleeds are a sign of an underlying disorder, such as *hypertension* (high blood pressure), a *bleeding disorder*, or a tumor of the nose or sinuses.

TREATMENT

Most nosebleeds can be controlled by simple first-aid measures (see box on previous page).

If first-aid treatment fails to stop bleeding within 20 minutes, a physician should be consulted. He or she may pack the affected nostril firmly with gauze (to apply constant pressure to the wound) or may cauterize the wound. In rare cases, surgery may be needed to stop the bleeding.

Nose, broken

Fracture of the nasal bones, sometimes with dislocation of the adjacent cartilage. A blow from the side may knock the bones or cartilage out of position or cause displacement of the *nasal septum*. A frontal blow tends to splay the nasal bones outward, depressing the bridge. Usually, the fracture is accompanied by severe swelling of overlying soft tissue, which can mask a minor fracture (revealed only when *X rays* are taken).

X ray showing broken nose
The nasal bones under the bridge of the nose and part of the ethmoid bone, which forms the top part of the nasal septum (partition between the two sides of the nose), have been broken.

A fractured nose is painful and remains tender for about three weeks after the injury.

TREATMENT

Resetting is usually carried out either before the swelling has started or when it has subsided, about 10 days after the injury. Occasionally, the displaced bridge can be manipulated into position using a local anesthetic, but usually a general anesthetic is needed. A plaster splint is sometimes required during healing.

Nose reshaping

See *Rhinoplasty*.

Nuclear energy

Also known as atomic energy, the energy released (principally in the form of heat, light, and "hard" *radiation* such as gamma rays) as a result of changes in the nuclei of atoms. Nuclear energy is released in certain natural processes, such as the spon-

taneous decay of naturally occurring radioactive substances (uranium ores, for example), and the nuclear reactions that power the sun and other stars. It is also released in man-made devices such as nuclear reactors and nuclear weapons.

Nuclear magnetic resonance

See *MRI*.

Nuclear medicine

Techniques that use radioactive substances to detect or treat disease.

The most important application of nuclear medicine is in diagnosis. Radioactive materials (which are injected or swallowed) are taken up by body tissues or organs in different concentrations, and an instrument called a gamma camera is used to detect and map the distribution of radiation within the body. The technique requires only a small amount of radiation, and produces images that reflect bodily functions—not simply anatomy. (See *Radionuclide scanning*.)

In techniques for treatment, higher doses of radiation are used. Diseased tissues are destroyed by exposing them to an external radioactive source or by inserting a radioactive substance into a body tissue or cavity. (See *Radiation therapy; Interstitial radiation therapy; Intracavitary therapy*.)

Nucleic acids

Substances found in all living matter that have a fundamental role in the propagation of life. Nucleic acids provide the inherited, coded instructions (or "blueprint") for an organism's development; they also provide some of the apparatus by which these instructions are carried out.

There are two types of nucleic acid, called deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). In all plant and animal cells (including humans), it is the DNA that permanently holds the coded instructions; RNA helps transport, translate, and implement the instructions. The DNA is the main constituent of *chromosomes*, which are carried in the nucleus (central unit) of the cell.

STRUCTURE

DNA and RNA are similar in their structure. Both have long, chainlike molecules. The main difference is that DNA usually consists of two intertwined chains, whereas RNA is generally single stranded.

The basic structure of DNA (shown at right) has been likened to a very long rope ladder, the chains of the DNA forming the two sides of the ladder with interlinking structures between the chains forming the rungs. The ladder is not straight, however, but twisted into a helical (spiral) shape, which gives it great stability. This shape is called a double helix.

If the two DNA chains are separated, it is found that each has a "backbone" (the side of the ladder) consisting of a string of sugar and phosphate chemical groups. Attached to each sugar in this string is a chemical called a base. The base can be any of four types, called adenine, thymine, guanine, and cytosine (or A,T,G, and C), and each forms half of one "rung" of the DNA ladder. The four bases can occur in any sequence along the chain (a sequence might be, for example, GTCGTATTTAGTCC). The sequence itself, which may be many millions of individual bases long, provides the code for the activities of the cell, just as the sequence of letters on this page provides a message to the reader (see *Genetic code*).

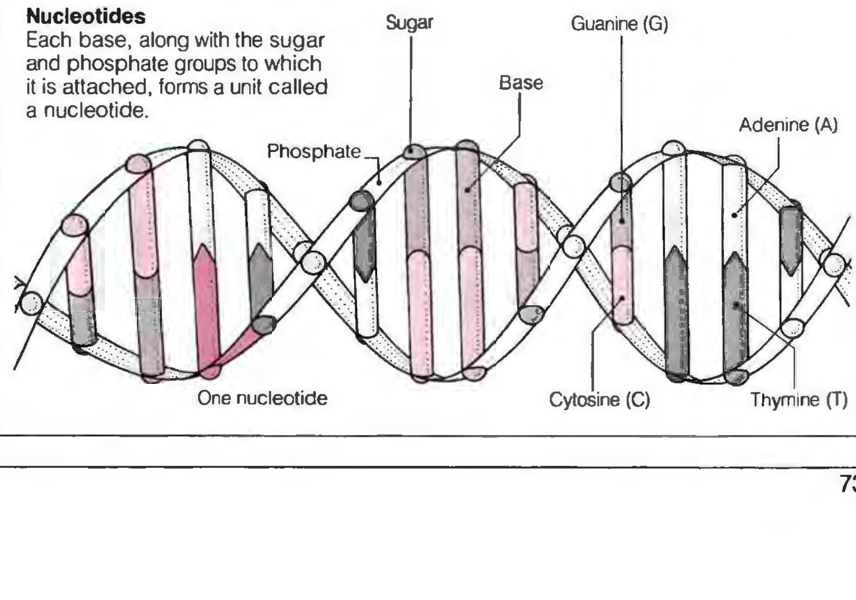
Because the two bases that form each rung of the ladder conform to certain pairings (A always pairing with T, and G with C), the sequence of bases on one chain always determines exactly the sequence on the second chain. This is of fundamental importance for the copying of DNA molecules when a cell divides.

RNA is like a single strand of DNA, except that the nucleotide base thymine in DNA is replaced by another base, uracil, in RNA, and the sugar and phosphate chain in RNA is slightly different chemically.

FUNCTION

DNA controls a cell's activities by specifying and regulating the synthesis of enzymes and other proteins in the cell, with different *genes* (sections of DNA) regulating the production of different proteins. For a particular protein to be made, an appropriate section of DNA acts as a template for an RNA chain. This "messenger" RNA then passes out of the nucleus into the cell cytoplasm, where it is decoded to form proteins (see *Genetic code; Protein synthesis*).

When a cell divides, identical copies of its DNA must go to each of the two daughter cells. The structure of DNA makes this process possible. Starting at one end of the molecule, the two chains separate, or "unzip." As they do so, two more chains are formed side by side to the original chains (these new chains are formed by the linking of free, unlinked, nucleotides that are present in cells). Because only certain base pairings are possible, the new double chains are identical to the original DNA molecule.



Thus, when a cell divides, it provides an exact copy of its DNA to its daughter cells. Each of a person's cells carries the same DNA replica that was present in the fertilized ovum. The DNA message is thus passed from one generation to another.

DNA STRUCTURE

A DNA molecule consists of two intertwined strands, the margins of which are chains of sugar and phosphate groups. The chains are linked by pairs of substances called bases, of which there are four types—adenine, guanine, thymine, and cytosine. An adenine on one chain is always paired with thymine on the second; similarly, cytosine is always paired with guanine. The sequence of bases in one chain thus exactly determines the sequence in the other chain.

Nucleotides

Each base, along with the sugar and phosphate groups to which it is attached, forms a unit called a nucleotide.

NUMBNESS AND TINGLING

Loss of feeling and/or a pins and needles sensation in any part of the body

Did you notice the numbness AND/OR tingling after sitting in one position for a long time or after waking from a deep sleep?

YES → Pressure on a nerve, which stretches it, or temporarily cuts off its blood supply, is often the cause of these sensations. Feeling should return to normal in a few minutes.

NO ↓

Are only your hands affected?

YES → Have you noticed any stiffness in your neck?

- YES → These symptoms suggest a disorder of the nerves and bones of the neck, especially if you are over 50.
  See • *Cervical osteoarthritis*
- NO ↓ Are the symptoms worse at night AND/OR do you have pains that shoot up the hand from your wrist?
  - YES → This suggests a disorder of the nerves that pass through the wrist.
    See • *Carpal tunnel syndrome*
  - NO ↓

NO ↓

Does the numbness AND/OR tingling affect only one side of your body?

YES → Have you also noticed one or more of the following symptoms?
- blurred vision
- confusion
- difficulty speaking
- loss of movement in your arms or legs
- dizziness

- YES → **EMERGENCY!** **GET MEDICAL HELP NOW!** Your symptoms may be caused by a disruption of the blood supply to the brain.
  See • *Stroke*
  • *Transient ischemic attack*
- NO ↓

NO ↓

Do your fingers or toes get numb and turn blue in cold weather, and then become red and painful as feeling returns?

YES → You may have a disorder that affects the small blood vessels in the extremities.
See • *Raynaud's disease*

NO ↓

If you are unable to make a diagnosis from this chart, consult your physician.

Nucleus
The central core, structure, or focal point of an object.

The nucleus of a living cell is a roughly spherical unit at the center of the cell. It contains the *chromosomes* (composed mainly of *nucleic acid*) responsible for directing the cell's activities, and is surrounded by a membrane. There are small pores in the membrane through which various substances can pass between the nucleus and the cytoplasm (the rest of the cell).

The nucleus of an atom, composed of protons and neutrons, accounts for nearly all the mass of an atom but only a tiny proportion of its volume. Nuclear energy is produced through changes in the mass and structure of atomic nuclei.

A nerve nucleus is a group of neurons (nerve cells) within the brain and spinal cord that work together to perform a particular function.

Numbness
Loss of sensation in part of the body caused by interference to the passage of impulses along sensory nerves.

CAUSES
Numbness can occur naturally and harmlessly (such as when blood supply to a nerve in the leg is cut off temporarily by sitting cross-legged), it can be induced artificially (e.g., by a dentist anesthetizing a nerve before filling a tooth), or it may be the result of a disorder or damage to the nervous system or its blood supply.

Multiple sclerosis can cause loss of sensation in any part of the body through damage to nerve pathways in the central nervous system (CNS). In *neuropathy*, it is the peripheral nerves (outside the CNS) that are damaged. In a *stroke*, pressure on, or reduced blood supply to, nerve pathways in the brain often causes loss of feeling on one side of the body.

Severe cold, as in frostbite, causes numbness by a direct action on the nerves. Numbness may also be a feature of various psychological disorders, such as *anxiety*, *panic attack*, or a hysterical *conversion disorder*.

DIAGNOSIS AND TREATMENT
Examination by a physician usually reveals an area of sensory loss or impairment that corresponds to the skin distribution of a single peripheral nerve, several nerves, or a sensory area in the CNS. The distribution of the affected area may suggest the site and mechanism of nerve damage. Treatment can then be prescribed.

Nurse
A person trained in *nursing care*. Registered nurses (RNs) are registered and licensed by a state to care for the sick and to promote health. They work in hospitals, nursing homes, physicians' offices, clinics, workplaces, schools, and patients' homes.

Some RNs concentrate on a particular field, engaging in the full-time practice of *anesthesia*, *psychiatry*, *pediatrics*, or *surgery*. Specific types of RN also exist. Nurse-midwives have special training in prenatal and postnatal care, labor, and delivery (see *Midwifery*). Nurse practitioners or nurse clinicians are trained to provide health services (such as preventive care, monitoring of chronic conditions, physical examinations, and health counseling) under the supervision of a physician.

Other types of nurses include licensed practical nurses (LPNs), who are trained to provide basic care for patients under the supervision of physicians and RNs. Nurses' aides assist nurses in hospitals, nursing homes, and clinics.

Nursing
See *Breast-feeding*.

Nursing care
The process by which a patient is helped by a *nurse* to recover from an illness or injury, or to regain as much independence as possible. The nurse is more concerned with the patient's overall reaction to the disorder than with the disorder itself, and is devoted to the control of physical pain, the relief of mental suffering, and, when possible, the avoidance of complications. In terminal cases, the nurse's responsibility is to help the patient meet death with as little distress and as much dignity as possible.

Working closely with physicians and other health care professionals, the nurse exercises continuous surveillance over the patient. This involves the measurement and recording of many bodily functions. The patient's pulse rate, respiratory rate, temperature, weight, and urine output are recorded daily—or more frequently in acute illness. The nurse may also monitor blood pressure and the ECG in an intensive-care unit, and may record the output of fluids and the intake of fluids and food.

In patients recovering from surgery, the nurse monitors the level of consciousness, ensures that there is no obstruction to breathing, maintains the correct rate of flow of any intravenous infusion, and records vital functions, such as pulse rate.

Prevention is another important aspect of nursing care. The nurse moves unconscious or immobile patients every few hours to prevent the development of bedsores; washing out the mouth, cleaning the teeth, and removing urine and feces guards against infection.

The nurse is also responsible for administering drugs.

From the patient's perspective, the most important quality the nurse can offer may be understanding care, which involves listening with patience to anxieties and fears, and providing emotional support and comfort.

Nursing home
A residential facility for the care of elderly people or, in some cases, for people who have serious illnesses or disabilities.

The rapid increase in the number of elderly people in the US (more than 11 percent of the population is now over 65) has resulted in an increased need for provision of long-term care. There are currently some 19,000 nursing homes in the US caring for more than 1.4 million people, including 20 percent of the people over 85.

Nursing homes as they exist today are partly a result of the Social Security Act of 1935, which refused benefits to people who were in public residential institutions. Consequently, many of the people concerned moved to private facilities.

TYPES OF NURSING HOME
There are three basic types of nursing home. Residential care facilities (RCFs) provide accommodation and food; staff members monitor the basic health of the residents. RCFs are appropriate for elderly people who are fairly independent and able, but who want someone to take over responsibility for basic housekeeping chores.

Intermediate care facilities (ICFs) provide food and lodging and regular custodial care for people who are too ill or frail to look after themselves. Recreational activities may be provided, and some ICFs have rehabilitation programs.

Skilled nursing facilities (SNFs) are overseen by physicians and provide 24-hour nursing. These facilities are for people who require intensive medical and rehabilitation care.

Most care in nursing homes is long-term, but short-term homes are available for people who are primarily

nursed at home. This allows caregivers (usually family members) some respite from their responsibility.

CARE IN NURSING HOMES

Approximately 50 percent of nursing home residents are demented, and most suffer from a number of medical conditions related to *aging*. In addition, because of changes in the Medicare system, patients tend to be discharged from hospitals to nursing homes at earlier stages in their convalescence. These factors place great demands on the medical care provided by nursing homes.

The ideal nursing home is well equipped with registered nurses as well as nurses' aides, has regular visits from a physician, provides access to advanced medical care facilities, and is closely linked, both organizationally and geographically, to community hospitals. It is also important for a nursing home to have a pleasant atmosphere, to treat its patients in a caring and sensitive manner, and to respect their rights to privacy. (See also *Geriatric medicine*.)

Nutrient

A substance that provides nourishment. Essential nutrients are those necessary for body function that are not synthesized in the body. They include proteins, carbohydrates, fats, vitamins, and minerals.

Nutrition

The science and study of the foodstuffs people eat and drink and the ways they are digested and assimilated. Both physicians and the public have shown growing interest in the relationship between diet and health. Until about 30 years ago the primary concern of nutritionists was dietary deficiencies; their recommendations concentrated on the minimum amounts of nutrients required for health. In Western societies the focus is now on the dangers of too much fat or sugar in the diet, and the effects of food additives, colorings, and preservatives on health.

ELEMENTS OF GOOD NUTRITION

Basic elements of the diet are proteins, carbohydrates, fats, fiber, vitamins, minerals, and water (see also entries on individual nutrients). A balanced diet contains adequate, not excessive, amounts of each (see box).

EATING A BALANCED DIET

People require different amounts of nutrients and energy. A precise assessment of each person's requirements would be ideal, but a general

ESSENTIAL NUTRIENTS

Proteins

The main structural component of tissue and organs. We need proteins for growth and repair of cells.

Each protein contains hundreds and sometimes thousands of units called amino acids in specific combinations. In the body there are 20 amino acids; 12 of these are manufactured by the body itself and the remaining eight are obtained from a balanced diet.

A vegetarian diet containing eggs, milk, and cheese provides sufficient amounts of all essential amino acids. A vegan diet, which also excludes dairy products, needs careful planning to prevent protein deficiency (see *Vegetarianism*).

Carbohydrates

The two carbohydrate food groups, sugars and starches, are the main energy sources required for metabolism (chemical processes that take place within cells).

Carbohydrates should make up at least half of our diet. Unrefined (unprocessed) carbohydrates found in cereals and fruit are usually richer in fiber and nutrients than refined carbohydrates, such as sugar and white flour.

Fats

Fats provide energy for metabolism and are a structural component of cells. Most people in developed countries eat too much fat; fats should constitute no more than 30 percent of total calorie intake.

There are three kinds of dietary fats—saturated fats (found mostly in meat and dairy products), monosaturated fats (found in olive oil and avocados), and polyunsaturated fats (found in fish and vegetable oils). Saturated fats tend to increase the amounts of unwanted types of cholesterol in the blood whereas polyunsaturated fats and monosaturated fats have the opposite effect.

Studies have indicated that a high level of low-density lipoprotein cholesterol in the blood is associated with coronary heart disease. Our bodies produce enough cholesterol for our needs; any excess is primarily due to eating too much saturated fat.

Fiber

This is the indigestible structural material in plants. Although fiber passes through the intestine unchanged, it is an essential part of a healthy diet. A low fiber diet may lead to constipation, diverticular disease, and other disorders.

High fiber diets (including plenty of fruit, raw vegetables, grains, and cereals) provide bulk without excess calories. Low fiber diets tend to be high in refined carbohydrates and fats, and thus are more likely to encourage obesity, heart disease, and other unwanted effects.

Water

Our bodies are composed of about 60 percent water. Water constitutes a high proportion of many foods and is essential to maintain metabolism (chemical processes within cells) and normal bowel function. It also determines the volume of blood in our circulation.

Vitamins

Regulators of metabolism. Vitamins ensure the healthy functioning of the brain, nerves, muscles, skin, and bones. Although vitamins do not supply energy, some enable energy to be released from the food.

A healthy, balanced diet contains enough vitamins for most people's needs and supplements are not usually necessary. Indeed, some vitamins, especially A, D, E, and K, are dangerous if taken in excess. Water-soluble vitamins (B and C) are stored in the body less well than fat-soluble vitamins, but even on a very restricted diet vitamin deficiency is rare until several months have elapsed.

Minerals

A balanced diet provides enough minerals for most people. Calcium is necessary for the maintenance of healthy bones and teeth. Other minerals, such as zinc and magnesium, are needed in minute amounts to control cell metabolism. The only mineral commonly required as a supplement is iron, which is used to prevent anemia in women who experience heavy periods.

Sodium chloride (table salt) is needed to maintain fluid balance. Excess may cause *hypertension*.

guide can be useful as well. The figures for the recommended daily allowances (RDAs) are based on average requirements to cover the needs of the majority; the variables are usually body size, age, sex, and lifestyle (active or sedentary).

Nutritional disorders

Nutritional disorders may be caused by a deficiency or an excess of one or more nutrients or by a toxin or poisonous element in the diet.

NUTRIENT DEFICIENCY

A diet deficient in carbohydrate is almost inevitably deficient in protein too (protein-calorie malnutrition). This deficiency is most often seen in people in Africa and Asia as a result of poverty and famine (see *Kwashiorkor; Marasmus*).

Inadequate intake of protein and calories may also occur in people who restrict their diet in an attempt to lose weight (see *Anorexia nervosa*); it can also occur because of mistaken beliefs about diet and health (see *Food fad*) or because of loss of interest in food associated with *alcohol dependence* and *drug dependence*.

In Western societies, deficiency of nutrients is usually associated with a disorder of the digestive system, such as *celiac sprue, Crohn's disease*, or pernicious anemia (see *Anemia, megaloblastic*).

NUTRIENT EXCESS

Obesity and dental *caries* are two of the most common disorders in the US; both are due to excessive intake of nutrients. Obesity is caused by an excess of refined carbohydrates and fat. Dental caries develop mainly in people who eat large amounts of refined carbohydrates.

TOXIC EFFECTS

A nutritional disorder may arise from the presence of toxic substances in the food. These may be naturally occurring substances, such as the *aflatoxin* fungus found on peanuts (which can cause *liver cancer*) or the *ergot* fungus found on rye (which can cause ergotism). Industrial pesticides, fertilizers, pollutants, and other chemicals may also contaminate food.

Nymphomania

A *psychosexual disorder* in which a woman is dominated by an insatiable appetite for sexual activity with numerous different male partners. Nymphomaniacs are often distressed by their own behavior and by their inability to see men as anything other than objects for sexual conquest. Nymphomania is generally thought to be an expression of some deep psychological disorder.

A similar behavior in men is called satyriasis or Don Juanism. It is said to be caused by intense narcissism and the need to control feelings of inferiority through sexual success.

Nystagmus

A condition in which there is involuntary movement of the eyes; the movement is usually horizontal, but can be vertical or rotary. In almost all types, both eyes move together.

CAUSES AND TYPES

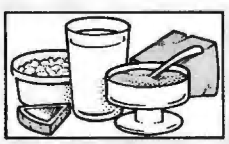
In the most common type, called jerky nystagmus, the eyes repeatedly move slowly in one direction and then rapidly in the other, giving a jerking effect. The disorder is almost always congenital and is usually unassociated with any abnormality of the eyes; the cause is unknown. Jerky nystagmus is permanent and, because steady gaze is impossible, there is almost always a moderate to severe defect of visual acuity. Nystagmus also occurs in *albinism* and as a result of any very severe defect of vision, such as congenital *cataract*, retinal disease, or *optic atrophy*, present at birth.

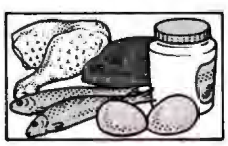
Persistent nystagmus appearing later in life indicates the presence of a disorder of the nervous system (such as *multiple sclerosis* or a brain tumor) or a disorder of the balancing mechanism in the inner ear. Nystagmus may also occur as a normal effect of a person's attempts to follow a sequence of objects rapidly passing the eyes. This phenomenon is known as "optokinetic nystagmus."

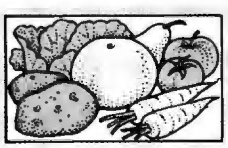
Electronystagmography, a method of recording eye movements, may be performed to identify different types of nystagmus.

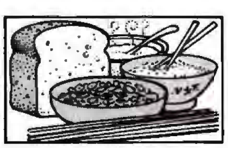
Nystatin

ANTIFUNGAL









Tablet Liquid Powder Vaginal suppository
Cream Ointment Eye drops

Prescription needed

Available as generic

An *antifungal drug* used in the treatment of *candidiasis* (thrush). Nystatin may be safely used during pregnancy. High doses taken by mouth may cause diarrhea, nausea, vomiting, and abdominal pain.

THE FOUR FOOD GROUPS AND RECOMMENDED DAILY SERVINGS

Food group		Typical servings	
Milk group Servings required per day: 2		Milk Yogurt, plain Hard cheese Cheese spread Cottage cheese	8 ounces (1 cup) 1 cup 1¼ ounces 2 ounces 2 cups
'Meat' group Servings required per day: 2		Meat, lean Poultry Fish Eggs Peanut butter	2 to 3 ounces (cooked) 2 to 3 ounces 2 to 3 ounces 2 to 3 4 tablespoons
Fruit and vegetable group Servings required per day: 4		Vegetables Fruits Grapefruit Potato Lettuce	½ cup ½ cup ½ medium 1 medium 1 wedge
Bread and cereal group Servings required per day: 4		Bread Cooked cereal Pasta Rice Dry cereal	1 slice ½ to ¾ cup ½ to ¾ cup ½ to ¾ cup 1 ounce

Essential nutrients are found in differing amounts in foods, so a varied diet is needed to ensure you get all you need. An easy way to plan a balanced diet is to use the above chart to select foods from each of the four basic food groups. Note that the meat group contains other protein-rich foods, such as eggs and peanut butter, as well as meat.

O

Obesity

A condition in which there is too much body fat. Being obese is not the same as being overweight. A person is usually not considered obese unless he or she weighs 20 percent or more over the maximum desirable weight for his or her height (see *Weight*).

INCIDENCE

It is estimated that about 25 percent of the US population carries too much fat. About 5 to 10 percent of children are overweight or obese. Between 13 and 23 percent of all adolescents (especially girls) are obese; 80 percent of obese teenagers are likely to grow into obese adults.

CAUSES

The reasons why some people become obese are unclear. Although obesity occurs when the net energy intake exceeds the net energy expenditure (that is, when more calories are taken in than are being used by the body), obese people do not always eat considerably more than thin people.

A person's energy requirements are determined partly by his or her basal metabolic rate (the amount of energy needed to maintain vital body functions at rest—see *Metabolism*) and partly by his or her level of physical activity. Obese people may have a very low basal metabolic rate, or they may need fewer calories because they are less physically active.

It is thought that genetic factors play a part in the development of obesity; children of obese parents are 10 times more likely to be obese than children with parents of normal weight. Some hormonal disorders are accompanied by obesity, but the overwhelming majority of obese people do not suffer from such disorders.

COMPLICATIONS

Obesity increases a person's chance of becoming seriously ill. *Hypertension* (high blood pressure) and *stroke* are twice as likely to occur in obese people than in lean people. *Coronary heart disease* is more common, particularly in obese men under the age of 40. Adult-onset *diabetes mellitus* is five times more common among obese people, the risk increasing with the degree and duration of obesity. Increasing degrees of extra weight in men are associated with an increased risk of cancer of the colon, rectum, and prostate. With increasing weight, women show a progressive increase in risk of cancer of the breast, uterus, and cervix. *Osteoarthritis* may be agravated by obesity. Extra weight on the hips, knees, and back places undue strain on these joints. Weight loss does not reverse the disease but does help relieve stress and pain.

TREATMENT

The first line of treatment for obesity is a weight-loss diet (see *Nutrition*; *Weight reduction*). An obese person should follow a diet that provides 500 to 1,000 calories less than his or her energy requirements. The energy deficit is met by using some of the excess stored fat, which is reflected by an average weight loss of 1 to 2 pounds a week. Regular exercise (especially *aerobics*) increases weight loss by burning extra calories and by increasing the metabolic rate.

Fad diets may cause a dramatic weight loss within a short period of time, but, in almost all cases, the weight is quickly regained when normal eating habits are resumed. The use of drugs as appetite suppressants was once popular, but is usually no longer recommended by physicians.

Various radical procedures are available for severely obese people who have failed to lose weight, but because of the possible adverse effects they are attempted only if the person's health is in danger.

Wiring the jaw to prevent the mouth from opening more than about half an inch makes it impossible to chew. Reduced calorie meals in liquid form are taken through a straw. The jaw is usually wired for up to a year and the patient is kept under constant medical supervision. Weight is often regained once the wiring is undone.

An operation in which part of the stomach is stapled together reduces its size and has the effect of making the person feel full after eating a small amount of food.

Intestinal bypass operations were popular in the 1970s but are now uncommon due to the frequency and variety of adverse effects. A large part of the small intestine is bypassed by cutting the jejunum and joining it to the ileum, thus reducing the length of the digestive tract and allowing less food to be absorbed.

OUTLOOK

Some people who have been seriously obese for much of their lives can lose weight without regaining it. As when trying to give up smoking or alcohol, the essential element in weight reduction is psychological motivation.

Obsessive-compulsive behavior

A neurosis in which sufferers are constantly troubled by persistent ideas (obsessions) that make them carry out repetitive, ritualized acts (compulsions). Obsessive-compulsive disorder usually starts in adolescence and runs a fluctuating course.

CAUSES AND INCIDENCE

The condition is partly inherited, but environmental factors also play a part. Personality traits of orderliness and cleanliness are said to be related, as is a tendency for other neurotic symptoms. Certain forms of brain damage (especially *encephalitis*) can result in obsessional symptoms.

Obsessive-compulsive disorder is rare, although minor obsessional symptoms probably occur in about one sixth of the population.

SYMPTOMS

People with this disorder usually suffer from both obsessions and compulsions, often accompanied by *depression* and *anxiety*.

Obsessions are recurrent thoughts or feelings that come into the mind seemingly involuntarily. Sufferers regard these thoughts as senseless and sometimes unpleasant, but are unable to ignore or resist them. Thoughts of violence, fears of being infected by germs or dirt, and constant doubts (e.g., whether or not the front door is shut) are the most common obsessions. One form is obsessional rumination, in which a person broods constantly over a word, phrase, or an unanswerable problem.

Compulsions are repetitive, apparently purposeful acts that are carried out in a ritualized fashion. They are performed for the purpose of warding off fears or relieving anxiety and are thus the physical form of an obsessional state. Sufferers do not usually derive any pleasure from performing the activities, but feel increasingly anxious if they try to resist the compulsion. Handwashing, counting, and checking are the most common compulsions.

Compulsive acts may have to be performed so many times in a particular way that they seriously disrupt work and social life. It may take some

sufferers two or three hours just to get up and wash in the morning. In addition, the constant use of soap may irritate the skin.

TREATMENT

Traditionally, obsessive-compulsive symptoms have been treated by *psychoanalysis*. Today, treatment may also consist of *behavior therapy*. It is often combined with *antidepressant drugs* (especially clomipramine) or *antianxiety drugs*.

OUTLOOK

At least two thirds of all people who have obsessive-compulsive disorder respond well to therapy. Symptoms may recur under stress but can usually be controlled. In severe cases, the affected person may become housebound and severely handicapped by indecision. In less than 3 percent of cases, sufferers go on to have psychotic symptoms (see *Psychosis*).

Obstetrician

A physician who specializes in the care of a woman during pregnancy, labor, delivery, and the period immediately afterward. Prenatal care may include periodic examinations of the woman and her developing baby with recommendations for changes in activity or diet. The obstetrician delivers the baby, performing a cesarean section if necessary. In many cases, the obstetrician is also the woman's *gynecologist*.

Obstetrics

The branch of medicine concerned with *pregnancy*, *childbirth*, and *postnatal care*. In conjunction with *gynecology*, obstetrics also involves the study of the structure and function of the female reproductive system (see *Reproductive system, female*).

Obstructive airways disease

See *Lung disease, chronic obstructive*.

Occiput

The lower back part of the head, where it merges with the neck.

Occlusion

Blockage of any passage, canal, opening, or vessel in the body. Occlusion may be the result of disease (as in *pulmonary embolism*) or may be induced for medical reasons (see *Embolism, therapeutic*). The term is also used to refer to the covering of the better-seeing eye during treatment of *amblyopia*. In dentistry, occlusion is the relationship between the upper and lower teeth when the jaw is shut.

Occult

A term meaning hidden or obscure. Occult blood in a sample of feces is invisible to the naked eye but can be detected by chemical tests.

Occult blood, fecal

The presence in the feces of blood that cannot be seen by the naked eye but can be detected by chemical tests. It may be a sign of various disorders of the gastrointestinal tract, including *esophagitis*; *gastritis* (inflammation of the stomach lining); *stomach cancer*; intestinal cancer (see *Intestine, cancer of*); rectal cancer (see *Rectum, cancer of*); *diverticular disease*; *polyps* in the colon; *ulcerative colitis*; or the use of medications that irritate the stomach or intestine, such as aspirin. Bleeding gums or *hemorrhoids* may also cause occult blood in the feces, although in most cases of hemorrhoids the blood is visible.

DETECTION

Screening for colorectal cancer is done by testing the stools of asymptomatic people for occult blood.

A thin film of feces is smeared on a chemically coated paper and a drop or two of oxidizing agent is placed on it. If blood is present, the feces-covered paper turns blue. (See also *Feces, abnormal*; *Rectal bleeding*.)

Occupational disease and injury

Illnesses, disorders, or injuries that occur as a result of work practices or exposure to chemical or physical agents or factors (e.g., dusts, poisons, or radiation) in the workplace. The efforts of specialists in this field mean that serious occupational diseases are much less common than they once were. Overall, however, occupational diseases make up an important and fairly common group of conditions (see table, overleaf).

TYPES

Some of the main types of occupational diseases are described below.

DUST DISEASES *Pneumoconiosis* refers to *fibrosis* of the lung caused by inhaled inorganic and organic dusts. It includes various diseases associated with mining (including coal and quartz mining), china clay processing, metal grinding, and foundry work. *Asbestosis* is a similar hazard for workers in the asbestos, mining, milling, and product manufacturing industries, and in shipbuilders.

Allergic *alveolitis* is a lung condition caused by inhalation of organic dusts (often containing fungal spores). It is often occupationally related and includes such conditions as *farmers' lung* in agricultural workers.

CHEMICAL POISONING A vast number of industrial chemicals can cause damage to the lungs if inhaled, or to the liver, kidneys, bone marrow, or other organs if they reach the bloodstream via the lungs or skin.

Exposure to the fumes of cadmium (in the welding and electroplating industries) or beryllium (in high-technology industries) can damage the lungs. Lead and arsenic compounds (in metal processing and other industries) and benzene (in various industries where solvents are used) can damage the bone marrow, leading to *anemia* and other blood abnormalities. Carbon tetrachloride and vinyl chloride (in chemicals and plastics manufacture) are causes of liver disease. Many of these compounds can also cause kidney damage.

OCCUPATIONAL SKIN DISEASE Contact *dermatitis* (skin inflammation) can occur as a result of an allergy or of direct irritation by chemicals contacting the skin at work. Many substances may be responsible, from wet cement to processing chemicals used in the rubber goods industry. Other skin problems may also be occupationally related (e.g., severe itching caused by glass fiber or *squamous cell carcinoma* through exposure to tar).

RADIATION HAZARDS People with outdoor occupations in sunny climates are at increased risk of skin disease (such as *basal cell carcinoma*).

Workers in the nuclear energy industry and in some health care professions should use precautions to reduce the risk of developing a disease caused by ionizing radiation (see *Radiation hazards*).

INFECTIOUS DISEASES Rare infectious diseases are more common in certain occupations. They include *brucellosis* and *Q fever* (acquired from livestock) among farmworkers, *psittacosis* (from birds) in pet store owners, and *leptospirosis* (from rats) in sewer workers, miners, ditchdiggers, and fishermen. Viral *hepatitis* and *AIDS* are hazards for people who work with blood and blood products.

MISCELLANEOUS Disorders caused by repetitive actions, or overuse of parts of the body, range from writers' cramp to *carpal tunnel syndrome* and *singers' nodes*. *Raynaud's phenomenon* is associated with the handling of vibrating tools; *deafness* may be caused by exposure to noise and *cataracts* by exposure to intense heat.

SAFETY AT WORK

A major method of preventing occupational disease and injury is the use of suitable protective clothing. This may include an air-filter mask in the presence of dust or fumes; earplugs where there is a noise hazard; eye shields to protect against radiation, chemicals, or metal dust; gloves for handling machinery; protective headgear and reinforced footwear where there is a risk of falling objects.

Chemical safety
Many chemical sprays are toxic. Protection for the eyes and lungs is advisable.

Tool safety
Before using any power tool, always read the instructions. Never leave the safety guard off.

OCCUPATIONAL INJURIES OR DISEASES

Injuries or diseases	Approximate no. of cases in US annually	Deaths	Examples
Disabling injuries at work caused by falls	250,000	Many thousands	All types of fractures, wounds, crush and penetrating injuries, sprains, burns, electrical injuries
All other disabling injuries at work	1,650,000		
Skin conditions	40,000	Few	Contact allergic or irritant dermatitis, some squamous cell carcinomas
Disorders associated with repeated trauma or overuse injury	26,000	Very few	Bursitis, tenosynovitis, tennis elbow, singers' nodes
Respiratory diseases caused by inhaled dusts or toxic agents	10,000	Several thousand	Pneumoconiosis, asbestosis, byssinosis, berylliosis, farmers' lung
Disorders caused by effects of physical phenomena	9,000	Few	Cancers, blood disorders (radiation), hearing loss (noise), cataract (heat), Raynaud's phenomenon (vibration)
Other types of poisoning	3,000	Several hundred	Diseases of the liver, kidneys, bone marrow, heart, nervous system, bladder
Other occupational diseases	18,000	Few	Brucellosis (slaughterhouse workers), decompression sickness (divers), viral hepatitis (health-care workers)

O

DIAGNOSIS AND PREVENTION

Sometimes the link between a disease and occupation may be obvious; sometimes it may become apparent only when a patient with mysterious symptoms mentions his or her occupation to the physician. Part of every medical history is a question regarding the patient's occupation. Even when an occupational disease is suspected, it may require extensive investigation at the workplace to determine the exact cause.

In more serious cases, the patient must quit his or her occupation, but then can make a claim for workers' compensation. In all cases, measures to prevent a recurrence are needed.

Occupational medicine

A branch of medicine concerned with the effects of a person's job on his or her health, with preventing *occupational disease and injury*, and with promoting general health in workers.

Occupational medicine has a long history. As early as the middle ages, it was recognized that miners were at risk of lung diseases caused by dust, and attempts were made to improve their working conditions by increasing ventilation. The scope of occupational medicine widened during the industrial revolution as research revealed the hazards of working with metals (such as lead and mercury) and minerals (such as phosphorus).

The occupational physician uses epidemiological (see *Epidemiology*) techniques to analyze patterns of absenteeism, injury, illness, and causes of death in working populations, and investigates and monitors the health of a particular work force. Health risks can be reduced in two ways: by primary prevention—the reduction of exposure to harmful substances and work practices by attention to dust control, safe work stations, and the disposal of wastes—and by secondary prevention, which involves regular screening of workers for early evidence of occupational disorders, such as dust diseases or damage to the liver from chemicals.

Today, the occupational physician is increasingly concerned with psychological stress at work, with the investigation of the hazards (known and unknown) of new technologies, and with promoting healthy personal habits in workers.

Occupational mortality
Death caused by disease contracted at the workplace or by injuries related to a person's work.

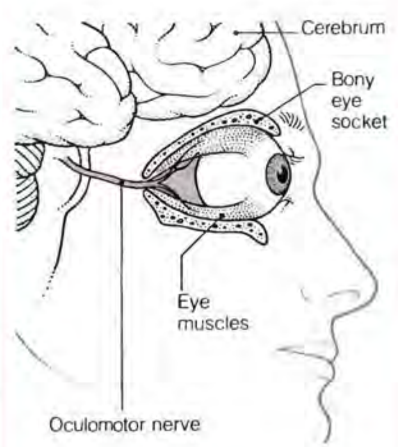
The death rate from work-related injuries in the US has been decreasing steadily for 50 years—from about 40 deaths annually per 100,000 working population in the 1930s to about 10 deaths per 100,000 in the middle 1980s. This last figure still represents approximately 10,000 injury-related deaths in the US each year.

In addition, there are several thousand deaths annually in the US attributable to occupational disease—principally to *pneumoconiosis* (dust disease of the lungs)—and to lung disease or cancers caused by exposure to asbestos.

While the precise number is unknown, it is estimated that one person in 200 in the US dies as a direct result of his or her occupation.

Occupational therapy
Treatment aimed at enabling people disabled by physical illness or a serious accident to relearn muscular control and coordination, to cope with everyday tasks (such as dressing), and, when possible, to resume some form of employment. Treatment, carried out by specially trained therapists, usually starts in the hospital and may be continued at an outpatient clinic or in the person's home.

Ocular
Relating to or affecting the eye and its structures. The term is also used to refer to the eyepiece of an optical device, such as a microscope.



Oculogyric crisis
A state of fixed gaze, lasting for minutes or hours, in which the eyes are turned in a particular direction (usually upward). The fixed-eye position is sometimes associated with spasm of the muscles of the tongue, mouth, and neck.

The crisis may occur in people with *parkinsonism* or those who have had *encephalitis*, or it may be induced by drugs (such as *reserpine* or the *phenothiazine* derivatives). It is often precipitated by emotional stress.

Oculomotor nerve
The third *cranial nerve*. The oculomotor nerve stimulates only motor functions. This nerve controls all the muscles that move the eye, except for two—the superior oblique muscle (which rotates the eyeball downward and outward and is controlled by the *trochlear nerve*) and the lateral rectus muscle (which moves the eye outward and is controlled by the *abducent nerve*). The oculomotor nerve also supplies the muscle that constricts the pupil, the ciliary muscle (which focuses the eye), and the muscle that raises the upper eyelid.

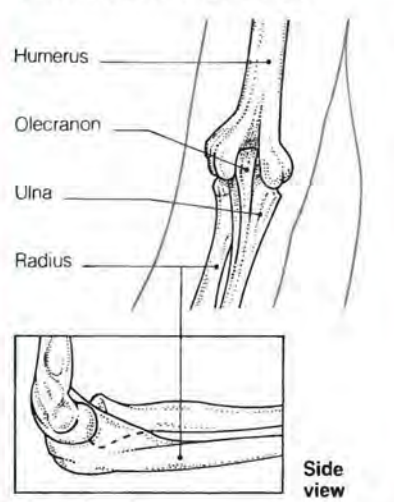
LOCATION OF THE OCULOMOTOR NERVE

The oculomotor nerve originates high in the brain stem and passes forward through a slit in the bony eye socket to reach the muscles that move the eye and eyelids.

The oculomotor nerve may be damaged as a result of a basal skull fracture or a disorder that distorts the brain, such as a tumor. Depending on the severity of damage, the following symptoms may occur: *ptosis* (drooping of the upper eyelid), *strabismus* (squint), dilation of the pupil, inability to focus the eye, double vision, and slight protrusion of the eyeball.

Oedipus complex
A term used in *psychoanalytic theory* to describe the unconscious sexual attachment of a child for the parent of the opposite sex and the consequent jealousy of, and desire to eliminate, the same-sexed parent. The name is derived from the Greek myth in which, unknowingly, Oedipus kills his father Laius and marries his mother Jocasta.

Sigmund Freud believed that the Oedipus complex (sometimes called the Electra complex in females) was present in all young children and that normal psychological development depended on the child coming to identify with the parent of the same sex and, later, making sexual attachments with members of the opposite sex outside the family.



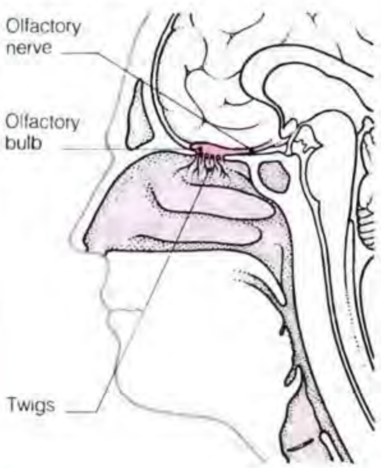
Oils
See *Fats and oils*.

Ointment
A greasy, semisolid preparation that is applied to the skin. Ointments are used to apply drugs to an area of skin or to act as a protective agent. Most ointments contain petrolatum or wax and have an *emollient* (soothing, moisturizing) effect.

Olecranon
The bony projection at the upper end of the ulna (the inner bone of the forearm) that forms the point of the *elbow*. The olecranon is commonly known as the "funny bone"; a blow to the nerve that passes across it produces a tingling sensation that passes down the forearm to the fourth and fifth fingertips.

LOCATION OF THE OLECRANON

This is the curved projection at the upper end of the ulna. It acts to prevent elbow overextension.



Olfactory nerve
The first *cranial nerve*, which conveys *smell* sensations (as nerve impulses)

from the *nose* to the brain. Each of the two olfactory nerves detects smells with hairlike receptors (nerve endings specialized in detecting stimuli) in the mucous membrane lining the roof of the nasal cavity. Nerve fibers pass from the receptors through tiny holes in the roof of the nasal cavity and come together to form two structures called the olfactory bulbs. From the bulbs, nerve fibers travel to the olfactory center in the brain.

LOCATION OF OLFACTORY NERVE

Each olfactory bulb lies on top of a thin bony plate in the roof of the nose and connects to the brain via an olfactory nerve. Nerve twigs pass through the bony plate to enter the nasal lining.

Damage to the olfactory nerves, which is usually caused by head injury, may result in loss or impairment of the sense of smell.

Oligo-

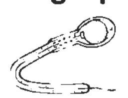
A prefix meaning few, little, or scanty, as in oligospermia (too few sperm in the semen). The prefix olig- is synonymous with oligo-.

Oligodendroglioma

A rare, slow-growing type of primary *brain tumor* that mainly affects young or middle-aged adults. Several hundred cases of oligodendroglioma occur in the US each year. Symptoms, diagnosis, and treatment are as for other types of brain tumor. Surgical removal of the tumor can, in some cases, lead to a complete cure. About one third of patients survive for five years or more.

Oligohydramnios

A rare condition in which there is an abnormally small amount of *amniotic fluid* surrounding the fetus in the uterus during pregnancy.



CAUSES

Amniotic fluid is normally produced by the placenta, swallowed by the fetus, and excreted as fetal urine. Oligohydramnios may occur if the placenta is not functioning properly, as in severe *preeclampsia* or *eclampsia*. Oligohydramnios may also occur if there is an abnormality of the fetal urinary tract or if a pregnancy continues beyond 41 weeks' gestation.

TREATMENT AND OUTLOOK

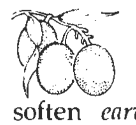
In some cases, the underlying disorder can be treated, but sometimes it cannot (particularly if the fetus is abnormal). If oligohydramnios occurs early in pregnancy, it usually results in *miscarriage*. If it occurs later in pregnancy, the pressure of the uterus on the fetus may cause deformity, such as *clubfoot*. If it occurs in an overdue pregnancy, induction of labor or cesarean section may be beneficial.

Oligospermia

A deficiency in the number of sperm per unit volume of seminal fluid; there are normally more than 20 million sperm per milliliter of semen. Oligospermia may be temporary or permanent. It is a major cause of *infertility*, especially when present with certain other disorders of the sperm.

CAUSES

Oligospermia may be caused by a number of different disorders, including *orchitis* (inflammation of a testis), failure of a testis to descend into the scrotum (see *Testis, undescended*), and, infrequently, a *varicocele* (varicose vein of the testis). Stress, cigarette smoking, alcohol abuse, and some drugs may cause temporary oligospermia.



DIAGNOSIS AND TREATMENT

A sperm count is performed as part of *semen analysis*. Treatment is of the underlying cause. *Gonadotropin hormones* may be prescribed for a short period when the cause is unknown. (See also *Azoospermia*.)

Oliguria

The production of a smaller-than-normal quantity of urine in relation to the volume of fluid taken in. Oliguria may be due simply to excessive sweating (without adequate fluid replacement) in a hot climate. In other cases oliguria may be a sign of failure of normal kidney function (see *Renal failure*).

Olive oil

An oil obtained from the fruit of the olive tree *OLEA EUROPAEA*. Warm olive oil is sometimes used to soften *earwax* before the ears are syringed. Olive oil is also used for its *emollient* (soothing, moisturizing) effect in the treatment of *cradle cap*.

-oma

A suffix that denotes a tumor, as in lipoma, a benign tumor of fatty tissue.

Omentum

An apronlike double fold of fatty membrane that hangs down in front of the intestines. The omentum contains blood vessels, nerves, lymph vessels, and lymph nodes. In addition to acting as a fat store, the omentum may limit the spread of infection within the abdominal cavity by adhering to the affected area.

Omphalocele

An alternative name for *exomphalos*.

Onchocerciasis

A tropical disease that is caused by infestation with the worm *ONCHOCERCA VOLVULUS*. The disease, which is a type of *filariasis*, affects more than 20 million people in portions of Central and South America and Africa. Many sufferers are blinded by the condition.

CAUSES AND SYMPTOMS

The disease is transmitted from person to person by small, fiercely biting, black *SIMULIUM* flies. These flies breed in, and always remain near, fast-running turbulent streams (hence the disease's alternative name, "river blindness").

The transmission of the disease and life cycle of the worm are shown opposite. Blindness may result as an allergic reaction to dead microfilariae (tiny worms) near the eyes.

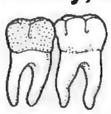
TREATMENT AND PREVENTION

The microfilariae are quickly killed by the drug diethylcarbamazine. This drug must be used with great care, however, because of the severe reactions caused by the dead worms.

Travelers to areas where the disease is prevalent should take measures to discourage the insects from biting (see *Insect bites*).

Oncogenes

Genes, found in all cells, that are responsible for cells becoming malignant (cancerous). Out of the complete



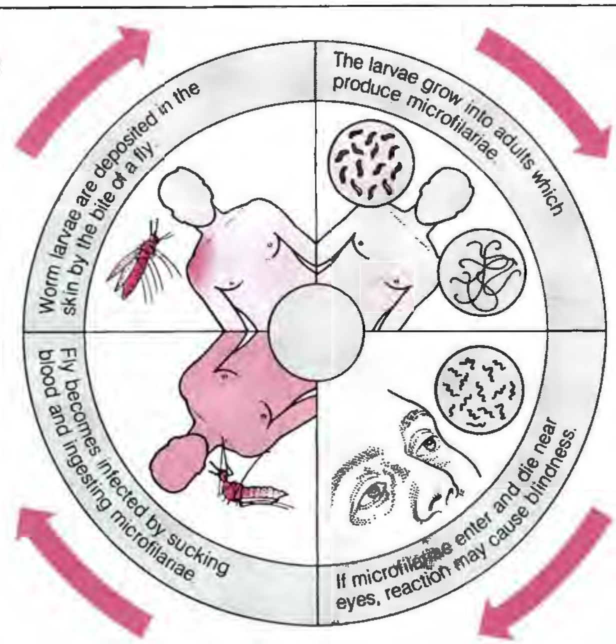
human gene complement of 50,000 genes, fewer than 100 are probably oncogenes; about half of them have been identified.

Cancer cells differ from healthy ones in various ways. Their growth is unrestrained, and they infiltrate and destroy normal tissues (see *Cancer*). These differences are induced by mutations (alterations) in certain key genes—the oncogenes—that cause them to be "switched on." Switching on of a cell's oncogenes may increase its rate of multiplication, alter its responsiveness to hormonal growth factors, or increase its invasiveness.

Oncogenes may be switched on by the various environmental factors that are known to cause cancer, such as ultraviolet light, radioactivity, tobacco smoke, alcohol, asbestos particles, carcinogenic chemicals, and certain viruses. To transform a cell from normal to malignant seems to require the switching on of between two and four oncogenes. Thus, cancer of the cervix may develop in a woman who smokes and whose cervix has been infected with papillomavirus (a potentially cancer-causing virus), whereas either of these factors by itself might not be sufficient to cause cancer.

Oncologist
A specialist in the diagnosis and treatment of *cancer*. Many oncologists specialize in a particular type of cancer, such as leukemia. The oncologist conducts tests to determine the location, type, and extent of the cancer. He or she administers or supervises treatment, which may involve several other specialists and take a number of forms, such as *radiation therapy*, *anticancer drugs*, surgery, or a combination of these.

Oncology
The study of the causes, development, characteristics, and treatment of *tumors*, particularly malignant (cancerous) ones. Because there are many different types of tumors, which can derive from virtually any tissue in the body, oncology encompasses a wide range of experimental techniques and investigative approaches. These include surveying the frequency and distribution of tumors, testing new treatments, investigating the biochemical processes involved in tumor formation, and studying abnormal genes associated with tumors.



Onlay, dental

A tooth restoration of gold made outside the mouth and fixed onto the biting surface and over one or more cusps of a tooth. An onlay may be used to strengthen an extensively restored tooth. It is also sometimes needed to build up teeth in cases of *malocclusion* in which the biting surfaces of certain upper and lower teeth fail to meet when the jaw is closed.

Onychogryphosis
Abnormal thickening, hardening, and curving of the nails, which occurs mainly in elderly people. Its cause is unknown, but onychogryphosis is associated with fungal infection or poor circulation.

Onychogryphosis
This extraordinary thickening and overgrowth, resembling the claws of the mythological griffin, may affect toenails or fingernails.

THE CYCLE OF ONCHOCERCIASIS
The infestation is spread by a fly that ingests microfilariae (tiny worms) from an infested person; the worms grow into larvae and are deposited in the skin of a new host when the fly bites.

Onycholysis
Separation of the nail from its bed, beginning at the tip. It occurs in many skin conditions, including *psoriasis* and fungal infections.

Onychosis
A general term for disease, deformity, or wasting of the *nails*. Onychosis caused by fungal infection is called onychomycosis.

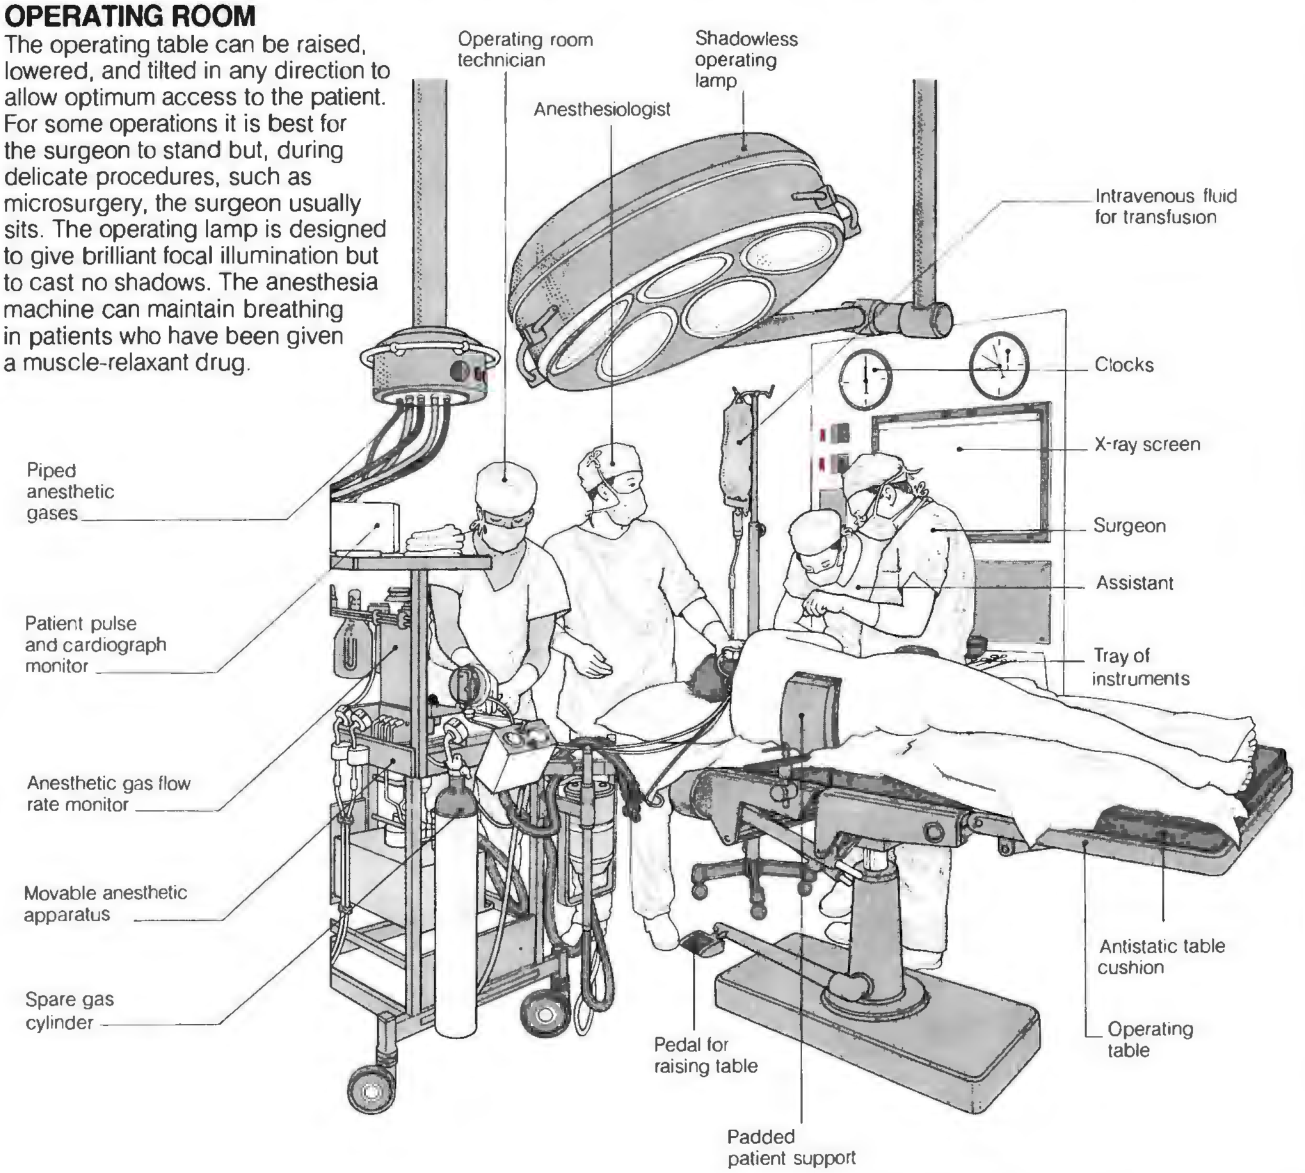
Oophorectomy
Removal of one or both ovaries.

WHY IT IS DONE

Oophorectomy is performed to treat *ovarian cysts* or ovarian cancer (see *Ovary, cancer of*). In women under 40, the surgeon attempts to preserve ovarian function by performing only a partial oophorectomy.

Both ovaries may be removed during a *hysterectomy* if disease has spread from the uterus to the ovaries. Removing both ovaries can also reduce the risk of ovarian cancer in women past the menopause.

HOW IT IS DONE



Oophorectomy is performed using general anesthesia and usually takes less than one hour. The ovaries are removed through an incision in the lower abdominal wall.

RECOVERY PERIOD

There is some pain and tenderness around the operation site. Most activities can be resumed within about a month of surgery, and sexual intercourse after about six weeks.

OUTLOOK

There are usually no adverse effects when one ovary or part of an ovary is

OPERATING ROOM
The operating table can be raised, lowered, and tilted in any direction to allow optimum access to the patient. For some operations it is best for the surgeon to stand but, during delicate procedures, such as microsurgery, the surgeon usually sits. The operating lamp is designed to give brilliant focal illumination but to cast no shadows. The anesthesia machine can maintain breathing in patients who have been given a muscle-relaxant drug.

removed because ovulation and hormone production continue. If both ovaries are removed, *hormone replacement therapy* may be necessary.

-opathy
A suffix that denotes a disease or disorder (often a noninflammatory one), as in neuropathy, any disorder of the peripheral nerves. The suffix -pathy is synonymous with -opathy.

Open heart surgery
Any operation on the heart in which the heart beat is temporarily stopped and its function taken over by a mechanical pump. The early heart surgeons carried out closed operations, inserting their fingers and specially designed knives into the heart (to open the channel of a narrowed valve) while the organ continued to beat. Such operations had only limited scope.

With the development of reliable *heart-lung machines* in the 1950s, the picture changed. Once the pump was connected, the surgeon could open the heart, repair defects, and even reconstruct the main chambers. During the operation, the heart is kept cool through techniques of surgical *hypothermia*, which help prevent damage to the heart muscle from lack of oxygen.

The main applications of open heart surgery have been the correction of congenital heart defects (see *Heart disease, congenital*), surgery for heart valve insufficiency or narrowed heart valves (see *Heart valve surgery*), and *coronary artery bypass* surgery.

Operable
A term applied to any condition that is suitable for surgical treatment, such as an accessible benign tumor that requires removal because it is causing symptoms. (See also *Inoperable*.)

Operating room
A hospital room in which surgical procedures are performed. The room is designed to reduce the risk of bacteria infecting open surgical wounds. A ventilation system provides a constant supply of clean, filtered air, the walls

and floors are easily washable and are cleaned at least once daily, and there are annexes with foot- or elbow-operated faucets where surgeons, assistants, and nurses use sterile brushes and bactericidal soaps to scrub their hands and forearms before putting on sterile gowns, masks, and gloves. Often built into the walls are light boxes for viewing images obtained by *X ray*, *CT scanning*, or *MRI*.

EQUIPMENT

During an operation using general anesthesia, the anesthesia machine stands at the head of the operating table (see *Anesthesia, general*) connected by tubes to oxygen and various anesthetic gases.

The surgeon's sterile instruments, covered with sterile towels before use, are arranged on stainless steel wheeled tables. There is also a *diathermy* machine, which controls bleeding. If required, other equipment, such as a *heart-lung machine* (which can take over the function of the patient's heart and lungs), is brought into the operating room.

Operation

Any surgical procedure, usually carried out with instruments but sometimes using only the hands (as in the manipulation of a simple fracture). Operations range from procedures performed quickly using a local anesthetic (such as draining a skin abscess) to surgery using general anesthesia lasting several hours (such as a heart or liver transplant).

COMMON SURGICAL OPERATIONS

Operation	No. performed in US per year
Inguinal hernia repair	585,000
Cholecystectomy (gallbladder removal)	490,000
Releasing of peritoneal adhesions	300,000
Appendectomy (removal of appendix)	285,000
Biopsy or local removal of breast abnormality	235,000
Debridement of wound, burn, or infection	220,000
Partial colectomy (excision of large intestine)	170,000
Hemorrhoidectomy	130,000
Free skin graft	120,000
Mastectomy (breast removal)	115,000

Ophthalmia

A word once used to describe any inflammatory eye disorder; its use is now restricted to the following two specific disorders.

Ophthalmia neonatorum (literally "eye inflammation of the newborn") is a discharge of pus from the eyes of an infant that starts within 21 days of birth. In many cases the cause is an infection (such as *gonorrhea* or a *chlamydial infection*) acquired during birth. It is treated with antibiotics.

Sympathetic ophthalmia is a rare condition that occurs at least 10 days after a penetrating eye injury. If the injured eye is not removed within this time, severe *uveitis* (inflammation of the iris and choroid) that threatens blindness in the uninjured eye may develop. *Corticosteroid drugs* are used to treat the inflammation.

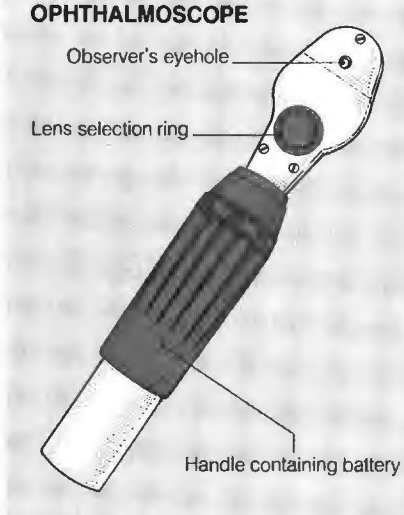
Ophthalmologist

A physician who specializes in care of the *eyes*. Ophthalmologists conduct examinations to determine the quality of *vision* and the need for corrective *glasses* or *contact lenses*. Ophthalmologists also check for the presence of any disorders, such as *glaucoma* or *cataracts*. Ophthalmologists may prescribe glasses and contact lenses, medication, or surgery, as necessary.

Ophthalmology

The study of the *eye*, and the diagnosis and treatment of disorders that affect it. Ophthalmology includes not only the assessment of *vision* and the prescription of *glasses* or *contact lenses* to correct defects, but also the surgery required to treat eye disorders such as *cataracts*, *glaucoma*, *retinal detachment*, and obstruction of tear ducts.

Ophthalmologists frequently work closely with other physicians because many disorders of the retina at the back of the eye are signs of nonoptical disorders, such as *hypertension* (high blood pressure), *atherosclerosis* (narrowing of arteries due to the deposition of fatty material inside them), or *diabetes mellitus*. Careful analysis of a person's field of vision (see *Eye, examination of*) can reveal defects that indicate neurological damage, such as that caused by a brain tumor.



Ophthalmoplegia

Partial or total paralysis of the muscles that move the eyes. Ophthalmoplegia may be caused by disease of the muscles themselves (as in *Graves' disease*) or by one of the conditions affecting the brain or the nerves supplying the eye muscles (including *stroke*, *encephalitis*, *brain tumor*, and *multiple sclerosis*).

Ophthalmoscope

An instrument used to examine the inside of the eye. The ophthalmoscope, by means of a deflecting prism or a perforated angled mirror, allows illumination and viewing of the entire area of the retina, the head of the optic nerve, the retinal arteries and veins, and the vitreous humor.

OPHTHALMOSCOPE

Opiate

Any drug derived from, or chemically similar to, *opium*. The term opiate is also used to refer to certain *receptors* (specific sites on the surface of cells) with which opiate drugs combine to initiate their effects.

Opium

A milky substance obtained from the unripe seed pods of the poppy *PAPAVER SOMNIFERUM*. Used as a drug for thousands of years, opium has an analgesic (painkilling) effect and may also cause sleepiness and euphoria. Opium and its derivatives, which include *codeine* and *morphine*, are among the drugs collectively known as *narcotic drugs*.

Opportunistic infection

Infection caused by organisms that do not usually produce disease in healthy

people; or widespread infection by organisms that normally produce only mild, local, infection.

Many of the causative organisms are normally present on or in the human body and cause disease only when the host's *immune system* is impaired. Impairment of natural defenses may be due to treatment with anticancer and immunosuppressant drugs, to radiation therapy, or to diseases such as leukemia. Opportunistic infections also affect premature or malnourished infants and people with *immunodeficiency disorders*.

Opportunistic infections, especially *pneumocystis pneumonia*, are the cause of death in most *AIDS* patients. Many fungal infections (such as *cryptococcosis* and *candidiasis*) and some viral infections (such as *cytomegalovirus* and the virus that causes *herpes simplex*) are opportunistic infections.

Opportunistic infections are often unavoidable because the underlying defects in the host's defenses cannot easily be rectified. However, treatment with appropriate antimicrobial drugs may be lifesaving.

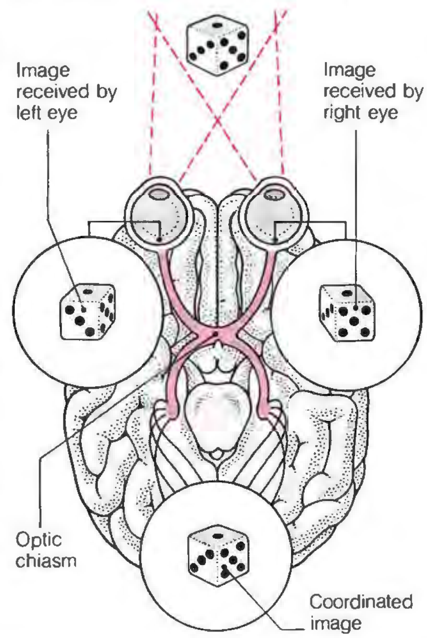
Optic atrophy

A shrinkage or wasting of the *optic nerve* fibers, which results in some or near total loss of vision. Optic atrophy is caused by disease or injury to the optic nerve and may occur without prior signs of nerve disease, such as inflammation or swelling.

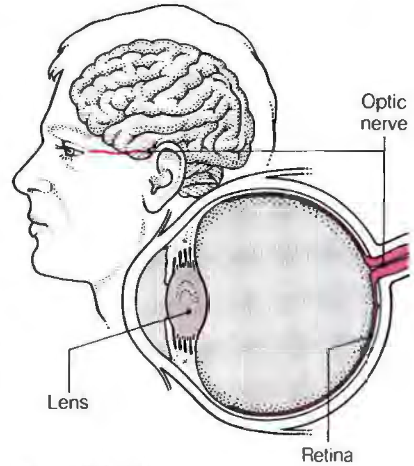
Optic disk edema

Swelling of the head of the *optic nerve*, visible when the eye is examined with an ophthalmoscope. Optic disk edema usually indicates a dangerous rise in the pressure of *cerebrospinal fluid* within the skull, but may also arise from conditions affecting the nerve itself, including damage from restriction of blood supply. Optic disk edema may be followed by *optic atrophy*. (See also *Papilledema*.)

Optician



A person who fits, supplies, and adjusts *glasses* or *contact lenses*. Because their training is limited, opticians may not examine or test eyes or prescribe glasses or drugs.



Optic nerve

The second *cranial nerve*. The nerve of *vision*, the optic nerve consists of a collection of about 1 million nerve fibers that transmit impulses from the *retina* (the layer of light receptors at the back of the eye) to the brain.

THE FUNCTION OF THE OPTIC NERVE

Each optic nerve is a bundle of long fibers originating from nerve cells in the retina and passing to the back of the brain. Because of the arrangement of the nerve fibers, disease or injury at any point causes a unique pattern of visual loss. Charting the pattern of visual loss allows accurate location of damage to the nerve.

Binocular vision
Because the eyes are a distance apart, they form slightly different images of a nearby object. The fusion of these two images into one provides the illusion of solidity. This is called stereopsis.

The two optic nerves converge at the optic junction behind the eyes, where fibers from the inner halves of the retinas cross over. As a result of this crossing over, nerve fibers from the right halves of both retinas pass to the right side of the occipital lobes at the back of the brain. The nerve fibers from the left halves of the retinas go to the left side of the brain.

Disorders of the optic nerve include *optic neuritis* (inflammation of the optic nerve) and *optic disk edema*, caused by external pressure from disease within the orbit or a brain tumor.

Optic neuritis

Inflammation of the optic nerve that often causes sudden loss of part of the field of vision. Optic neuritis is usually accompanied by pain on moving the eyes and tenderness when the eyes are touched. In some cases, however, there may be little or no pain.

The cause of optic neuritis often remains uncertain, but most cases are thought to be due to *demyelination* (destruction of the myelin sheaths) of the optic nerve fibers, which occurs in *multiple sclerosis*. The condition may also result from inflammation or infection of tissues around the optic nerve.

Optic neuritis causes loss of vision, usually in the central part of the visual field. Vision usually improves substantially within six weeks, but each attack causes damage to a proportion of the optic nerve fibers; recurrent attacks usually lead to permanent loss of visual acuity.

Treatment with *corticosteroid drugs* may aid the return of vision but seems to have little effect on the long-term outcome of the inflammatory process. (See also *Optic atrophy*.)

Optometrist

A specialist trained to examine the *eyes* and to prescribe, supply, and adjust *glasses* or *contact lenses*. Because they are not physicians, optometrists may not prescribe drugs or perform surgery. An optometrist refers patients requiring these types of treatment to an *ophthalmologist*.

Optometry

The practice of assessing *vision* and establishing whether *glasses* or, for certain people, *contact lenses* are needed to correct any visual defect. (See also *Optometrist*.)

Oral

Concerning the mouth.

Oral contraceptives

COMMON DRUGS

Estrogens
Conjugated estrogens Diethylstilbestrol
Ethinyl estradiol

Progesterones
Norethindrone Norgestrel

WARNING
If you vomit or have diarrhea while taking an oral contraceptive, follow the advice for missing a pill. If you have missed two consecutive periods, you should have a pregnancy test.

A group of oral drug preparations containing a *progesterone drug*, often combined with an *estrogen drug*, taken by women to prevent pregnancy. All types of oral contraceptives—combined pills, phased pills, and minipills—are commonly known as the pill.

HOW THEY ARE TAKEN

All types of oral contraceptives need to be taken on a monthly cycle for as long as a woman wishes to avoid pregnancy. The first course of pills is started on the first day of a period or on the fifth day after bleeding starts. Additional contraceptive precautions are usually needed for the duration of the first course of combined pills or phased pills or if the minipill is commenced on day 5.

Each course of pills is usually taken as described (right). Some brands of phased pills contain seven additional inactive pills, which may contain an iron supplement, so that the habit of taking a pill each day is not broken. It is possible to take a combined or phased pill continuously and thus avoid bleeding, but most physicians do not recommend this.

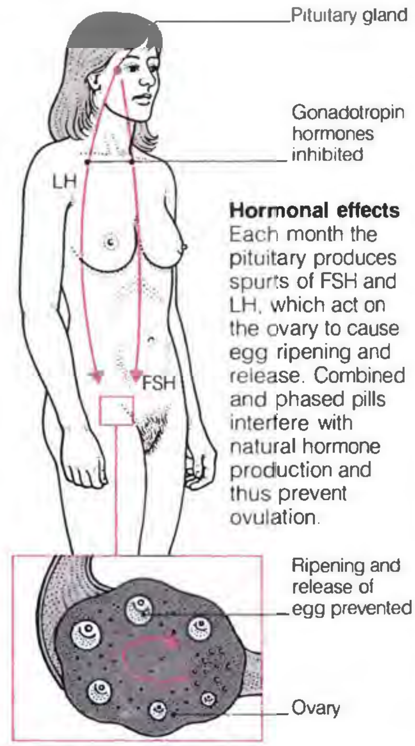
In some women, the use of oral contraceptives may cause menstruation to cease.

MISSING A PILL

For maximum contraceptive effect, each type of pill should be taken at approximately the same time each day. This is particularly important with the minipill, which should be taken within three hours of the chosen time each day.

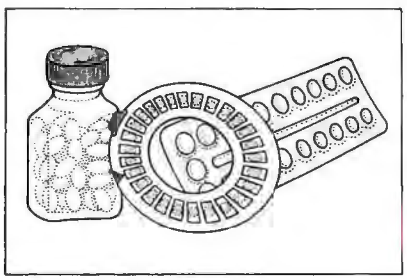
A forgotten combined or phased pill should be taken as soon as remembered even if it means taking two pills the next day. Pills for the rest of the course should be taken at the correct time. A different form of contraception should be used for seven days after missing the pill.

If between three and 12 hours have elapsed from the time a minipill was due to be taken, the pill should be taken and additional contraceptive precautions used for 48 hours. If more than 12 hours have elapsed, the minipill should be taken and additional contraceptive precautions used for as long as your physician advises. (For more information, see the illustration below.)



EFFECTIVENESS

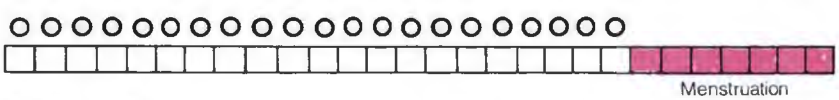
Used correctly, oral contraceptives have a failure rate of less than one



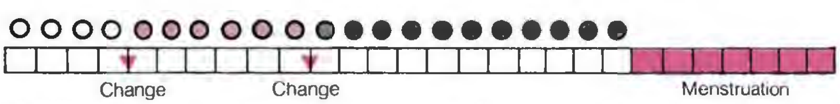
HOW ORAL CONTRACEPTIVES WORK

The combined and phased pills increase the levels of estrogen and progesterone in the body, which interferes with the production by the pituitary gland of two *gonadotropin hormones* called follicle-stimulating hormone (FSH) and luteinizing hormone (LH). This action in turn prevents ovulation.

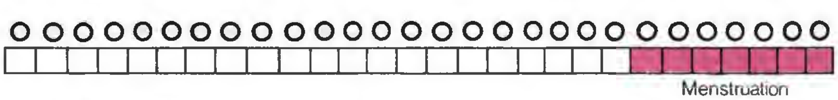
The minipill works mainly by making the mucus that lines the inside of the cervix (neck of the uterus) so thick that it is impenetrable to sperm.



Hormonal effects
Each month the pituitary produces spurts of FSH and LH, which act on the ovary to cause egg ripening and release. Combined and phased pills interfere with natural hormone production and thus prevent ovulation.



Pill packaging
Most oral contraceptives come in packs that clearly indicate the day on which each pill should be taken.



Effects on eggs
FSH normally brings about egg ripening and LH the egg's release from the ovary; combined and phased pills prevent this.

Combined pill
This pill contains an estrogen and a progesterone drug in fixed doses. A course usually consists of one pill per day for 21 days, followed by seven tablet-free days, during which bleeding may occur. A new course is then started, whether or not bleeding has occurred.

Phased pill—a typical program
These pills contain both an estrogen and a progesterone drug, but are divided into two or three groups or phases. The dose of the progesterone drug, and sometimes of estrogen as well, changes from phase to phase. A course lasts for 21 days followed by seven tablet-free days.

Minipill—progesterone only
These pills contain a progesterone drug only in a fixed dose. The pills are taken continuously, one every day with no tablet-free days. Bleeding usually occurs during the last few days of each cycle. The minipill has a slightly higher failure rate than the combined and phased pills.

pregnancy per 100 woman-years (i.e., the number of pregnancies among 100 women using the method for one year). Allowing for incorrect use or other factors, the actual failure rates may be as high as between two and three pregnancies per 100 woman-years for the combined or phased pill, and between two and a half to four pregnancies for the minipill.

Certain other drugs (such as *barbiturate drugs*, *anticonvulsant drugs*, *griseofulvin*, and some *antibiotic drugs*) may impair the effectiveness of oral contraceptives. A woman should always inform her gynecologist if she is taking other medication.

ADVANTAGES AND DISADVANTAGES

In addition to providing excellent protection against pregnancy, the main advantage of oral contraceptives is that they do not interfere with the spontaneity of sex.

Estrogen-containing pills seem to protect against cancer of the uterus and ovaries, *ovarian cysts*, *endometriosis*, and iron-deficiency *anemia*. They also tend to make periods regular, lighter, and relatively free of menstrual pain.

The main disadvantages of oral contraceptives are that they are medically unsuitable for some women and that they may produce adverse effects.

CONTRAINDICATIONS

Estrogen-containing pills increase the risk of certain disorders and are therefore not usually prescribed if a woman suffers from *hypertension* (high blood pressure), *hyperlipidemia* (high levels of fat in the blood), *liver* disease, *migraine*, *otosclerosis* (an ear disorder), or if she has previously had a *thrombosis* (abnormal blood clot).

The chances of a thrombosis occurring are increased in women who smoke or who are over the age of 35. An estrogen-containing pill is usually not given during the first few months after childbirth or in the four weeks before a major operation because of the increased risk of thrombosis. *Obesity* and *diabetes mellitus* also make a woman more susceptible to thrombosis.

Oral contraceptives are not usually prescribed to women with heart or circulatory disorders, a family history of certain disorders, or unexplained vaginal bleeding.

Combined or phased pills interfere with milk production and should not be taken during breast-feeding. The minipill is usually considered unsuitable for a woman who has had an ectopic pregnancy.

POSSIBLE ADVERSE EFFECTS

Estrogen-containing pills may cause nausea and vomiting, weight gain, depression, breast swelling, reduced sex drive, increased appetite, cramps in the legs and abdomen, headaches, and dizziness. A more serious adverse effect of these pills is the risk of a thrombosis causing a *stroke*, *embolism*, or *myocardial infarction* (heart attack). Estrogen-containing pills may also aggravate heart disease or cause hypertension, *gallstones*, *jaundice*, and, very rarely, *liver cancer*.

Medical evidence suggests that cancer of the cervix is more common in women taking estrogen-containing pills. This risk may be outweighed by the reduced risk of other cancers of the reproductive system.

All forms of oral contraception can cause bleeding between periods, but this is especially true of the minipill. Other possible adverse effects of the minipill are irregular periods, ectopic pregnancy, and ovarian cysts.

There is no evidence that use of an oral contraceptive reduces a woman's fertility permanently (although menstruation may be irregular or absent for some months after stopping the pill). Likewise, there is no evidence that a fetus can be harmed if conceived while the woman is taking the pill or has recently stopped doing so.

Adverse effects usually disappear within a few months. If they persist, it may be necessary to change to a different type of pill or to an alternative method of contraception. Because adverse effects are more likely to occur with high doses of estrogen, low-estrogen preparations are prescribed whenever possible. The minipill may be used by women who suffer adverse effects even with low estrogen doses or who should not take estrogen drugs for other medical reasons.

Women taking oral contraceptives should receive checkups, including blood pressure and weight checks and *cervical smear tests*. (See also *Contraception*; *Contraception, hormonal methods*.)

Oral hygiene

Measures that keep the mouth and teeth clean and healthy. Good oral hygiene reduces the incidence of tooth decay (see *Caries, dental*), prevents *gingivitis* and other *gum* disorders, and helps prevent *halitosis* (bad breath). Oral hygiene is broadly divided into personal and professional care.

PERSONAL CARE

The most important aspect of personal oral hygiene is daily removal of dental *plaque* (a sticky, bacteria-containing substance) by thorough *toothbrushing* and use of dental floss (see *Floss, dental*). Use of a fluoride mouth rinse or an oral irrigator (a device that produces a forceful water stream) may also be helpful, but these are aids that cannot remove plaque or replace brushing and flossing. *Disclosing agents* can help make tooth cleaning more efficient by showing the location of plaque. Dentures must always be kept scrupulously clean by brushing every surface and soaking them in a cleansing solution.

PROFESSIONAL CARE

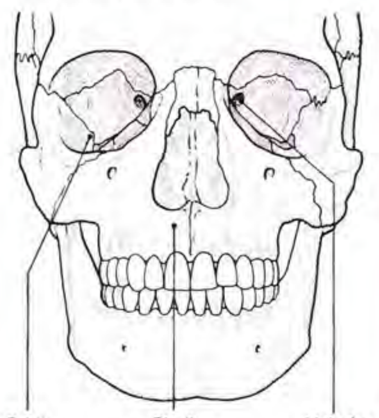
A *dentist* or hygienist (see *Hygienist, dental*) removes stubborn plaque and *calculus* (a hard mineral deposit that forms on the teeth above and below the gums) by *scaling* and polishing. These procedures are usually carried out during a routine checkup; in cases of *periodontal disease*, they may need to be performed more often.

Oral surgeon

A surgeon who specializes in operations on the teeth, jaws, and other parts of the mouth and face (see *Oral surgery*). The qualifications required include a degree in general dentistry and specialization through a four-year training program in oral and maxillofacial (pertaining to the upper jaw and face) surgery. Many oral surgeons also have medical degrees, although it is not required.

Oral surgery

Surgery to treat disease, deformity, or injury of the mouth, face, and jaws.



Among the dental procedures carried out by oral surgeons are the extraction of severely impacted wisdom teeth (see *Impaction, dental*) and *alveolectomy* (removal of part of the jaw that holds the teeth) to improve the fitting of dentures.

More complicated oral surgery includes *orthognathic surgery* to correct deformities of the jaw that result in an abnormal relationship between the upper and lower teeth; repairing a broken jaw; plastic surgery to correct *cleft lip and palate*; and the removal of certain types of benign tumors from tissues within the mouth.

Orbit

The socket in the skull that contains the eyeball, protective pads of fat, and various blood vessels, muscles, and nerves. An opening in the back of the orbit allows the *optic nerve* to pass from the eyeball into the brain.

LOCATION OF ORBIT
The orbits are the deep cavities in the skull in which the eyeballs and muscles that move the eyes are protectively enclosed.

DISORDERS

INJURY A blow of great force, as in a car crash or a sports injury, may fracture the orbit; the eyeball itself often escapes damage because it is squeezed backward by protective muscles during reflex blinking. Many such fractures heal without treatment, but some result in facial deformity that requires corrective surgery. An operation also may be needed to reinforce the floor of the orbit if a fracture causes downward displacement of the eye.

INFECTION Rarely, bacteria infect the fatty tissue lining the orbit, causing orbital *cellulitis*. Usually the infection originates in a nearby sinus, but sometimes it spreads in the blood from a facial infection. The affected eye protrudes, is extremely painful and red, and there is severe swelling of the lids and conjunctiva (the membrane lining the inside of the lids and front of the eye).

Orbital cellulitis is a serious disorder. The pressure on the eye may damage it and there is a slight risk that the infection may spread inward to the meninges (the membranes covering the brain) and the brain itself, causing *meningitis*. Prompt treatment with high doses of antibiotics usually clears up the condition.

Orchiectomy

The surgical removal of a single testis or of both the testes.

WHY IT IS DONE

Orchiectomy may be performed to deal with a testicular cancer (see *Testis, cancer of*) or *gangrene*, or to reduce production of the hormone testosterone as part of the treatment of cancer of the prostate gland (see *Prostate, cancer of*). Because the prostate gland depends on male sex hormones for its normal growth, orchiectomy is often effective in reducing the growth of a prostatic cancer. It is especially effective in controlling the symptoms of secondary tumors in the bones.

HOW IT IS DONE

The scrotum is cut open (using spinal and local anesthesia), the blood vessels and nerves leading to the scrotum are cut free, the testis is cut away from surrounding tissue and removed, and the skin is stitched.

After the operation, *analgesics* (painkillers) may be needed and an *ice pack* may be applied to the surgical area for the first 24 hours to prevent excessive swelling.

OUTLOOK

Complete healing can be expected without complications. Removal of one testis does not affect sex drive, potency, or the ability to have children. The patient is advised to wear an athletic supporter and to avoid vigorous exercise for a month or so after the operation.

Orchiopexy

An operation in which an undescended testis (see *Testis, undescended*) is brought down into the scrotum. It is usually performed before a boy is 5 to avoid the risk of the condition causing infertility or even cancer of the testis (see *Testis, cancer of*).

An incision is made in the groin (using a general anesthetic) and the testis is gently maneuvered down the inguinal canal leading from the abdomen to the scrotum. The base of the testis is then usually attached to the scrotum with a few stitches to prevent it from retracting.

Pain and swelling are relieved with *analgesics* (painkillers) and an *ice pack*. Healing usually takes place without any complications.

Orchitis

Inflammation of a testis. Orchitis may be caused by infection with the virus that causes *mumps*.

Orchitis develops in about one quarter of males who contract mumps after puberty. It is characterized by swelling and severe pain in the affected testis and a high fever. In *epididymo-orchitis* (which has different causes), the tube that carries sperm from the testis is also inflamed.

Treatment is with *analgesics* (painkillers) and *ice packs* to reduce swelling and pain; antibiotics are usually given. The condition usually begins to subside after three to seven days. Occasionally, orchitis is followed by shrinking of the testis.

Organ

A collection of various *tissues* integrated into a distinct structural unit that performs specific functions. For example, the brain consists of nerve tissue and supporting tissue (called neuroglia) organized to receive, process, and send out information.

Organ donation

The agreement of a person (or his or her relatives) to the surgical removal of one or more organs for use in *transplant surgery*. Most organs used as transplants are removed immediately after death, but a kidney is also commonly taken from living *donors*.

The donation of kidneys by living donors is usually confined to relatives of the transplant patient. This occurs for medical reasons (because a relative is more likely to have the same or a similar tissue type as the patient) and for ethical reasons (because physicians discourage the sale of living organs). The risks of donation are carefully explained and the kidney is removed only after the donor gives clear voluntary consent.

The range of organs removed after death is much greater, including the heart, lungs, liver, pancreas, and kidneys. Most organs can be transplanted successfully only if removed immediately after death; the best results often require surgical removal of organs before the donor's heart has stopped beating. In practice this means that most donations of major organs are made from patients who die in an intensive-care unit and are certified as "brain dead" while still having the heart and lung function maintained by a machine (see *Death*).

People who want to donate some or all of their organs after death should make their intentions clear to their relatives and sign a donor card. In most Western countries the demand for donated organs is far greater than the supply. Some countries have introduced laws that allow physicians to remove organs after death unless the patient has specifically forbidden it. In practice, physicians are reluctant to carry out such legislation and the supply of donor organs continues to depend on voluntary donations. (See

also *Corneal graft; Heart valve surgery; Heart transplant; Heart-lung transplant; Kidney transplant; Liver transplant.*)

Organic
Related to a body organ; having organs or an organized structure; or related to organisms or to substances from them. In chemistry, the term refers to any of the group of compounds that contain carbon, with the exception of carbon oxides (such as carbon dioxide) and sulfides and metal carbonates (such as calcium carbonate). The term also signifies the presence of disease, in contrast to a *functional disorder* or psychosomatic complaint. (See also *Inorganic.*)

Organic brain syndrome
See *Brain syndrome, organic.*

Organism
A general term for any individual animal or plant. Medically, the most important are humans and disease-causing *microorganisms*, such as *bacteria, fungi, protozoa*, and *viruses.*

Orgasm
Intense sensations resulting from the series of muscular contractions that occur at the peak of sexual excitement. Orgasm is usually followed by physical relaxation and often drowsiness.

In men, contractions of the muscles of the inner pelvis massage seminal fluid from the prostatic area into the urethra, from which it is forcefully propelled from the urethral orifice (see *Ejaculation*). Following orgasm, the penis becomes soft again and there is a refractory period during which there is no physical response to further sexual stimulation.

Orgasm in women is associated with irregular contractions of the voluntary muscles of the walls of the vagina and, in some women, of the uterus, followed by relief of congestion in the pelvic area. Orgasm usually lasts about three to 10 seconds, but can last up to a minute in some women. There is no refractory phase; some women experience multiple orgasms if stimulation is continued.

Both men and women may have problems with orgasm (see *Ejaculation, disorders of; Orgasm, lack of*).

Orgasm, lack of
The inability to achieve orgasm. Lack of orgasm is the most common sexual problem in women. Between 30 and 50 percent experience difficulties at some time in their lives. The once-used term "frigidity" to describe lack of orgasm is outmoded and considered perjorative by many women. Lack of orgasm is rarer in men (see *Ejaculation, disorders of*).

Some women (10 to 15 percent) are not able to achieve orgasm under any circumstances. Others experience orgasm only occasionally or under special circumstances.

CAUSES

Lack of orgasm is usually caused by sexual inhibition, inexperience, lack of knowledge, or psychological factors (such as anxiety or early sexual trauma). In some cases it may be due to alcohol dependence, certain drugs, or pain during intercourse (see *Intercourse, painful*).

Inability to achieve orgasm under any circumstances may stem from poor sex education or lack of familiarity with the body's sexual responses. Psychological attitudes also contribute. Some women are ashamed of their bodies, are inhibited about the sex act, have deep-seated guilt feelings about sexual pleasure, fear pregnancy, feel uncertain about intimacy, or fear "letting go" or losing momentary control during an orgasm. They therefore cannot relax during sex. Additionally, some women have difficulties with physical arousal and never reach or get past the excitement stage (see *Sexual desire, inhibited*) due to not receiving or not allowing sufficient foreplay.

A woman may be able to achieve orgasm through masturbation but fail to achieve orgasm with her partner. This may occur with a new partner who is unfamiliar with the woman's sexual responses. In other cases, a woman may be able to achieve orgasm through stimulation by a partner, but not through intercourse. This is sometimes attributable to the longer time a woman needs to attain coital climax (about 13 minutes for a woman compared to less than three minutes for the average man). Lack of experience or knowledge, impatience, or premature ejaculation of the partner are factors. Problems in a long-term relationship may be due to underlying feelings of hostility, boredom, or distrust. Performance anxiety caused by the pressure to have an orgasm may also be an inhibiting factor, which in time sets up a cycle of failure.

TREATMENT

Any physical problems should be treated. Otherwise, women may be helped to achieve orgasm or to increase the frequency of orgasms through *sex therapy* or *marital counseling. Psychotherapy* may be helpful for women in whom the problem is related to deep-seated feelings of guilt or insecurity.

Ornithosis
A disease of birds that is caused by the microorganism *CHLAMYDIA PSITTACI.* It can be transmitted to humans, causing *psittacosis*, a feverish illness accompanied by pneumonia.

Orphan drugs
Drugs that have been developed to treat rare conditions but are not manufactured because the potential sales are small while the cost of carrying out the necessary safety tests is high. Reluctance to market an orphan drug may increase if the drug is out of patent (i.e., available for other companies to market) or cannot be patented because it is a known substance. However, changes in the law have made it profitable to provide certain orphan drugs.

An example of an orphan drug is tetrahydroaminoacridine (THA). Although clinical trials suggest THA may improve orientation and memory in people who have *Alzheimer's disease*, it has not been manufactured because the patent has expired.

Orphenadrine
A *muscle-relaxant drug* used to relieve painful muscle spasm caused by injury to soft tissues (such as muscles and ligaments). Orphenadrine is also given to reduce muscle rigidity in *Parkinson's disease.*

Possible adverse effects include dryness of the mouth and blurred vision.

Ortho-
A prefix meaning normal, correct, or straight, as in orthopedics (from the Greek for "straight child"), which originally concerned the correction of skeletal deformities in children. Today it includes all bone or joint problems in any age group.

Orthodontic appliances
Devices, commonly known as braces, worn to correct *malocclusion* (poorly positioned teeth). Braces are most commonly fitted during childhood and adolescence when the teeth and jaws are still developing.

WHY THEY ARE USED

Braces are usually worn to correct overcrowded teeth that splay outward, tilt inward, or rotate (see *Overcrowding, dental*). Braces are fre-

O

quently used on *buck teeth* (projecting upper front teeth) and may also be used to reposition upper and lower premolars and molars (back teeth) when a faulty relationship between the upper and lower jaws prevents the teeth from meeting properly and interferes with chewing. Sometimes braces are required when permanent teeth fail to develop; in such cases, it may be necessary to move teeth to create room for artificial teeth.

TYPES

FIXED APPLIANCES These braces, which cannot be removed by the wearer, exert a continuous pressure and can move teeth in any direction. They are usually fitted to all the upper and/or lower teeth and are used when many teeth need repositioning.

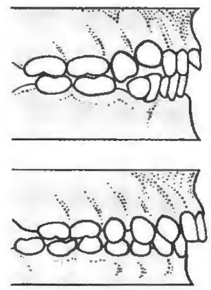
The tooth-moving part of a fixed appliance is the arch wire, an adjustable, high-tensile steel wire, threaded through a bracket on each tooth.

To allow extra force to be applied to specific teeth, some brackets may be fitted with small hooks to which headgear (straps that fit around the back and over the top of the head) can be attached when the wearer is at rest.

Fixed appliances are kept in the mouth until the teeth have moved into the correct position, which may take a year or more. Thereafter, a fixed or removable retainer plate may need to be worn for anywhere from six months to five years to hold the teeth in their correct place until tooth and jaw growth stop in late adolescence.

Fixed appliances give more precise control over tooth movement than removable braces, but they are more expensive and take longer to fit and adjust. They also trap *plaque* (the sticky coating that forms on teeth and causes decay) and make cleaning of the teeth more difficult.

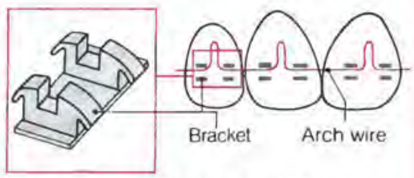
Lingual braces ("invisible" braces) also can be used by some people in the inner arch (the tongue side) of teeth. These braces pull rather than push teeth into place.



REMOVABLE APPLIANCES These braces are used when only one or several teeth need correcting. They consist of a plastic plate that covers the roof of the mouth (or, much less commonly, the floor of the mouth) with attachments that anchor over the back teeth. Force is applied by means of springs, wire bows, screws, or rubber bands fitted to the plate, sometimes combined with the use of headgear.

Occasionally, removable appliances are used in younger children before facial growth has stopped. They consist of interconnected upper and lower plates that force the jaw into a position of slight tension against the pull of the surrounding muscles, translating this force to move the teeth.

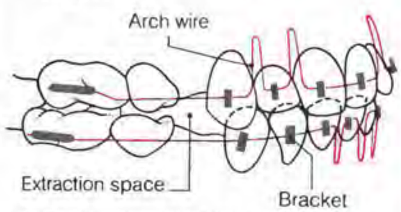
Potential disadvantages of removable appliances are that their bulk may interfere with speech and that wearers may remove them so often that they become ineffective.



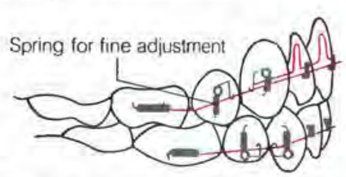
HOW ORTHODONTIC APPLIANCES WORK

The tooth sockets are remarkably responsive to sustained pressure against the teeth. Orthodontic appliances, which may be fixed or removable, provide such pressure. Even gentle pressure applied in a particular direction will move teeth. As they move, bone is remodeled so that the new position is stable.

Overcrowding
This is frequently associated with malocclusion (poor alignment between upper and lower teeth). Teeth may have to be extracted to make room for those to be straightened.



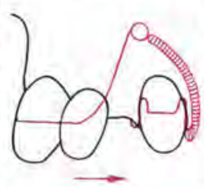
FIXED APPLIANCES



Appearance of brackets and wires
Brackets are fixed appliances cemented to the outer surface of the teeth; they have slots into which arch wires can be fitted.

By careful design of the arrangement of wires and springs, force can be exerted in any direction to move a tooth into the desired position.

1 Teeth are removed to create space and an appliance made to correct the alignment of the remaining teeth and to close gaps between them.



2 Once the teeth in the upper and lower jaws are aligned, the appliance is adjusted to tip or rotate the teeth to give a good appearance and bite.

REMOVABLE APPLIANCES

These are easier to keep clean than fixed appliances and are less obtrusive, but they may interfere with speech; their efficiency relies on patients using them as directed. This type exerts pressure to push the teeth at the sides outward.

Bow device
This simple wire spring acts by exerting force to straighten the tooth. Many bow devices are more complicated.

A removable bow
One of the many forms of orthodontic wire appliance, this bow device exerts pressure on the teeth at the sides, which straightens and moves them outward.

Orthodontics

A branch of dentistry concerned with the prevention and treatment of *malocclusion* (irregularities of the position of teeth or an abnormal relationship between the upper and lower teeth). In most cases, the orthodontist performs orthodontic procedures on children and adolescents while the teeth are still developing and are

relatively maneuverable. However, adults are also able to benefit from orthodontic treatment.

Diagnosis of the exact type of malocclusion involved may require making models of the teeth (see *Impression, dental*) to see clearly how they come together when clenched, taking X rays of the head to relate the position of the teeth to that of the facial bones, and taking X rays of the jaws to study their structure and relationship.

Orthodontic treatment consists of moving poorly positioned teeth by means of gentle pressure exerted by *orthodontic appliances* (braces). To achieve this, the orthodontist may first need to extract certain teeth, often the first molars, to provide growing room for the teeth being moved.

Orthodontist
A dentist who specializes in preventing or correcting crooked, crowded, or irregularly spaced teeth and abnormal relationships between the upper and lower teeth (see *Malocclusion*). To achieve this, the orthodontist makes use of various *orthodontic appliances*.

Orthognathic surgery
An operation to correct deformity of the jaw and the severe *malocclusion* (abnormal relationship between the upper and lower teeth) that is invariably associated with it.

HOW IT IS DONE

The operation, which usually requires a stay in the hospital, is carried out using a general anesthetic.

A jaw that projects too far can be shortened by removing a block of bone from each side and maneuvering the front of the jaw backward. A jaw that is too short can be remedied by dividing the bone on each side, sliding the front of the jaw forward, and inserting bone grafts (taken from elsewhere in the body) into the gaps.

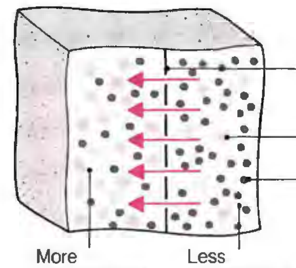
After repositioning, the bones often require splinting (see *Splinting, dental*) until healing occurs.

Orthopedics
The branch of surgery concerned with disorders of bones and joints and the muscles, tendons, and ligaments associated with them. Orthopedists perform many tasks, including setting broken bones and putting on casts; treating joint conditions, such as dislocations, slipped disks, arthritis, and back problems; treating bone tumors and birth defects of the skeleton; and surgically repairing or replacing hip, knee, or finger joints.

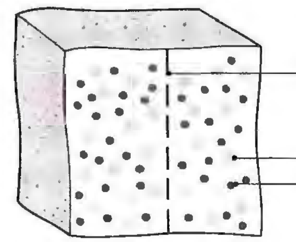
Orthopedist
A physician who specializes in problems affecting bones, joints, and related structures (see *Orthopedics*).

Orthopnea
Breathing difficulty brought on by lying flat. Orthopnea is a symptom of *heart failure* (reduced pumping efficiency) and is caused by *edema* (fluid collection) in the lungs. It also occurs with *asthma* and chronic obstructive lung disease (chronic *bronchitis* with or without *emphysema*).

Orthoptics
A technique used to measure and evaluate *strabismus* (misalignment of the eyes). Orthoptics sometimes includes eye exercises, which may or may not help the strabismus.



Os
An anatomical term for a bone, as in os coxae, the hip bone. The plural of os is ossa, as in ossa cranii, the skull bones. The term os also refers to an opening in the body, usually the cervical os (entrance to the uterus).



Osgood-Schlatter disease
Painful enlargement of the tibial tuberosity, the bony prominence of the tibia (shin) just below the knee. Osgood-Schlatter disease occurs in children (usually boys) aged 10 to 14.

The condition is caused by excessive, repetitive pulling of the quadriceps muscle (at the front of the thigh) on the patellar tendon, which is attached to the tibial tuberosity. There is usually pain above and below the knee, which is worse during strenuous activity, and the tibial tuberosity is tender when touched.

Osgood-Schlatter disease usually clears up completely without treatment; if pain is severe, the knee may be immobilized in a plaster cast.

Osmosis
The passage of a solvent (such as water) through a semipermeable membrane (one that acts like a sieve) from a less concentrated (weaker) solution to a more concentrated (stronger) one. Osmosis occurs whenever solutions of different strengths are separated by a semipermeable membrane and continues until the two solutions are of equal strength unless the movement of solvent is opposed by applying pressure to the stronger solution. The pressure needed to stop the movement completely is called the osmotic pressure.

Osmosis
If two solutions, consisting of different concentrations of a solute (e.g., salt) in a solvent (e.g., water), are separated by a semipermeable membrane, solvent moves from the weaker to stronger solution until the two solutions attain equal concentration.

Semipermeable membranes are widespread in the body—they surround all cells. These membranes allow water, salts, simple sugars (such as glucose), and amino acids (but not proteins) to pass through. Consequently, osmosis plays an important part in regulating the distribution of water and other substances.

Ossicle
A small bone, particularly the malleus (hammer), incus (anvil), and stapes (stirrup)—the three tiny bones in the middle *ear* that conduct sound from the eardrum to the inner ear.

Ossification
The process by which *bone* is formed, renewed, and repaired. Ossification begins in the embryo and continues throughout life. There are three main types of ossification: bone growth, during which new bone is formed mainly from *cartilage* at the *epiphyses* (bone ends); bone renewal, which occurs as part of the normal regeneration process; and bone repair, which fuses broken bones after a fracture.

Osteitis
Inflammation of bone. The most common cause is infection (see *Osteomyelitis*). Other causes are *Paget's disease* and *hyperparathyroidism*.

Osteo-

A prefix that denotes a relationship to bone, as in *osteoporosis*, a condition in which the bones become thin and weak. The prefix oste- is synonymous with osteo-.

Osteoarthritis

A joint disease aggravated by mechanical stress. Osteoarthritis is characterized by degeneration of the cartilage that lines joints or by *osteophyte* (bony outgrowth) formation, which leads to pain, stiffness, and occasionally loss of function of the affected joint.

INCIDENCE

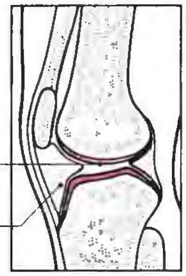
Osteoarthritis occurs in almost all people over age 60, although not all have symptoms. Various factors lead to the development of osteoarthritis earlier in life, including an injury to a joint or a congenital joint deformity. Osteoarthritis may occur with *rheumatoid arthritis*. Severe osteoarthritis affects three times as many women as men.

SYMPTOMS

Osteoarthritis causes pain, swelling, creaking, and stiffness of one or more joints. Pain and stiffness may interfere with activities (such as walking and dressing) and may disrupt sleep.

Weakness and shrinkage (*atrophy*) of surrounding muscles may occur if pain prevents the joint from being used regularly. The affected joints become enlarged and distorted by osteophytes, which account for the gnarled appearance of hands affected by osteoarthritis.

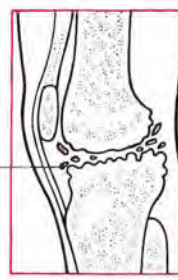
DIAGNOSIS AND TREATMENT



A diagnosis is generally made on the basis of a person having a history of joint pain with use and on physical findings of joint tenderness, swelling, and pain on motion. An X ray can confirm cartilage loss and osteophyte formation and assess the extent of the degenerative process. As yet there is no cure for osteoarthritis; symptoms may be relieved by *analgesics* (painkillers) and *nonsteroidal anti-inflammatory drugs*, which reduce joint inflammation. Sometimes a painful joint can be eased by injection of a *corticosteroid drug*.

Physical therapy, including exercises and heat treatment, can often relieve symptoms. If the condition is severe, various aids can make coping at home easier (see *Disability*).

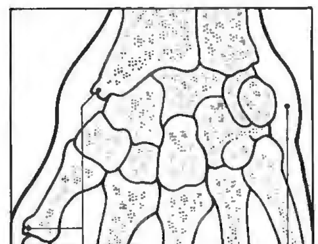
Surgical treatment for severe osteoarthritis includes *arthroplasty* (joint replacement surgery) and *arthrodesis* (immobilization of a joint).



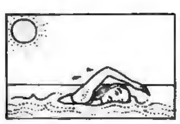
OSTEOARTHRITIS

This differs from rheumatoid arthritis and has a better outlook. It results from excessive wear on joints, sometimes due to obesity or to slight deformity or misalignment of bones in a joint. Inflammation from disease, such as gout, may also proceed to osteoarthritis. Weight-bearing joints, such as those in the neck, the lower back, and the knees and hips, are the most commonly affected by this type of arthritis.

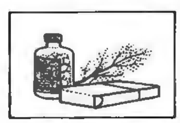
Normal joint surface
The healthy joint is lined with smooth cartilage and lubricated by synovial fluid.



Osteoarthritic joint
In osteoarthritis (below), the cartilage becomes rough and flaky and small pieces break off to form loose bodies.



X-ray signs of osteoarthritis
This X ray shows narrowing of the joint space with osteophyte production and an increase in density of the bone ends.



Osteophytes
These are outgrowths of new bone that tend to occur at the margins of the joint surfaces in osteoarthritis.

TREATMENT AND SELF-HELP MEASURES

An important self-help measure is to shed excess weight to reduce wear and tear on joints. Measures to increase muscle power help to stabilize the affected joint and reduce symptoms.

Swimming
Regular exercise, to strengthen muscles and maintain joint mobility, can be valuable. Swimming in a heated pool increases muscle power without putting undue strain on joints.

Other treatment
Drugs such as aspirin or indomethacin are useful; sometimes corticosteroid injections are advised. There is little evidence that special diets or herbal treatments are effective.

Osteochondritis dissecans

Degeneration of a bone just under a joint surface, causing fragments of bone and cartilage to become separated from surrounding bone.

Osteochondritis dissecans frequently affects the knee and usually starts in adolescence. The exact cause is unknown but the disorder is thought to be caused by damage to a small blood vessel beneath the joint surface, which may be initiated by injury. The separated fragment sometimes reattaches but usually forms a *loose body* within the joint. Symptoms include aching discomfort and inter-

O

mittent swelling of the affected joint. The presence of a loose body may cause locking of a joint in one position.

X rays show damage to the joint and reveal the presence of any loose bodies. If a fragment has not completely separated, the joint may be immobilized in a cast to allow reattachment. Loose bodies of the knee are removed during *arthroscopy*.

The cavity left in the bone by a detached fragment disrupts the smoothness of the joint surface, increasing the likelihood of developing *osteoarthritis* in later life.

Osteochondritis juvenilis

Inflammation of an *epiphysis* (growing area of bone) in children and adolescents. The exact cause is unknown, but the condition is thought to be due to disrupted blood supply to the bone.

There are several distinct types of osteochondritis juvenilis, each involving different bones in the body. *Perthes' disease* affects the epiphysis of the head of the femur (thigh bone), while Scheuermann's disease affects epiphyses of several adjoining vertebrae. Other types affect certain bones in the foot and wrist.

SYMPTOMS AND SIGNS

Osteochondritis juvenilis causes localized pain and tenderness and, if the epiphysis forms part of a joint, restricted movement. Inflammation leads to softening of the bone, which may result in deformity because of surrounding pressure. X rays of the affected area show a patchy appearance and flattening of the bone.

TREATMENT AND OUTLOOK

Immobilization by use of a brace or plaster cast may be used to relieve pain and reduce the risk of deformity. In some cases of Perthes' disease, an operation is required to relieve the pressure on the diseased bone to prevent more deformity.

The bone usually regenerates within three years and rehardens. In many cases, however, deformity is permanent and increases the likelihood of the development of *osteoarthritis* in later life.

Osteochondroma

A benign bone tumor made up of a stalk of bone capped with cartilage. It grows from the side of a bone, usually at the end of a long bone in the region of the knee or shoulder. The osteochondroma develops in late childhood and early adolescence and stops growing when the skeleton is fully developed.

X ray of osteochondroma
The X ray shows a typical osteochondroma protruding from the bone. The tumor has a bony stalk and a cap made of cartilage.

The tumor, which appears as a hard round swelling near a joint, causes problems only if it interferes with the movement of tendons or the surrounding joint. In such cases, surgical removal may be necessary. A large osteochondroma can interfere with skeletal growth, causing deformity.

Osteochondrosis

See *Osteochondritis juvenilis*.

Osteodystrophy

Any generalized defect of the bones caused by a metabolic disorder (an abnormality of the body chemistry). Examples include *rickets*, a childhood condition in which the bones fail to harden properly due to a deficiency of vitamin D; *osteomalacia*, the equivalent condition in adults; *osteoporosis* (wasting away of bone) when it is caused not by aging but by the hormonal disorder *Cushing's syndrome* or by an excessive intake of *corticosteroid drugs*; and bone cysts and reduction of bone mass, which occasionally occur in chronic *renal failure* or *hyperparathyroidism* due to a disturbance in calcium metabolism in the body.

An osteodystrophy is usually reversible if the underlying cause can be treated effectively.

Osteogenesis imperfecta

Abnormally brittle bones from birth caused by a familial (inherited) congenital defective development of the *connective tissue* that forms the basic material of bone.

SYMPTOMS AND SIGNS

Severely affected infants, born with multiple fractures and a soft skull, usually do not survive. Those less severely affected have many fractures, often brought about by minimal force, during infancy and childhood. A physician examining such children may sometimes find it difficult to determine whether the cause is osteogenesis imperfecta or *child abuse*. Very mild cases may not be detected until adolescence or later.

A common accompanying sign of the disorder is abnormal thinness of the sclera (whites of the eyes), making them appear blue. In addition, sufferers of osteogenesis imperfecta may be deaf due to *otosclerosis*.

Osteogenesis imperfecta
Affected children may suffer recurrent fractures of the limbs that lead to deformity and shortening, and to abnormal growth. At right is an X ray of the leg of a sufferer.

TREATMENT AND OUTLOOK

Fractures are generally treated in the usual way (by immobilization); otherwise, there is no specific treatment for the condition. The fractures usually heal quickly but often cause severe shortening and deformity of limbs, resulting in stunted, abnormal growth. Skull fractures may cause brain damage or death.

Osteogenic sarcoma

See *Osteosarcoma*.

Osteoid osteoma

An abnormal area of bone that causes deep pain, which is usually worse at night. An osteoid osteoma is extremely small—about 0.2 inch (0.5 cm)—and can be definitely diagnosed only by X ray. It most commonly affects a long bone of the arm or leg.

Pain can usually be relieved by *aspirin*. The condition is cured by removing the affected area of bone. (See also *Osteochondroma*; *Osteoma*.)

Osteoma

A benign bone tumor. It is hard, usually small, and may occur on any

bone. An osteoma is usually harmless, but surgical removal may be necessary if the tumor causes symptoms by pressing on surrounding structures.

Osteomalacia

Softening, weakening, and demineralization of the bones in adults due to *vitamin D* deficiency (in children, the condition is called *rickets*).

The development of healthy bone requires an adequate intake of calcium and phosphorus from the diet, but these minerals cannot be absorbed by the body without a sufficient amount of vitamin D. A deficiency of this vitamin, which is obtained from certain foods and from the action of sunlight on the skin, results in softening and weakening of the bones, which then become vulnerable to distortion and fractures.

CAUSES

Osteomalacia is usually caused by any of the following, alone or in combination: an insufficient amount of vitamin D in the diet (due to a lack of milk, butter, eggs, or fish liver oils), insufficient exposure to sunlight, or inadequate absorption of vitamin D from the intestine (see *Malabsorption*), which may be caused by a disorder such as *celiac sprue* or by intestinal surgery. Rare causes include *renal failure*, *acidosis* (increased acidity of body fluids), and certain metabolic disorders that are inherited.

Osteomalacia is rare in developed countries. Most commonly affected are people with an inadequate diet, people who rarely or never go outdoors, and dark-skinned immigrants living in a country that has much less sunlight than their countries of origin.

SYMPTOMS AND SIGNS

Osteomalacia causes pain in the bones (particularly those in the neck, legs, hips, and ribs), muscle weakness, and, if the blood level of calcium is very low, *tetany* (muscle spasms) in the hands, feet, and throat. If the bones become greatly weakened, they may break after a minor injury.

DIAGNOSIS AND TREATMENT

Osteomalacia is diagnosed from the symptoms and signs, along with blood tests, urine tests, and bone X rays. In some cases, a bone *biopsy* (removal of a small sample of bone for examination) is performed.

Treatment consists of a diet that is rich in vitamin D and regular supplements of the vitamin. Supplements are usually taken as tablets; if tablets cannot be absorbed by the intestine, injections may be necessary. In some cases of osteomalacia due to malabsorption, calcium supplements may also be taken.

Osteomyelitis

Infection of bone and bone marrow, usually by bacteria. It can affect any bone in the body, is more common in children, and most often affects the long bones of the arms and legs and the vertebrae. In adults, it usually affects the pelvis and the vertebrae. In developed countries, adequate nutrition and a generally high resistance to infection have made the disease, which may be acute or chronic, much rarer than it once was.

ACUTE OSTEOMYELITIS

The infecting microorganism (generally the bacterium *STAPHYLOCOCCUS AUREUS*) enters the bloodstream via a skin wound or an infection (usually in the nose or throat) and is carried to the bone in the blood. The infected bone and marrow become inflamed and pus forms, causing fever, severe pain and tenderness in the infected bone, and inflammation and swelling of the skin over the affected area.

The diagnosis may be confirmed by blood *culture*, bone scanning, and bone *X rays*. Treatment is with high doses of *antibiotic drugs* over several weeks or months. With prompt antibiotic treatment, acute osteomyelitis usually clears up completely. If the condition fails to respond to antibiotics, an operation is performed to expose the bone, to clean out the areas of infected and dead bone, and to drain the pus.

CHRONIC OSTEOMYELITIS

This form may develop when an attack of acute osteomyelitis is neglected or fails to respond to treatment. It may also occur after a compound *fracture* or, occasionally, as a result of *tuberculosis* spreading from another part of the body.

Chronic osteomyelitis causes constant pain in the affected bone. Complications include persistent deformity and, in children, arrest of growth in the affected bone. In the later stages of the disease (which may have been recurring for many years) *amyloidosis* (harmful deposits of a starchy substance in vital organs) may develop.

Chronic osteomyelitis requires surgical removal of all affected bone, sometimes followed by a *bone graft* to replace the removed bone; antibiotics are also prescribed. If the cause is tuberculosis, antituberculous drugs are prescribed for at least one year after surgery.

Osteopathic medicine

A system of diagnosis and treatment that recognizes the role of the musculoskeletal system (bones, muscles, tendons, tissues, nerves, and spinal column) in the healthy functioning of the human body.

Osteopathic medicine was founded on the Missouri frontier in 1874 by Andrew Taylor Still, MD. It is based on the concept of the human body as a unified organism, with the musculoskeletal system as central to the patient's well-being.

The Doctor of Osteopathy (DO) is a fully licensed physician with additional training in osteopathic palpatory diagnosis and manipulative therapy. The DO prescribes drugs and is qualified to practice all branches of medicine and surgery.

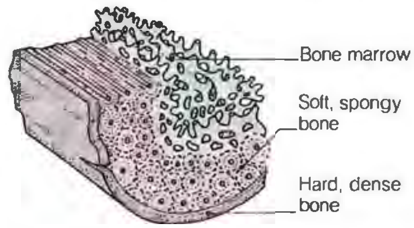
Osteopathic physicians emphasize that all body systems operate in unison, and that disturbances in one system can alter the functions of other systems in the body.

The osteopathic physician uses manipulation techniques, as well as traditional diagnostic and therapeutic procedures, to diagnose and treat dysfunction. Manipulation includes thrusting techniques and rhythmic stretching and pressure to restore motion to the joints.

Osteopetrosis

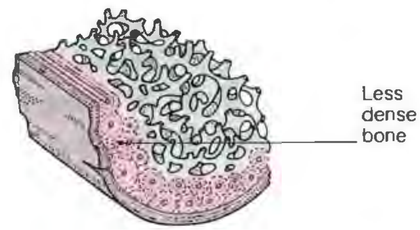
A rare, inherited disorder in which bones harden and become more dense. The growth of healthy bone is a balance between the activity of its two constituent cells, bone-forming osteoblasts and bone-reabsorbing osteoclasts. In osteopetrosis, there is a deficiency of osteoclasts, which results in the disruption of normal bone structure.

The mildest form of osteopetrosis may not cause any symptoms. More severe forms can result in greater susceptibility to fractures, stunted growth, deformity, and anemia. Pressure on nerves may cause blindness, deafness, and facial paralysis.



Bone marrow transplants have been attempted on an investigational basis. The transplant supplies the recipient with cells from which healthy osteoclasts might develop.

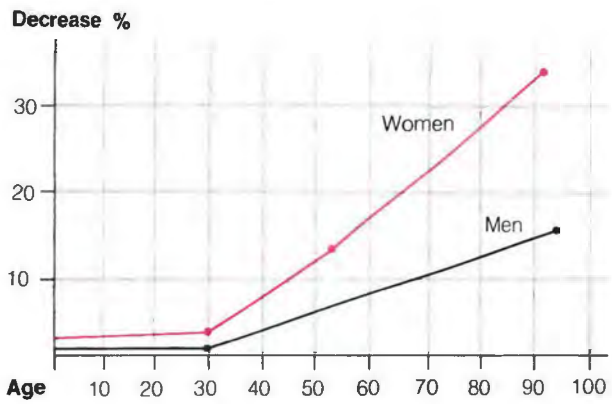
Osteophyte



A localized outgrowth of bone that forms at the boundary of a joint. Osteophytes are a characteristic of *osteoarthritis* and are partly responsible for the deformity and restricted movement of affected joints.

OSTEOPOROSIS

In osteoporosis, the density of bones decreases, and their brittleness increases, although there is no change in size or composition. Women past the menopause are the most commonly affected because their ovaries no longer produce estrogen, which helps to maintain bone mass. The risk of the condition is greater in a woman who undergoes the menopause early, or whose mother had osteoporosis.



Normal bone cross section
Bone consists of fibers of collagen (a protein), which give elasticity, and calcium, which gives hardness.

Osteoporotic bone
Thinning is mainly due to loss of collagen, which takes calcium with it. Both hard and spongy bone tissue are affected

Bone loss with age
The graph at right shows how the percentage of bone lost increases in both sexes from age 30 onward, with the losses particularly marked in women after the menopause. By age 75, about half of all women have sustained at least one fracture due to osteoporosis, a much higher proportion than in men.

Spine affected by osteoporosis
The X rays show progressive thinning of the vertebrae, giving a characteristic "codfish" appearance to the spine.

Osteoporosis

Loss of protein matrix tissue from bone, causing it to become brittle and easily fractured.

Many physicians do not discriminate between osteoporosis and *osteomalacia*, diagnosing any decreased density of bone (thinning) as osteoporosis. In fact, decreased density may be caused by osteomalacia or by osteomalacia with osteoporosis.

Osteoporosis is a natural part of aging. By age 70, the density of the skeleton has diminished by about one third. However, for hormonal reasons, the condition is much more common in women than in men. Also, for reasons that are unknown, osteoporosis is more common in whites than in blacks.

CAUSES

Bone naturally becomes thinner as a person ages, but women are especially vulnerable to osteoporosis after the *menopause* because their ovaries no longer produce *estrogen hormone*, which helps maintain bone mass.

Other causes of the disorder include removal of the ovaries; a diet deficient in calcium, which is essential for bone health; certain hormonal disorders, such as *Cushing's syndrome*, or prolonged treatment with *corticosteroid drugs*; and prolonged immobility. Osteoporosis is more common in smokers and drinkers and, for unknown reasons, is associated with chronic obstructive lung disorders, such as *bronchitis* and *emphysema*.

SYMPTOMS AND SIGNS

In many cases, osteoporosis produces no obvious symptoms; the first sign is often a fracture after a fall that would not cause a fracture in a young adult. Typical sites for such fractures are just above the wrist and the top of the femur (thigh bone). Another type of fracture that occurs in osteoporosis is a spontaneous fracture of one or several vertebrae, which causes the bones to be compressed, leading to a progressive loss of height or to pain due to compression of a spinal nerve.

DIAGNOSIS

The condition is diagnosed from the symptoms and from bone X rays. In some cases, blood tests and a bone *biopsy* (removal of a sample of bone for examination) may also be necessary to exclude osteomalacia.

TREATMENT AND PREVENTION

Lost bone tissue cannot easily be replaced, but more bone loss can be minimized by preventive measures. For example, both men and women should ensure that their *calcium* intake is adequate. The richest dietary sources of this mineral are milk and milk products, green leafy vegetables, citrus fruits, sardines, and shellfish. Calcium tablets may be needed.

Exercise also helps to build bones, but anything less than three brisk three-mile walks a week (or the equivalent) is unlikely to be of much benefit in preventing osteoporosis.

Hormone replacement therapy to compensate for reduced estrogen production after the menopause has been shown to prevent osteoporosis in women; in the US, it has halved the rate of fractures caused by osteoporosis in menopausal women.

Osteosarcoma

A malignant bone tumor that occurs primarily in adolescent and elderly people. It spreads rapidly to the lungs and, less commonly, to other areas.

In young people, osteosarcoma develops for no known reason; in elderly people, it is a late, rare complication of *Paget's disease*.

SYMPTOMS AND DIAGNOSIS

The most common site of the tumor in young people is in a long bone of the leg or arm, or around the knee, hip, or shoulder. The first symptom is usually a painful visible swelling of the affected bone (if it is near the surface) or a deep-seated pain (if the affected bone cannot be felt through the skin).

As a complication of Paget's disease, an osteosarcoma may develop in several bones; its pain may be indistinguishable from that caused by the original disease.

Diagnosis is usually based on *X rays* of the bone. Other imaging techniques (e.g., *MRI*) may also be used.

TREATMENT AND OUTLOOK

Although *radiation therapy* is sometimes used to treat the tumor, the bone is usually surgically removed. In most cases, this means *amputation* of a limb; in some cases, a prosthesis can be fitted immediately after the amputation (see *Limb, artificial*). The tumor can also be treated by removal and bone graft or bone transplant.

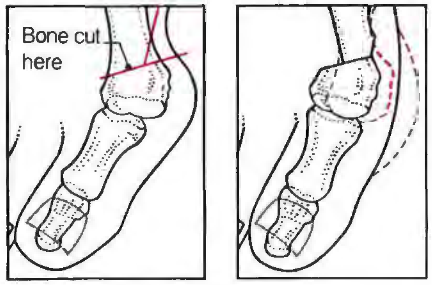
Treatment with *anticancer drugs* is usually given for several months after the operation to destroy any cancer cells that may have spread to other parts of the body. With this additional treatment, the outlook is good; about half of all patients whose disease is discovered early are cured.

Osteosclerosis

Increased bone density, usually detected on *X-ray* film as an area of extreme whiteness.

Localized osteosclerosis may be caused by a severe injury that compresses the bone; by *osteoarthritis*, in which bone around affected joints thickens; by chronic *osteomyelitis*, in which healthy bone next to the infected area thickens and becomes more dense; or by an *osteoma* (benign bone tumor), which consists of a hard, dense, usually harmless outgrowth of normal bone tissue.

Osteosclerosis occurs throughout the body in *osteopetrosis*, an inherited bone disorder.



Osteotomy

An operation in which a bone is cut to change its alignment or to shorten or lengthen it.

WHY IT IS DONE

Osteotomy is performed on a deformity of the big toe that has caused a bunion (see *Hallux valgus*). It is also performed to straighten a long bone that has healed crookedly after a *fracture* or to shorten the uninjured leg after a fractured leg has shortened during healing (see *Leg, shortening of*).

Osteotomy may be used to correct the deformity caused by congenital dislocation of the hip (see *Hip, congenital dislocation of*) that has not been detected until after about age 10. It is also used to correct *coxa vara* (hip deformity usually caused by injury).

Example of an osteotomy
This procedure is performed to correct a hallux valgus (outward protrusion of the joint at the base of the toe), usually because it has caused a bunion. Part of the top of the first metatarsal bone is removed.

HOW IT IS DONE

Using general anesthesia, bones are straightened by cutting through them and repositioning the ends; sometimes a wedge of bone is inserted or removed to achieve the correct alignment. Bones can be lengthened by making an oblique cut and displacing the two parts slightly before rejoining them. Bones can be shortened by cutting out a section of bone and rejoining the two parts.

After the operation, bones that were corrected during surgery are held in position by a metal plate or nail or by a plaster cast or splint.

Ostomy

The term used to describe a surgical opening or junction of two hollow organs (e.g., *colostomy* and *ileostomy*).

Ot-

A prefix that denotes a relationship to the ear, as in otitis, inflammation of the ear. The prefix oto- is also used to denote the ear.

Otalgia

The medical term for *earache*.

OTC

The abbreviation for over-the-counter. OTC refers to drug preparations that may be purchased from a drugstore without a prescription from a physician.

Otitis externa

Also called swimmers' ear, inflammation of the outer-ear canal that is caused by infection.

CAUSES

Generalized infection, affecting the whole canal and sometimes also the pinna (the external ear), may be caused by bacteria or by fungi, which produce a persistent inflammation known as otomycosis. Bacterial infection may also cause a localized infection in the form of a *boil*. In some cases, the outer-ear canal becomes inflamed as part of a generalized skin disorder, such as atopic *eczema* or seborrheic *dermatitis*.

Malignant otitis externa is an uncommon and occasionally fatal form of the disorder caused by the bacterium *PSEUDOMONAS AERUGINOSA*. It usually affects elderly diabetics, whose resistance to infection is reduced, and spreads rapidly into surrounding bones and soft tissue.

SYMPTOMS AND SIGNS

Otitis externa usually causes redness and swelling of the skin of the ear canal, a discharge from the ear, and sometimes an area of eczema around the opening of the ear. The ear may itch only in the early stages, but can become painful. Occasionally, pus blocks the ear, causing deafness.

DIAGNOSIS AND TREATMENT

The physician examines the ear with an *otoscope* (a viewing instrument) and may take a sample of any pus for laboratory analysis.

Often the only treatment required is a thorough cleaning and drying of the ear by the physician, sometimes using a suction apparatus. Antibiotic, antifungal, or anti-inflammatory drugs are often necessary. Oral antibiotics are used for the treatment of severe bacterial infections. If the ear canal is very swollen, a wick should be placed in the canal to allow drops to enter. The sufferer should avoid getting the ear canal wet until the infection has cleared up.

Otitis media

Inflammation of the middle ear (the cavity between the eardrum and the inner ear).

CAUSES

The inflammation occurs as the result of an upper respiratory tract infection (such as a cold) extending up the eustachian tube, the passage that connects the back of the nose to the middle ear. The tube may become blocked by the inflammation or sometimes by enlarged *adenoids*, which are often associated with infections of the nose and throat. As a result, fluid produced by the inflammation—along with pus in bacterial infections—is not drained off through the tube but accumulates in the middle ear.

The chronic phase of otitis media (otitis media with effusion) follows an upper respiratory infection that has produced acute otitis media.

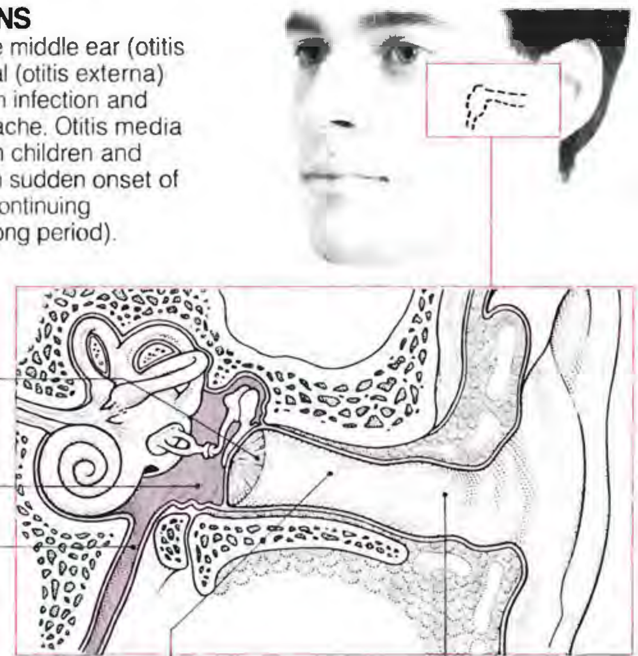
INCIDENCE
Children are particularly susceptible to otitis media, probably because of the shortness of their eustachian tubes. About one in six children suffers from the acute form in the first year of life and about one in 10 in each of the next six years. Some children have recurrent attacks. Chronic otitis media is much less common because, in most cases, attacks of acute middle-ear infection clear with treatment.

SYMPTOMS AND SIGNS
Acute otitis media is marked by sudden, severe earache, a feeling of fullness in the ear, deafness, tinnitus (ringing or buzzing in the ear), and fever. Sometimes the eardrum bursts, relieving the pain and resulting in a discharge of pus. In this case, healing usually occurs in several days.

In chronic otitis media, pus constantly exudes from a perforation in the eardrum and there is some degree of deafness. Complications of the condition include *otitis externa* (inflammation of the outer ear); damage to the bones in the middle ear, causing more deafness (sometimes total) in the affected ear; or a *cholesteatoma* (a matted ball of sometimes infected skin debris). In rare cases, infection spreads inward from an infected ear, causing *mastoiditis* or a *brain abscess*.

DIAGNOSIS
The diagnosis is usually made from examining the ears with an *otoscope* (a viewing instrument). A swab may be taken of any discharge so that the organism responsible for the infection can be cultured and identified.

TREATMENT
Acute otitis media is treated by giving antibiotic drugs and analgesics (painkillers). Usually, the condition clears up completely with treatment, but in some cases there is continual production of sticky fluid in the middle ear, a condition known as persistent *middle-ear effusion*.



Chronic otitis media is treated by sucking out pus and infected debris from the ear as necessary. Antibiotic ear drops may be given if this does not adequately control the condition.

Otolaryngologist, head and neck surgeon

A specialist in the medical and surgical treatment of disorders of the head and neck, excluding the brain, eyes, spinal cord, and spinal column. The term "head and neck surgery" refers to surgical procedures on certain tumors of the sinuses, throat, and neck, and to facial plastic surgery.

EAR INFECTIONS

Inflammation of the middle ear (otitis media) or ear canal (otitis externa) usually results from infection and may cause an earache. Otitis media is more common in children and may be acute (with sudden onset of pain) or chronic (continuing painlessly over a long period).

Otitis media
This usually occurs through spread of infection from the back of the nose to the middle ear via the eustachian tube.

Otitis externa
The ear canal is susceptible to infection if it is moist (after swimming) or damaged by attempts to remove earwax.

Much of an otolaryngologist's time is spent treating common conditions, such as *sinus* infections, acute *otitis media* (middle-ear infection), persistent *middle-ear effusion*, *tonsillitis*, and minor hearing loss. The otolaryngologist is often faced with complex and difficult problems, such as *otosclerosis*, *Meniere's disease*, airway problems in children, uncontrollable bleeding from the nose, and cancer of the larynx and sinuses.

Otoplasty

Cosmetic or reconstructive surgery on the outer ear. Otoplasty is usually performed to flatten protruding ears. It may also be done to construct or repair a missing or badly damaged ear.

PROTRUDING EARS
The operation, as described at right, is usually done as an outpatient procedure using local anesthesia. After the operation, the ear is dressed until the wound has healed 10 to 14 days later, when the stitches are removed. The scar is hidden in the crease between the ear and scalp.

LACK OF AN OUTER EAR
Some children are born with part or all of the outer ear missing. These children may also lack an external ear passage; in some cases there is also underdevelopment of the same side of the face.

Treatment involves transferring a piece of rib cartilage, which is sculpted to resemble the normal ear, to a pocket of skin in the position that the ear will be placed. The procedure usually involves three operations. Hearing in the reconstructed ear may be abnormal but, if the child has a normal range of hearing in the other ear, no attempt is made to improve hearing in the reconstructed ear.

Otoplasty for protruding ears
A strip of skin is removed from behind each ear. The underlying cartilage is remolded and the two edges of the wound stitched together, thus pulling the ear closer to the head. The appearances before and after are shown

Otorhinolaryngology
The full title for the surgical specialty concerned with diseases of the ear, nose, and throat (see *Otolaryngologist, head and neck surgeon*).

Otorrhea
The medical name for a discharge from the ear (see *Ear, discharge from*).

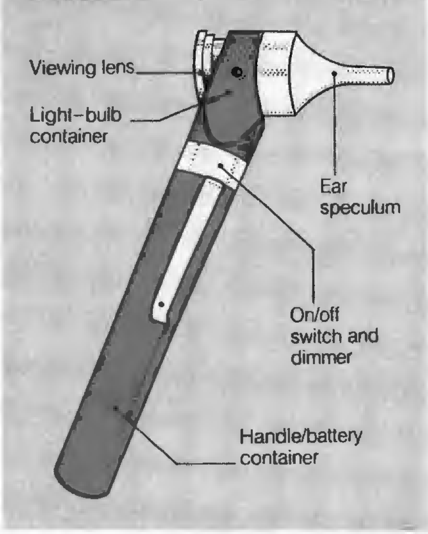
Otosclerosis
A disorder of the middle ear that causes progressive deafness. Otosclerosis is often inherited.

CAUSES AND INCIDENCE

Otosclerosis occurs when, for unknown reasons, an overgrowth of bone immobilizes the stapes (the innermost bone of the middle ear). This prevents sound vibrations from being passed to the inner ear, resulting in conductive *deafness*. In most cases of otosclerosis, both ears are ultimately affected.

About one person in 200 is affected by the disease, which usually starts in early adulthood. It is more common in women than in men and often develops during pregnancy.

SYMPTOMS AND SIGNS



Sound is heard as muffled but is more distinguishable when there is background noise. Affected people tend to talk quietly. Hearing loss progresses slowly over a period of 10 to 15 years and is often accompanied by *tinnitus* (noises in the ear) and sometimes by *vertigo* (dizziness). Some sensorineural deafness (caused by damage spreading to the inner ear) may eventually occur, making high tones difficult to hear and resulting in the sufferer speaking loudly.

DIAGNOSIS AND TREATMENT

The diagnosis is based on abnormal results of *hearing tests*. A *hearing aid* is an excellent treatment for otosclerosis; the deafness can be cured only by *stapedectomy*, an operation in which the stapes is replaced with an artificial substitute. Stapedectomy is usually performed on only one ear at a time because there is a risk that total deafness may result in the operated ear.

Otoscope
An instrument for examining the ear. An otoscope includes magnifying lenses, a light, and a speculum (a funnel-shaped tip that is inserted into the ear canal). The instrument allows easy inspection of the outer-ear canal and the eardrum. With an otoscope it is also possible to detect certain diseases of the middle ear through the semitransparent eardrum.

OTOSCOPE

Ototoxicity
Having a poisonous effect on the ear. High doses of certain drugs (especially aminoglycoside *antibiotic drugs*) can damage the cochlea and the semicircular canals in the inner ear, impairing hearing and balance.

Outpatient treatment
Medical care given to a person on a day basis in a clinic or other facility.

Ovarian cyst
An abnormal, fluid-filled swelling in an ovary. Ovarian cysts are common and are benign in about 95 percent of cases. Many ovarian cysts disappear without treatment.

TYPES

The most common type of ovarian cyst is a follicular cyst, in which the egg-producing follicle of the *ovary* enlarges and fills with fluid. Cysts may also occur in the corpus luteum, a yellow mass of tissue that forms from the follicle after *ovulation*.

Other types of ovarian cysts include *dermoid cysts* and malignant cysts (see *Ovary, cancer of*).

SYMPTOMS AND SIGNS

Ovarian cysts often cause no symptoms, but some cause abdominal discomfort, pain during intercourse, or menstrual irregularities including *amenorrhea* (lack of menstruation), *menorrhagia* (heavy periods), or *dysmenorrhea* (painful periods). Severe abdominal pain, nausea, and fever, which necessitate surgery, may develop if twisting of a cyst occurs.

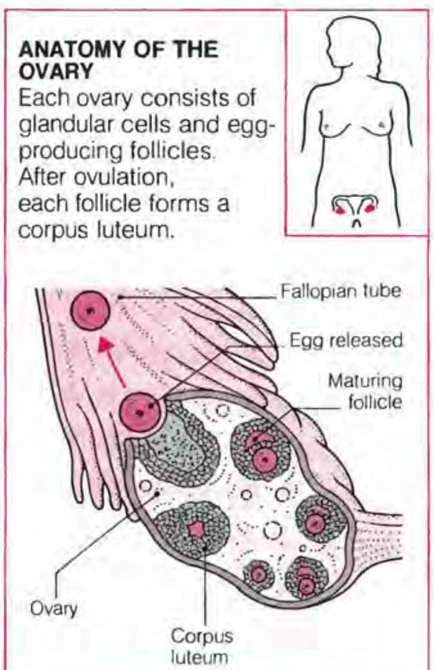
DIAGNOSIS AND TREATMENT

A cyst may be discovered during a routine *pelvic examination*. *Ultrasound scanning* or a *laparoscopy* (examination of the abdominal cavity through a viewing tube) may be necessary to confirm the diagnosis and to determine the size and position of the cyst.

Simple cysts (thin-walled and filled with fluid) often go away on their own, but complex cysts (such as dermoid cysts) do not. They often require surgical removal. In many cases, only the cyst needs to be removed, but if a cyst is large it is sometimes necessary for the surgeon to remove the entire ovary (see *Oophorectomy*).

Ovary
One of a pair of almond-shaped glands situated on either side of the *uterus* immediately below the opening of the *fallopian tube*. Each ovary is about 1.25 inch (30 mm) long and 0.75 inch (20 mm) wide and contains numerous cavities called follicles in which egg cells (see *Ovum*) develop. In addition to producing ova, the ovaries also produce the female sex hormones estrogen and progesterone.

DISORDERS



Absence or failure of normal development of the ovaries is a rare disorder usually caused by a chromosomal abnormality (see *Turner's syndrome*).

Oophoritis (inflammation of the ovary) may be caused by the *mumps* virus or by other infections such as *gonorrhea* or *pelvic inflammatory disease*.

Ovarian cysts may develop at any age; about 95 percent of them are benign. *Polycystic ovary* syndrome, in

ANATOMY OF THE OVARY

Each ovary consists of glandular cells and egg-producing follicles. After ovulation, each follicle forms a corpus luteum.

which multiple ovarian cysts form, is an uncommon disorder thought to be due to the body's inappropriate hormonal stimulation of the ovaries. The cysts may produce male sex hormones, leading to *amenorrhea*, *infertility*, and *hirsutism*.

Cancer of the ovary (see *Ovary, cancer of*) occurs mainly in women over 50 and usually causes few symptoms (if any) in the early stages, although it can cause symptoms similar to those of an ovarian cyst.

Ovarian failure, in which the ovaries cease to function, causes premature *menopause* in about 5 percent of all women.

Ovary, cancer of

Malignant growth of the *ovary*. Ovarian cancer is the fourth leading cause of cancer death in women. Cancer of the ovary can occur at any age but is most common after 50. It is three times more common in women who have never had children and less common in women who have taken oral birth-control pills.

The growth may be primary (arising in the ovary) or may be a secondary growth that has spread to the ovary from some other part of the body, often the breast.

SYMPTOMS AND SIGNS

In most cases ovarian cancer causes no symptoms until it is widespread. The first symptom is usually vague abdominal discomfort and swelling. There may be digestive disturbances, such as nausea and vomiting, abnormal vaginal bleeding, and ascites (excess fluid in the abdominal cavity). A physical examination may reveal a swelling in the pelvis.

DIAGNOSIS AND TREATMENT

A *laparoscopy* (examination of the abdominal cavity through a viewing tube) or *laparotomy* (opening of the abdomen wall) may be necessary to confirm the diagnosis. Treatment is surgery to remove the cancer or as much of the malignant tissue as possible. This usually involves *salpingo-oophorectomy* (removal of the ovaries and fallopian tubes) and *hysterectomy* (removal of the uterus). Surgery is usually followed by *radiation therapy* and *anticancer drugs*.

OUTLOOK

If the growth is confined to one or both ovaries, 60 to 70 percent of patients survive at least five years. If the growth is more widespread, only about 10 to 20 percent of patients survive five years. New drug combinations may improve this survival rate.

Overbite

Overlapping of the lower front teeth by the upper front teeth. A slight degree of overbite is normal because the upper jaw is larger than the lower one. In *malocclusion*, overbite may be greater than normal or may be reversed (with the lower teeth projecting in front of the upper ones).

Overcrowding, dental

Excessive crowding of the teeth so that they are unable to assume their normal positions in the jaw.

Severe case of overcrowding
The front teeth are crowded together because the two molars, just behind them, have grown too far forward.

CAUSES

Overcrowding frequently occurs through heredity when the teeth are relatively too large or there are too many for a person's jaw. The condition also can occur or worsen with the premature loss of primary molar teeth. This can cause the permanent teeth growing beneath them to move out of position and leave insufficient space for the developing permanent teeth further forward in the mouth.

PROBLEMS

Overcrowded teeth may lead to *malocclusion* (incorrect relationship between the upper and lower teeth) and may prevent certain teeth from erupting through the gum (see *Impaction, dental*). There is an increased risk of dental decay in crowded teeth because they are more difficult to clean. Overcrowding can also increase the risk of *periodontal disease* because of more difficult cleaning and more unusual stress being placed on supporting tissues.

TREATMENT

An orthodontist decides whether one or more teeth should be extracted to allow room for others to grow. Often the remaining teeth require fitting with an *orthodontic appliance* to move them into their correct positions.

Overuse injury

A term for any injury that has been caused by repetitive movement of part of the body. A common example is *epicondylitis*, painful inflammation of one of the epicondyles (bony prominences) at the elbow, caused by the pull of the attached forearm muscles during gardening, painting, or playing certain sports (see *Golfers' elbow*; *Tennis elbow*).

Overuse injuries of the finger and wrist joints may affect assembly line workers and typists. Musicians are also prone to a variety of problems; the thumb may be affected in players of woodwind instruments and the neck may be affected in violinists.

Symptoms, which usually disappear with rest, include pain and stiffness in the affected joints and muscles. It is sometimes possible to avoid a recurrence by altering technique during the activity.

Overweight

See *Obesity*.

Ovulation

The development and release of an *ovum* (egg) from a follicle within the *ovary*. Ovulation occurs midway through the menstrual cycle and is regulated by hormones. During the first half of the cycle, the follicle-stimulating hormone (FSH) causes several ova to mature in the ovary. At mid-cycle, the luteinizing hormone causes one ripe ovum to be released. The follicle then forms a small mass of yellow tissue called the corpus luteum, which secretes the hormone *progesterone* during the second half of the menstrual cycle.

After its release, the ovum travels along the fallopian tube and, unless *fertilization* occurs, is shed during *menstruation*. Regular menstruation usually means that a woman ovulates, but this is not always the case, especially around *puberty* and approaching the *menopause*.

Some forms of contraception (see *Contraception, periodic abstinence*) are based on predicting when ovulation occurs each month and avoiding sexual intercourse at that time. Signs of ovulation include a rise in body temperature and changes in the amount and consistency of cervical mucus; there may also be mild abdominal pain (see *Mittelschmerz*).

If a woman does not ovulate, she cannot conceive. Investigation of female *infertility* includes tests to determine whether ovulation occurs.

Ovum

The egg cell (female cell) of reproduction. Each ovum measures about 0.04 inch (0.1 mm) in diameter. There are about 1 million immature ova present in each ovary at birth; only about 200 per ovary ever mature to be released at *ovulation* during a woman's fertile years. If *fertilization* occurs, the ovum develops into an *embryo*.

Oxacillin

A *penicillin*-type *antibiotic drug*. Oxacillin is especially useful in the treatment of *staphylococcal infections* resistant to other antibiotic drugs.

Oxandrolone

An anabolic steroid (see *Steroids, anabolic*) used after a major illness or injury to help increase weight. It is also sometimes used in the treatment of *hyperlipidemia*.

Oxandrolone may cause swollen ankles and, in women, irregular periods. Rare adverse effects include nausea, vomiting, jaundice, and, in men, difficulty passing urine.

Oxazepam

A *benzodiazepine drug* used in the treatment of *anxiety* and *insomnia*. Like other benzodiazepines, oxazepam may cause dependence if taken regularly for more than two weeks (see *Drug dependence*).

Oxtriphylline

A *bronchodilator drug* related to *theophylline*, used in the treatment of *asthma* and *bronchitis*. Oxtriphylline may cause adverse effects, such as nausea, vomiting, and headache.

Oxycodone

A narcotic *analgesic* (painkiller) derived from *morphine*. It is used in the treatment of severe pain.

Oxygen

A colorless, odorless gas that makes up 21 percent of Earth's atmosphere. Oxygen is essential for almost all forms of life, including humans, because it is necessary for the metabolic "burning" of foods to produce energy—a process known as *aerobic* metabolism.

To reach the body cells, where aerobic metabolism takes place, oxygen in the air is absorbed through the lungs and into the blood, where it binds to the *hemoglobin* in red blood cells. In this form, the oxygen is distributed throughout the body, being released from the hemoglobin and taken up by cells in areas where the oxygen level is low.

Oxygen is used therapeutically to treat conditions such as severe *bronchitis* or *hypoxia* (an inadequate supply of oxygen to body tissues). In some cases, high pressure oxygen (see *Hyperbaric oxygen treatment*) is used to treat the bends (*decompression sickness*) or poisoning from *carbon monoxide*. (See also *Ozone*.)

Oxygen therapy

Supplying a person with oxygen-enriched air to relieve severe *hypoxia* (inadequate oxygen in the tissues).

In hospitals, oxygen is usually piped to a terminal at the patient's bedside and is administered as necessary through a face mask or nasal cannulas (tubes inserted into the nostrils). The concentration of oxygen is varied according to the patient's needs.

People at home can be supplied with oxygen in cylinders for use during acute attacks of hypoxia (which occur in severe *asthma*). People with persistent hypoxia due to severe, chronic *bronchitis* or *emphysema* may benefit from long-term oxygen therapy. These patients may be supplied with a machine called an oxygen concentrator, which separates oxygen from the air and remixes it in a higher-than-normal concentration. Oxygen-rich air is then piped to different rooms for prolonged inhalation.

People receiving oxygen therapy should not smoke, since smoking not only presents a fire risk but also reduces the oxygen-carrying capacity of the blood and aggravates the underlying condition for which the oxygen is being given. (See also *Hyperbaric oxygen treatment*.)

Oxymetazoline

A *decongestant drug* used in the treatment of allergic *rhinitis* (hay fever), *sinusitis*, and the common *cold*. Oxymetazoline has a longer-lasting effect than other decongestants; it needs to be taken only twice a day.

Oxymetazoline may irritate the nose. Prolonged use causes rebound congestion (increased congestion when the drug is withdrawn).

Oxytetracycline

A type of *antibiotic drug* known as a *tetracycline drug*. Oxytetracycline is used to treat *chlamydial infections* such as *nonspecific urethritis*, *psittacosis*, and *trachoma*. It is also used to treat a variety of other infections, including *bronchitis*, pneumonia caused by *mycoplasma*, *syphilis*, *brucellosis*, *Rocky Mountain spotted fever*, and *cholera*. Oxytetracycline may be used to treat severe *acne*.

POSSIBLE ADVERSE EFFECTS

Oxytetracycline occasionally causes nausea, vomiting, diarrhea, rash, or increased sensitivity of the skin to sunlight. It may also discolor developing teeth and is therefore not prescribed for children under 12 or during pregnancy.

Oxytocin

A hormone produced by the *pituitary gland* that causes contractions of the uterus during labor and stimulates the flow of milk in nursing women.

USE AS A DRUG

Synthetic oxytocin is commonly used to induce childbirth (see *Induction of labor*). It is sometimes used to help expel the placenta (afterbirth) after delivery or to empty the uterus after an incomplete *miscarriage* or a fetal death. Oxytocin is sometimes given as a nasal spray to stimulate milk flow.

POSSIBLE ADVERSE EFFECTS

Contractions may be stronger and more painful than usual, increasing the need for stronger *analgesic drugs* (painkillers). Rare adverse effects include nausea, vomiting, palpitations, seizures, and coma.

Ozena

A severe and rare form of *rhinitis* (inflammation of the mucous membrane in the nose) in which the membrane atrophies (wastes away) and a thick nasal discharge dries to form crusts. It often causes severe *halitosis* (bad breath).

Ozone

A rare form of oxygen, ozone is a poisonous, faintly blue gas that is produced by the action of electrical discharges (such as lightning) on oxygen molecules.

Ozone occurs naturally in the upper atmosphere (about 15 to 20 miles above the Earth's surface), where it screens the Earth from most of the sun's harmful ultraviolet radiation.

However, there are claims that the ozone layer is being depleted by various environmental chemicals (notably the chlorofluorocarbons in aerosols). The result is that stronger and more potent forms of ultraviolet radiation are reaching the Earth's surface. Increased ultraviolet levels could lead to an increase in the incidence of skin cancer and cataracts.

P

PABA

The abbreviation for *para-aminobenzoic acid,* a sunscreen ingredient.

Pacemaker

A device that supplies electrical impulses to the heart to maintain the heart beat at a regular rate. A pacemaker consists of a small electronic device and power source connected to the heart via an electrical wire.

In a healthy heart, the beat is maintained by a nucleus of specialized muscle called the sinoatrial node; it sends out regular electrical impulses that pass through the heart muscle and trigger heart contractions. An artificial pacemaker is implanted when a person's sinoatrial node is not functioning properly, or when there is some impairment to the passage of the normal electrical impulses (see *Heart block; Sick sinus syndrome*). Each year, tens of thousands of Americans have a pacemaker implanted.

Two main types of pacemaker—fixed rate and demand—are shown in the box below. More advanced types can increase the heart rate during exercise. Dual-chamber devices utilize one electrode in the atrium and another in the ventricular wall.

IMPLANTATION

Implantation is carried out using local anesthetic. Patients can expect complete healing without complications and should return to normal work and activity as soon as possible. Vigorous exercise should be avoided for two weeks after the operation.

Modern microelectronic circuits require little power and lithium batteries have a long life. Unless the demand on the battery is excessive, a pacemaker usually runs satisfactorily for several years. Battery replacement requires a minor operation.

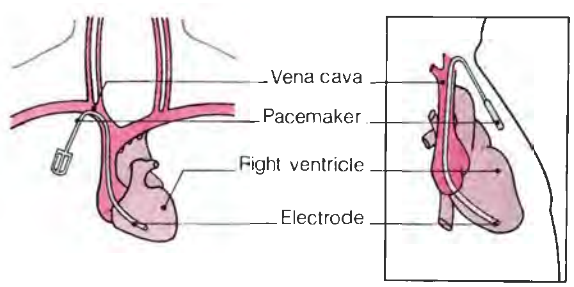
PRECAUTIONS

Modern pacemakers are relatively insensitive to interference but may be affected by powerful electromagnetic pulses. Anyone with a pacemaker should avoid powerful radio or radar transmitters and should not pass through security screens at airports. Precautions may also be required with some physical therapy or surgical *diathermy* machines.

Paget's disease

A common disorder of middle-aged and elderly people in which the normal process of bone formation is disrupted, causing the affected bones to weaken, thicken, and become deformed. Also known as osteitis deformans, Paget's disease usually involves only limited areas of the skeleton. The bones usually affected are the pelvis, skull, collarbone, vertebrae, and long bones of the leg.

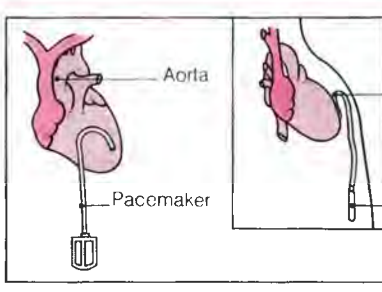
CAUSE AND INCIDENCE



The normal maintenance of healthy bones by the body involves a balance between the actions of cells that break down bone tissue and those that rebuild it. In Paget's disease, this balance is disturbed. The disease varies in frequency from one part of the country to another, suggesting an infective cause, which is thought to be

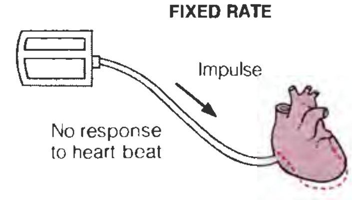
PACEMAKERS

A pacemaker may be external (worn on a belt) or internal (implanted in the chest), like those shown below.



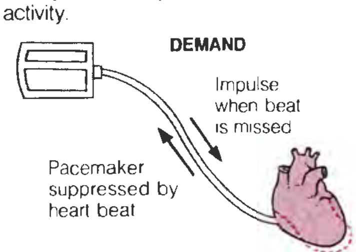
External pacing is used only as a temporary measure. There are two main methods of implantation.

Transvenous implantation
An insulated wire is inserted into a major vein in the neck and guided down into the heart until the electrode at its far end is secured within the part of the heart muscle to be stimulated. The free end is connected to the pacemaker, which is fitted into a pocket created under the skin of the abdomen or below the collarbone.



Side view
The pacemaker is usually well hidden by overlying tissue

Epicardial implantation
The electrode is attached to the outer surface of the part of the heart muscle to be stimulated and the pacemaker is fitted into a pocket constructed underneath the skin of the abdomen.



TYPES OF PACEMAKERS
The two main types are shown. In some cases, an external programmer can adjust the rate

FIXED RATE

Fixed-rate pacemaker
This type discharges impulses at a steady rate, irrespective of the heart's activity.

DEMAND

Demand pacemaker
This type discharges impulses only when the heart rate slows or a beat is missed. A normal heart rate and beat suppresses the pacemaker.

viral. Overall, Paget's disease affects about 3 percent of the population over the age of 40, the incidence increasing with age. The disorder has a tendency to run in families and affects more men than women.

SYMPTOMS AND SIGNS

Paget's disease often causes no symptoms and is usually discovered from an X ray taken for some other reason. The most common symptoms are bone pain and deformity, especially bowing of the legs. Affected bones are prone to fracture.

Changes in the skull may lead to leontiasis (distortion of the facial bones that produces a lionlike appearance) and to inner-ear damage, sometimes resulting in deafness, tinnitus (ringing in the ear), vertigo, or headaches. Enlarged vertebrae may press on the spinal cord, causing pain and sometimes paralysis of the legs. If the pelvis is affected, it can result in severe arthritis of the hips. Occasionally, *bone cancer* may develop, and, in rare cases, when many bones are involved, increased blood flow through the affected bones may cause *heart failure*.

DIAGNOSIS

X rays reveal areas of porous, thickened bone. *Blood tests* that show an elevated level of the enzyme alkaline phosphatase (which is associated with bone cell formation) give an indication of the extent and activity of the disease.

TREATMENT AND OUTLOOK

Most people with the disorder do not require treatment, and many others simply need to take *analgesic drugs* (painkillers). In severe cases, the hormone *calcitonin* may be prescribed. It relieves pain, reduces alkaline phosphatase levels, and promotes normal bone formation. Other drugs that have the same effect (including disodium etidronate and plicamycin) may also be used. Surgery may be required to correct deformities or treat secondary arthritis.

Paget's disease of the nipple

A rare *breast cancer* in which the tumor starts in the milk ducts of the nipple. Paget's disease of the nipple looks similar to *eczema*, causes the nipple to itch and burn, and may feature a sore on the nipple that will not heal. Usually only one nipple is affected. If left untreated, the tumor may gradually spread into the breast. Eczema of the nipple should be reported to a physician and a *biopsy* of the underlying breast taken.

Pain

A localized sensation that can range from mild discomfort to an unbearable and excruciating experience. Pain is the result of stimulation of special sensory nerve endings following injury or caused by disease.

THE MECHANISM OF PAIN

The basic mechanism of pain is shown in the illustrated box on the next page. The skin contains many specialized nerve endings (nociceptors). Stimulation of these receptors leads to transmission of pain messages to the brain. Nociceptors have different sensitivities, some responding only to severe stimulation, such as cutting, pricking, or heating the skin to a high temperature; others respond to warning stimuli, such as firm pressure, stretching, or temperatures not high enough to burn. Pain receptors are present in structures other than the skin, including blood vessels and tendons. Most internal organs have few, if any, nociceptors. The large intestine, for example, can be cut without causing any pain. It does, however, have nociceptors that respond to stretching, which, in severe cases, may cause pain.

PSYCHOLOGICAL ASPECTS OF PAIN

Pain is usually associated with distress and anxiety, and sometimes with fear. People vary tremendously in their pain thresholds (the level at which the pain is felt and the person feels compelled to act). The cause and circumstances of the pain may also affect the way it is perceived by the sufferer. The pain of cancer, because of fear of the disease, may seem much greater and cause more suffering than similar pain resulting from persistent indigestion. Unexplained pain is often worse because of the anxiety it can cause; once a diagnosis is made and reassurance given, the pain may be perceived as less severe.

The experience of pain may be reduced by arousal (e.g., an injury sustained during competitive sport or on the battlefield may go unnoticed in the heat of the moment); strong emotion can also block pain. Some people believe that mental preparation for pain (e.g., in childbirth or in experiments to test pain) can greatly reduce the response.

A person's response to pain is greatly modified by past experience; the outcome of previous episodes of pain may affect the way the individual copes with subsequent pain. Factors such as insomnia, anxiety, and depression, which often accompany incapacitating illness, lower pain tolerance. Treatment for these symptoms is given along with treatment for the pain to allow the minimum dose for pain relief.

Cultural differences exist in the expression of pain. In some parts of the world self-inflicted torture and the ability to withstand great pain are a mark of a person's strength and character. However, the pain of even mild torture inflicted by captors may be perceived as much worse than a similar degree of pain that occurs under different circumstances.

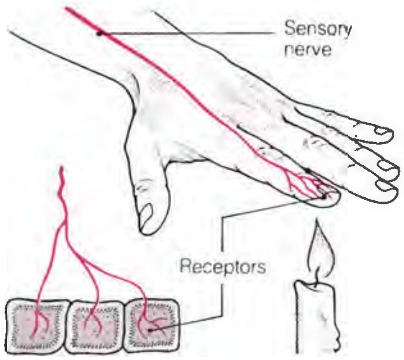
TYPES OF PAIN

Many adjectives are used to describe different types of pain. Common descriptive terms include throbbing, penetrating, gnawing, aching, burning, and gripping. The extent to which a patient is accurately able to describe his or her pain to the physician is highly variable, even though it can be a vital clue to the diagnosis.

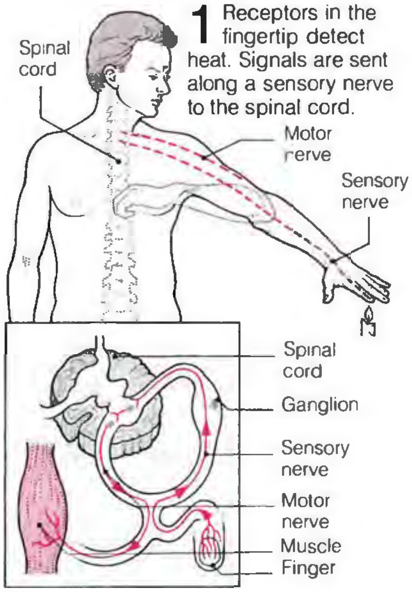
Attempts have been made to categorize pain according to intensity, ranging from a minor cut or sore throat at the lower end to childbirth and renal or biliary colic at the upper.

If the pain comes from an internal organ it is often difficult for the sufferer to pinpoint its origin with any precision. For example, in the early stages of appendicitis, pain may be felt in the region above the navel. In the later stages, when infection has caused inflammation of the peritoneum (lining of the abdominal cavity), the pain becomes localized above the right groin.

Pain may be felt at a point some distance from the disorder. This is called *referred pain* (see illustrated box overleaf). A person who has lost a limb may experience pain that seems to come from the amputated limb (see *Phantom limb*). Sometimes the person can localize the pain (e.g., to a toe, despite having had a mid-thigh amputation). See also *Endorphins; Enkephalins*.



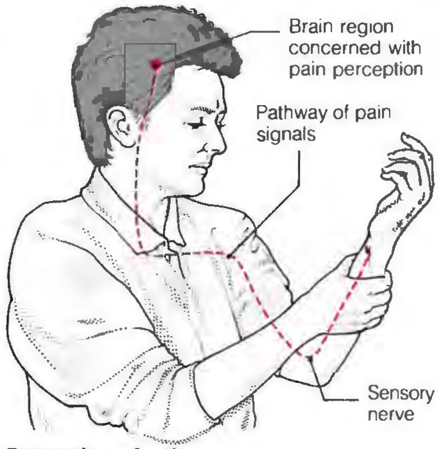
Painful arc syndrome



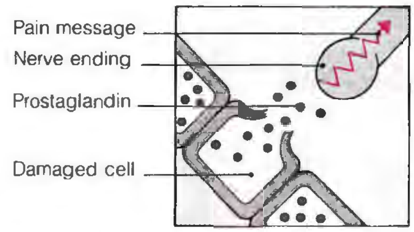
A condition in which pain occurs when the arm is lifted between 45 degrees and 160 degrees away from the side of the body. Movement either side of this range is pain-free. Painful arc syndrome is usually caused by inflammation of tendons or bursae (see *Bursa*) around the shoulder joint. The pain is caused by the inflamed tendon or bursa being squeezed between the upper parts of the shoulder blade and the *humerus*.

PAIN

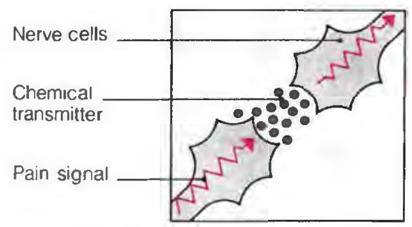
Pain mechanisms exist to provide a useful warning of possible injury or to caution against repeating an action that has led to injury. Certain diseases, such as arthritis and extensive cancer, may set off these same mechanisms, causing chronic pain that has no apparent function.



Reflex action
The nerve pathways that warn of noxious stimuli (through the sensation of pain) may also initiate automatic, reflex actions that help prevent harm.



1 Receptors in the fingertip detect heat. Signals are sent along a sensory nerve to the spinal cord.



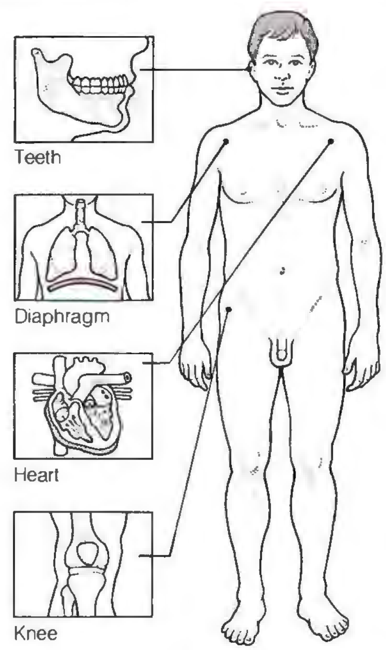
2 The signals arriving in the spinal cord pass instantaneously to a motor nerve that connects to a muscle in the arm. The signals received via the motor nerve cause the muscle in the arm to contract, moving the arm away from the source of danger (the flame).

Perception of pain
When an injury occurs, signals pass along nerve pathways concerned with pain, first to the spinal cord and then to the thalamus in the brain; there the pain is perceived.

Initiation of pain signals
The signals are set off by stimulation of special nerve endings - by pressure, heat, or release of chemicals, including prostaglandins, by damaged cells.

Signal transmission to brain
Within the brain and spinal cord, pain signals pass between nerve cells by means of chemicals that cross the gaps between the cells.

REFERRED PAIN



A referred pain is one felt in a site other than an injured or diseased part. Sensory nerves from certain body areas converge before they enter the brain, causing confusion about the source of pain signals.

Tooth to ear region
A toothache may be felt in the ear, because the same sensory nerve supplies both parts.

Diaphragm to right shoulder
Inflammation of the diaphragm, often due to pneumonia, may be felt as a pain in the right shoulder.

Heart to left arm
Angina, a pain caused by reduced blood supply to the heart muscle, is often felt in the left shoulder or arm.

Knee to hip
Disorders affecting the knee, such as arthritis, may be felt as pain in the hip.

Painkillers

See *Analgesic drugs*.

Pain relief

The treatment of *pain*, usually with *analgesic drugs*. Methods of treatment depend on the severity, duration, location, and cause of the pain.

DRUG TREATMENT

Mild analgesics, available over-the-counter, are usually effective in the treatment of mild pain, such as headache, toothache, or dysmenorrhea (menstrual pain). *Acetaminophen* and *aspirin* are the most widely used drugs in this group.

Mild or moderate pain, such as that caused by arthritis or sports injuries, is often treated with a *nonsteroidal anti-inflammatory drug* (NSAID).

Severe pain, such as that caused by serious injury or kidney stones, may require treatment with a *narcotic* analgesic. Narcotic analgesics are also

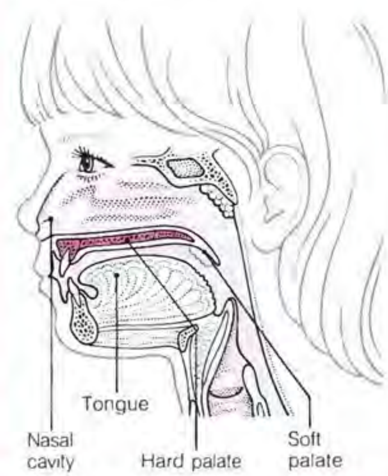
used to prevent pain after surgery. Long-term use of narcotic analgesics may be necessary to prevent or relieve pain in cancer.

NONDRUG TREATMENT

Massage, *ice packs*, or *poultices* may be used for the relief of localized pain caused by muscle spasm, inflammation, or injury.

Chronic or recurrent pain that has not responded to drug treatment may be relieved by *acupuncture* or *hypnosis*.

Surgical procedures to relieve pain may be performed if all other treatments have failed. These procedures may involve destruction of nerves that transmit pain (as is done in a *cordotomy*). Alternatively, nerve fibers in the thalamus (the part of the brain that responds to pain) may be cut to prevent perception of pain.



Palate

The roof of the mouth. The palate separates the mouth from the nasal cavity. Covered with *mucous membrane*, it consists, in the front, of the hard palate, whose substructure is a plate of bone forming part of the *maxilla* (upper jaw). At the rear is the soft palate, a flap of muscle and fibrous tissue that projects into the *pharynx* (throat). During swallowing, the soft palate presses against the rear wall of the pharynx, preventing food from being regurgitated into the nose.

About one in 500 babies is born with a gap along the midline of the palate (see *Cleft lip and palate*).

LOCATION OF THE PALATE

The palate forms the floor of the nasal cavity and roof of the mouth, providing a surface against which the tongue can push during chewing and swallowing.

Palliative treatment

Therapy that relieves the symptoms of a disorder but does not cure it. Treatment for the symptoms of widespread cancer is considered palliative.

Pallor

Abnormally pale skin, particularly of the face. Pallor may be a symptom of disease, but more often has an innocent explanation. Possible causes include a deficiency of the skin pigment *melanin*, constriction of the small blood vessels in the skin, or *anemia*.

Melanin deficiency may result from lack of exposure to the sun, occurring in people (such as nightworkers or miners) who spend very little time in daylight. A deficiency of melanin can also be hereditary when it is associated with *albinism*.

Constriction of small blood vessels in the skin may occur in response to shock, severe pain, injury, heavy blood loss, fainting, or extreme cold. Cutting off the blood flow to the skin ensures that the brain and other vital organs are adequately supplied and that body heat is conserved. In anemia, pallor results from lack of *hemoglobin* pigment in blood vessels in the skin.

Certain kidney disorders, such as *pyelonephritis* and *renal failure*, produce a sallow appearance akin to pallor, as does *hypothyroidism*. Rare conditions that give rise to pallor include *scurvy* and lead poisoning.

Palpitation

Awareness of the heart beat.

CAUSES

A palpitation is usually felt after strenuous exercise, in tense situations, or after a severe scare, when the heart is beating harder and/or faster than normal. When experienced at rest or in a calm mood, palpitation is usually due to *ectopic heart beats* (premature beats followed by a prolonged pause) and is felt as a fluttering or thumping in the chest, sometimes with a brief but alarming sense that the heart has stopped beating. Ectopic beats do not normally indicate heart disease; they are often caused by heavy smoking, alcohol, or a large intake of caffeine.

An *arrhythmia* (irregularity of the heart beat) may cause palpitation. An example of an arrhythmia is atrial *tachycardia*, a condition in which the heart suddenly starts to beat very rapidly; the affected person may feel faint and breathless. The pulse may be as high as 200 beats per minute but remains regular. In *atrial fibrillation*, the atria (upper chambers of the heart) beat in a disorganized manner and the impulses passed to the ventricles (lower pumping chambers) are very irregular. *Hyperthyroidism* (overactive thyroid gland) may cause palpitation by speeding up the heart beat.

DIAGNOSIS AND TREATMENT

If palpitation lasts for several hours or recurs over several days, or if it causes chest pain, breathlessness, or dizziness, a physician should be consulted as soon as possible, as there may be a serious underlying disorder. Recurrent palpitations can be investigated by means of a *Holter monitor* and *thyroid function tests*. Treatment depends on the underlying cause.

Palsy

A term applied to certain forms of *paralysis*. Examples are *cerebral palsy*, Bell's palsy (paralysis of one side of the face), and Erb's palsy (paralysis of the upper arm and shoulder on one side of the body).

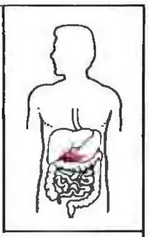
Panacea

A remedy for all diseases; a cure-all. No such remedy is known, despite claims to the contrary made by numerous quacks through the ages.

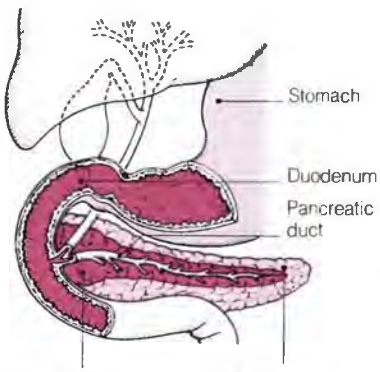
Pancreas

An elongated, tapered gland that lies across the back of the abdomen, behind the stomach. Its right-hand end (called the head) is the broadest part and lies in the loop of the duodenum. Tapering from the head, the main part of the gland (the body) extends left and slightly upward; the left-hand, narrower end (the tail) terminates near the spleen.

STRUCTURE



Most of the pancreas consists of exocrine tissue, embedded in which are "nests" of endocrine cells (the islets of Langerhans). The exocrine cells secrete digestive enzymes into a network of ducts that meet to form the main pancreatic duct. This duct joins the common bile duct (which carries bile from the gallbladder) to form a small chamber, called the ampulla of Vater, that opens into the duodenum. The islets of Langerhans are surrounded by many blood vessels into which they secrete hormones.



FUNCTION

The pancreas has two functions: digestive and hormonal. The exocrine tissue secretes various digestive

P

LOCATION OF THE PANCREAS
This organ lies under the stomach, except for its head, which lies within the curve of the duodenum.

enzymes that break down carbohydrates, fats, proteins, and nucleic acids (see *Digestive system*). Most of these enzymes are secreted in inactive form and are activated in the duodenum by other enzymes. Also secreted by the exocrine tissue is bicarbonate, which neutralizes stomach acid entering the duodenum. The endocrine cells in the islets of Langerhans secrete the hormones *insulin* and *glucagon*, which regulate the level of glucose in the blood. (See also *Pancreas* disorders box.)

Pancreas, cancer of

A malignant tumor of the exocrine tissue of the *pancreas* (the main tissue in the gland). The cause of the condition is unknown, although it has been linked to heavy smoking and to certain dietary factors, such as a high intake of fats or alcohol.

The incidence of pancreatic cancer in the US has increased threefold during the past 50 years, to about 11 per 100,000 people. Today, it is the fourth most common cancer in men, and the sixth most common in women. Approximately 80 percent of cases occur in people older than 50.

SYMPTOMS AND DIAGNOSIS

The most common symptom is pain in the upper abdomen, which often spreads to the back. Other common symptoms are appetite and weight loss, and jaundice. There may also be indigestion, nausea, vomiting, diarrhea, and tiredness. In most cases, the symptoms do not appear until the cancer is well advanced, often not until it has spread to other parts of the body (typically to the liver or lungs).

Diagnosis of pancreatic cancer usually requires *ultrasound scanning* or *CT scanning* of the upper abdomen, or endoscopic examination of the ducts of the pancreas (see *ERCP*). In some cases, the condition is detected during exploratory surgery on the abdomen (see *Laparotomy, exploratory*).

TREATMENT AND OUTLOOK

If the condition is detected in its early stages, surgical removal of the malig-

DISORDERS OF THE PANCREAS

Serious disruption of pancreatic function occurs only when the secretory tissue of the gland has been damaged or destroyed in advanced disease. The most common pancreatic disorder is *diabetes mellitus*, in which the insulin-producing cells in the gland are destroyed.

CONGENITAL AND GENETIC DISORDERS

About 85 percent of people with the genetic disorder *cystic fibrosis* produce totally inadequate quantities of pancreatic digestive enzymes, which results in *malabsorption* of fats and proteins. This, in turn, may produce steatorrhea (excess fat in the feces) and muscle wasting.

Genetic factors are thought to play some part in diabetes mellitus, although they are not the primary cause of the disease.

Chronic *pancreatitis* (inflammation of the pancreas) may, in rare cases, be hereditary; chronic pancreatitis often causes diabetes.

INFECTION

Acute pancreatitis may result from certain viral infections, especially infection with the *mumps* virus. Other viruses, such as coxsackievirus and echoviruses, may also cause pancreatitis. In some cases, coxsackievirus infection may contribute to the development of diabetes.

TUMOR

Pancreatic cancer is one of the most common cancers in the US (see *Pancreas, cancer of*). It is difficult to diagnose and often has spread extensively by the time it is detected.

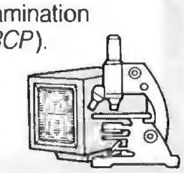
TRAUMA

Injury to the pancreas—which may result from a powerful blow to the abdomen, for example—may cause acute pancreatitis. The mechanism by which this happens is not fully established, but it is believed that pancreatic enzymes (most of which are inactive until they reach the intestine) are released within the tissue of the gland and then activated, with the result that they digest the pancreas.

POISONS AND DRUGS

Excessive alcohol intake is a common cause of pancreatitis. It can also be caused by various drugs, such as sulfa drugs, estrogens (including estrogen-containing contraceptive pills), and thiazide *diuretic drugs; corticosteroid drugs* may also cause pancreatitis.

AUTOIMMUNE DISORDERS



The cause of the damage to the pancreas in diabetes mellitus remains controversial. However, there is increasing evidence that, possibly in response to a viral infection, the body's immune system produces *antibodies* (proteins with a role in the defense against infection) that inappropriately attack and destroy the pancreatic cells.

OTHER DISORDERS

Other than alcohol overuse, the condition most commonly associated with pancreatitis is *gallstones*. They occasionally block the exit of the pancreatic duct into the duodenum, which leads to inflammation of the pancreas.

INVESTIGATION

Diagnosis of pancreatic disorders may involve *ultrasound scanning* of the abdomen, tests to measure levels of pancreatic enzymes in the blood or duodenum, and endoscopic examination of the gland (see *ERCP*).

P

nant tissue (see *Pancreatectomy*) along with *radiation therapy* and *anticancer drugs* may cure it. However, in most cases the cancer is not diagnosed until it is well advanced, and little can be done apart from relieving the pain with *analgesics* (painkillers), alleviating any other symptoms, and bypassing the growth if it is causing obstruction of the bile duct or bowel. In such cases, the outlook is poor; death occurs in about 90 percent of the cases within a year of diagnosis.

Pancreatectomy

Removal of all or part of the pancreas. Pancreatectomy may be performed to treat *pancreatitis* (inflammation of the pancreas), localized pancreatic cancer (see *Pancreas, cancer of*), or carcinoma of the ampulla of Vater (the small chamber formed by the union of the common bile duct and pancreatic duct that opens into the duodenum). Rarely, it is done to treat some endocrine tumors, such as *insulinomas* (*insulin*-producing tumors).

Removal of all or part of the gland depends on the disorder involved and/or on how much of the pancreas is affected. Obstruction of the pancreatic duct may require removal of only the tail of the gland (the narrower end, nearest the spleen) and the linking of the duct with a small piece of small intestine. Disease of the head of the pancreas (the broader end, situated in the loop of the duodenum) may necessitate removal of both the pancreatic head and duodenal loop (Whipple's operation).

COMPLICATIONS

Because the pancreas produces insulin and a variety of digestive enzymes, removal of the entire gland results in *diabetes mellitus* (which requires insulin therapy) and *malabsorption* (which requires oral supplements of pancreatic enzymes). Such treatment may also be necessary after a partial pancreatectomy, depending on how much function remains.

Pancreatin

A drug obtained from the pancreas of pigs and used to supplement a deficiency of pancreatic *enzymes* (proteins that stimulate digestion of nutrients).

Pancreatitis

Inflammation of the pancreas. In acute pancreatitis, the gland usually returns to normal after a single attack (although sometimes attacks recur). In chronic pancreatitis, there is permanent damage to the structure and to the function of the pancreas due to persistent inflammation, which causes fibrosis (the formation of fibrous scar tissue) in the gland.

CAUSES

The principal causes of acute pancreatitis are *gallstones* and alcohol abuse. Less commonly, pancreatitis results from a viral infection (such as *mumps*), injury (such as through surgery on the biliary tract or a blow to the abdomen), or certain drugs (such as *tetracycline*).

The most common cause of chronic pancreatitis is alcohol abuse. It may also result from *hemochromatosis* (excess iron in the body) or, rarely, it may be hereditary. In some cases, severe acute pancreatitis causes it.

SYMPTOMS AND DIAGNOSIS

Acute pancreatitis produces a sudden attack of severe upper abdominal pain, often accompanied by nausea and vomiting. The pain may spread to the back and is made worse by movement; sitting up may relieve it. An attack, which usually lasts for about 48 hours, is accompanied by the release of pancreatic enzymes into the blood; measurement of these enzymes is an important diagnostic test. *Ultrasound scanning* or *CT scanning* of the abdomen may also be performed.

Chronic pancreatitis usually produces the same symptoms as the acute form, although the pain may last from hours to several days, and attacks become more frequent as the condition progresses. However, in some cases there may be no pain and the principal signs may be *malabsorption* (due to a deficiency of pancreatic enzymes) or *diabetes mellitus* (due to insufficient *insulin* production by the pancreas). Measuring pancreatic enzyme levels in the blood is of little value in diagnosing chronic pancreatitis, although measuring the output of such enzymes into the duodenum may be useful. Abdominal X rays or scans are the principal diagnostic methods, along with endoscopic examination of the ducts of the gland (see *ERCP*) to visualize the extent of tissue damage.

COMPLICATIONS

If acute pancreatitis causes severe damage to the gland, hypotension (low blood pressure), failure of the heart, kidneys, and respiratory system, and *ascites* (accumulation of fluid in the abdomen) may occur. In some cases, cysts or abscesses may develop in the damaged gland.

Ascites and cysts may also develop as a result of chronic pancreatitis. Other possible complications include obstruction of the common bile duct (which drains the gallbladder and joins the pancreatic duct), permanent diabetes mellitus, and blood clots in the splenic vein (which drains the spleen and pancreatic veins).

TREATMENT

There is no specific remedy for acute pancreatitis. Treatment consists of giving fluids and salts by intravenous infusion to replace those lost through vomiting; pain is relieved by giving narcotic analgesics. Nothing is given by mouth, because anything in the digestive tract stimulates pancreatic activity and makes the symptoms worse. A recurrence of the condition may be prevented by treating the underlying cause, when possible. Occasionally, surgery is necessary to remove the pancreas (see *Pancreatectomy*) or any gallstones that are blocking the drainage of pancreatic juice.

Chronic pancreatitis is treated by providing pain relief, controlling blood sugar levels by giving insulin, and giving preparations of pancreatic enzymes to correct the underproduction that the condition causes. In some cases, a pancreatectomy may be necessary to relieve pain.

Pancreatography

Imaging of the pancreas or its ducts. The methods usually used include *CT scanning*, *ultrasound scanning*, *X rays* (with a radiopaque dye) during exploratory surgery of the pancreas, and endoscopic retrograde cholangiopancreatography (see *ERCP*), an X-ray procedure in which a radiopaque dye is introduced into the ducts of the pancreas through an *endoscope* (flexible viewing tube).

Pancrelipase

A preparation of *enzymes* (proteins that stimulate chemical reactions) obtained from the pancreas of pigs.

Pancrelipase is given by mouth to supplement a deficiency of pancreatic enzymes and thus prevent *malabsorption* of fats, carbohydrates, and proteins. Deficiency may be caused by *pancreatectomy* or by disorders that affect the pancreas, such as chronic *pancreatitis*, cancer of the pancreas, and *cystic fibrosis*.

Pandemic

A medical term applied to a disease that occurs over a large geographical area (sometimes the whole world) and affects a high proportion of the population; a widespread *epidemic*.

P

Panic attack
A brief period of acute *anxiety*, often dominated by an intense fear of dying or losing one's reason. Panic attacks occur unpredictably at first, but tend to become associated with certain places, such as a crowded supermarket or a cramped elevator.

The symptoms begin suddenly and usually include a sense of breathing difficulty, chest pains, palpitations, feeling light-headed and dizzy, sweating, trembling, and faintness. *Hyperventilation* (fast, shallow breathing) often accompanies and worsens the symptoms, leading to a *pins and needles sensation*, and to feelings of *depersonalization* and *derealization*.

Most often, these symptoms are the result of underlying emotional conflicts (such as a fear of being trapped or fear of loss of dependency). Psychoanalytically, the person is often unconsciously feeling threatened by the loss of his or her relationship with the mother. Anxiety about heights may represent the fear of losing emotional support. Fear of being closed in may symbolize fear of being trapped or overwhelmed.

Although unpleasant and frightening, panic attacks last for only a few minutes, cause no physical harm, and are rarely associated with serious physical illness. The symptoms of hyperventilation may be relieved by covering the mouth and nose with a small paper bag and breathing into the bag for a few minutes.

In general, panic attacks are a symptom of *panic disorder*, *agoraphobia* (if they lead to avoidance of certain situations), or other *phobias*. Less often they are part of a *somatization disorder* or *schizophrenia*.

Panic disorder
A common form of *anxiety disorder* dominated by repeated *panic attacks* that are not caused by other illnesses or brought on by intense exercise or truly dangerous situations. A panic disorder runs a fluctuating course, tending to become worse during periods of stress. Underlying emotional anxieties cause panic reactions.

Psychotherapy is an effective treatment. Medication is often effective in treating the symptoms.

Papaverine
A *vasodilator drug* sometimes used in the treatment of patients with *peripheral vascular disease* (reduced blood supply to the legs and sometimes the arms) and in those with *transient ischemic attacks* and *impotence* of unknown cause.

Possible adverse effects of papaverine include flushing, nausea, loss of appetite, and drowsiness.

Papilla
Any small, nipple-shaped projection from the surface of a tissue, such as the mammary papilla (the nipple of the breast) and the lingual papillae (the numerous projections from the surface of the tongue, some of which contain taste buds).

Papilledema
Optic disk edema (swelling of the head of the optic nerve) caused by a rise in pressure within the brain. Papilledema, which is visible through an *ophthalmoscope*, may be a sign of a *brain tumor*.

Papilloma
A usually nonmalignant tumor, often resembling a wart, that arises from *epithelium* (the cell layer that forms the skin and mucous membranes, and that lines most of the hollow organs of the body). Although papillomas may develop from epithelium anywhere in the body, they are most common on the skin, tongue, or larynx (voice box), and in the urinary tract, digestive tract, or breasts.

Skin papilloma
This harmless type of growth is common in elderly people. It can easily be snipped off at skin level and the base cauterized.

Pap smear
See *Cervical smear test*.

Papule
A small, solid, slightly raised area of skin. Papules are usually less than half an inch (1 cm) in diameter and may be rounded or flat, with a smooth or warty texture. Papules may be the color of surrounding skin or pigmented. Many skin conditions, including *acne* and *lichen planus*, start as papules.

Par-/para-
Prefixes with several meanings: beside or beyond, as in the parathyroid glands (which are situated behind the thyroid at its sides); closely related to or closely resembling, as in paratyphoid fever (a disease that is similar to typhoid); faulty or abnormal, as in paresthesia (abnormal sensation); or associated with an accessory capacity, as in paramedical workers (personnel who supplement the work of physicians).

Para-aminobenzoic acid
The active ingredient in many *sunscreen* preparations, commonly abbreviated to PABA.

Paracentesis
A procedure in which a body cavity is punctured with a needle from the outside. Paracentesis is most often performed to remove fluid for analysis to aid diagnosis of conditions causing *ascites*, in which fluid collects in the abdominal cavity. It may also be performed to relieve pressure due to excess fluid or to instill drugs. Abdominal or thoracic paracentesis is most common, but other sites include the pericardium and the scrotum.

The procedure is usually carried out using local anesthesia; it is quick and relatively painless.

Paraffinoma
A tumorlike swelling under the skin caused by prolonged exposure to paraffin. Paraffinomas may occur in the lungs due to inhalation of paraffin, usually in someone who uses liquid paraffin as a laxative. They were once an uncommon side effect of augmentation *mammoplasty* (enlargement of the breast) when paraffin wax was used in this operation.

Paraldehyde
An unpleasant-smelling hypnotic sedative that has been used in the treatment of alcohol withdrawal. Paraldehyde is administered as an enema or by injection. This drug dissolves plastic, so a glass syringe must be used to inject it.

Paralysis
Complete or partial loss of controlled movement caused by the inability to contract one or more muscles. Weakness, rather than complete loss of movement, is often referred to as *paresis*. Paralysis may be temporary or permanent, and can affect a range of muscles—from a small facial muscle to

many of the major muscles in the body. Loss of feeling in the affected parts may accompany the inability to move them.

TYPES

Paralysis of one half of the body is called *hemiplegia*; paralysis of all four limbs and the trunk is called *quadriplegia*. *Paraplegia* is paralysis of both legs and sometimes part of the trunk. *Palsy* is an outdated general term for paralysis; it is still used in the names of certain disorders (such as *cerebral palsy*).

Paralysis may be flaccid, which gives the limbs a floppy appearance, or spastic, in which case the affected parts of the body are rigid.

CAUSES

Muscles that control movement of the body are stimulated to contract by impulses originating in the motor cortex of the brain; they travel via the spinal cord and peripheral nerves to reach the muscle. Paralysis may be caused by any form of injury or disorder anywhere along this nerve pathway, or by a muscle disorder.

BRAIN DISORDERS A very common cause of paralysis is a *stroke*, in which damage to part of the brain is caused by bleeding from or blood clotting in a blood vessel that supplies that area of the brain. Because motor fibers cross in the brain stem, paralysis occurs on the side opposite to the site of the brain damage.
